Foreword to the Second English Edition

The Mathematical Society of Japan takes pleasure in presenting this second edition of our *Encyclopedic Dictionary of Mathematics* to every researcher and user of mathematics. It is intended to be a compact, up-to-date source of information comprising, as completely as possible, all significant results in all fields of our Science, pure and applied, from the elementary to the advanced level. The success of the first edition owed much to the kind assistance given by the American Mathematical Society. As described in the preface, the members of our Society have taken responsibility for compiling this new edition. We hope that it will be as useful to the mathematicians of today as the first edition was to the mathematicians of yesterday. We also hope that this edition will be followed in years to come by subsequent ones incorporating the future development of our Science.

Hikosaburo Komatsu
President 1985–1987
Mathematical Society of Japan

Foreword to the First English Edition

The American Mathematical Society welcomes the publication of the *Encyclopedic Dictionary of Mathematics*. For many years we have been fascinated by the publication in Japanese, *Iwanami Sūgaku Ziten*, because we saw that this was an encyclopedia that contained effective and penetrating information about all the fields of advanced mathematical research. We were also frustrated because we could not read Japanese and so we could not really reach out to this expert and effective source of information. We now welcome the fact that the second Japanese edition has been translated into English and we look forward to the fascination which we can now have in getting at this rich mine of information.

Saunders MacLane
President 1973–1974
American Mathematical Society

Preface to the Second English Edition

This second edition of the *Encyclopedic Dictionary of Mathematics* is in substance an English version of the third edition of *Iwanami Sūgaku Ziten* (in Japanese). We shall explain how these two versions are related to each other and how the present edition differs from the first English edition. For the sake of simplicity we abbreviate *Encyclopedic Dictionary of Mathematics* and *Iwanami Sūgaku Ziten* to EDM and ISZ, respectively, and indicate the numbers of editions beyond the first by Arabic numerals.

The prefaces of the previous editions will clarify how ISZ, its augmented edition, ISZ2, ISZ3, and EDM came into existence in 1954, 1960, 1968, 1985, and 1977, respectively. EDM, published nine years later than ISZ2, consisted of its English translation and some new materials added to update its contents. In retrospect, it was felt that this procedure was not adequate to cope with the recent rapid progress of mathematics, and a suggestion was raised in the Mathematical Society of Japan that ISZ3 and EDM2 be produced simultaneously. The favorable reaction of the mathematical public to EDM encouraged us greatly.

In 1978 an agreement was made among the Society, Iwanami Shoten, Publishers, and The MIT Press for the publication of ISZ3 and EDM2. An editorial committee was established in the Society with the members named in the preface to ISZ3. Manuscripts were prepared simultaneously in Japanese and English by each contributor, with Yuji Ito acting as linguistic consultant.

I should mention that we benefited greatly from the kind comments on EDM by the following mathematicians: J. F. Adams, M. Atiyah, A. Borel, H. Cartan, K. Chandrasekharan, S. S. Chern, J. Dieudonné, E. Hewitt, F. Hirzebruch, O. Lehto, J. L. Lions, L. Markus, and J. P. Serre. In particular, we are deeply grateful to J. Dieudonné for his many detailed comments.

Compared with ISZ3 and EDM, EDM2 has the following characteristics:

(1) EDM2 contains many more new mathematical results than EDM. For the details we refer the reader to the main points of revision mentioned in the preface to ISZ3, because EDM2 has the same mathematical content as ISZ3 and the additions made to ISZ2 and subsequently in EDM are of relatively minor importance.

(2) The Japanese textbooks listed in the article references of ISZ3 are replaced in EDM2 by references to standard textbooks

written in English. Such replacement was not done in compiling EDM.

(3) Years of birth and death are included in the Name Index of EDM2 as far as possible. This information was given in ISZ2 but was removed in compiling EDM.

(4) The Subject Index of EDM2 is so designed that every concept consisting of two or more words can be traced from each of these component words. (This principle was adopted in ISZ2 and EDM but was not rigidly followed in ISZ3 due to the lack of space.)

(5) While all editions of ISZ were in one volume and EDM was in two volumes, EDM2 is in four volumes: I. Forewords, prefaces, introduction, text A–E; II. Text F–N; III. Text O–Z; IV. Appendices, indexes and other backmatter. The Systematic List of Articles appears in volume IV, page 1857.

While EDM2 is more voluminous than ISZ3, we hope that, being written in English and printed with generous margins, it can easily provide readers with information on every significant result of today's mathematics and so will be useful to a large number of mathematicians. I am responsible for any shortcomings that may exist despite all our efforts, and I would appreciate any remarks from the readers. I hope to have occasion to remedy any such shortcomings in the future.

Finally I would like to repeat my thanks to all the collaborators named in my preface to ISZ3. Also I express my gratitude to Yuji Ito for his tremendous effort to polish the English of all manuscripts, to Shigeru Iitaka for his laborious assistance in the final stage of the work, to Mrs. M. Nawata for her excellent secretarial work, and to the staff of the Department of Mathematics at Gakushuin University for providing me with an office for compilation for eight years.

Preface to the Third Japanese Edition

The first edition of *Iwanami Sūgaku Ziten* was published in 1954, and a revised and augmented edition appeared in 1960. Extensive revision of the work was carried out subsequently, and the result was published in 1968 as the second edition, which has retained its valuable and useful life for the past 17 years. The English translation of this second edition published by The MIT Press has achieved international recognition. In the meantime, remarkable progress has been made in mathematical sciences: recognition of the interrelationships amongst various branches within mathematics has increased significantly, and the formulation of mathematics as a synthetic entity is in the making. Furthermore, advanced mathematical theories have been utilized frequently in the physical, biological, and social sciences, and expectations for mathematics to be the basis of all the sciences have been increasing. In order to cope with these developments, it was decided that the second edition of *Sūgaku Ziten* should be further revised and an updated version be published as the third edition. The English translation of this third edition will also be published by The MIT Press.

The main points of the revision are as follows:

(1) On the Size and Scope of the Encyclopedia: The total number of articles has increased only slightly from that of the second edition, from 436 to 450. However, in view of the rapid and extensive development in mathematics in recent years, many old articles have been reorganized and unified, and much new material has been added. Consequently, the mathematical content of the encyclopedia has increased a great deal over that of the second edition, and this, together with the authors' efforts to render the articles more readable than before, necessitated a 50% increase in the number of pages devoted to the main text. The account of computer science has been taken out of the subject area of Numerical Analysis, and a new subject area has been created for it; thus mathematics is now classified into 21 subject areas altogether instead of 20.

(2) On the Arrangement of the Articles: In the second edition, the title of each article was spelled out in Romanized Japanese, and articles were arranged alphabetically. In the third edition, however, the titles of the articles are arranged in the order of the Japanese syllabary (*katakana*) and each article is numbered

accordingly. To each article a parenthetical number is also attached, giving the subject area to which the article belongs and its place in that list.

(3) On the Text: Sections within each article are headed by letters A, B, C, ...; the initial section of each article gives an outline and is devoted to an introductory and general account of the topic with which the article is concerned. In the actual exposition of the articles, every effort has been made to pay close attention to the interrelationships amongst various fields of mathematics. Even when there was no need to revise the original article, changes were made in the bibliography to list items that would be more accessible to the readers.

(4) On the Appendices: The appendices have been revised and augmented along with the text. Numerical tables were deleted whenever it was felt that scientific calculators or microcomputers could easily reproduce their contents.

(5) On the Indexes: The listing of mathematical terms in Japanese has been changed, as in the case of the arrangement of articles, from the alphabetical order to the order of the Japanese syllabary. However, terms in Japanese that start with a European word have been separated out, and, in order to facilitate finding, have been listed independently in an Index for Mathematical Terms in Japanese with European Headings. The location of a term listed in the indexes is indicated by the article number and the letter heading of the section in the article where the term appears.

We here outline briefly how the process of compilation of this edition was organized. In the summer of 1978 the Mathematical Society of Japan decided, following a proposal by Professors Shōkichi Iyanaga and Yukiyo Kawada, the chief editors of the previous editions of *Sūgaku Ziten*, to undertake the compilation of the third edition. Following a resolution by the members of the Society, Kunihiro Kodaira, Sigeru Mizohata, Itiro Tamura, Nagayoshi Iwahori, Tosihisa Kimura, and myself have joined Iyanaga and Kawada to form an editorial committee and have formulated basic guidelines for the compilation of the third edition. The work of editing and compiling articles in each subject area was delegated to the editors designated for the areas, and I was asked to undertake the responsibility of putting the entire volume in order.

The subject areas and their editors are as follows:

- I Logic and Foundations: Shôji Maehara
- II Sets, General Topology, and Categories: Shôji Maehara, Hikosaburo Komatsu, Masayoshi Nagata
- III Algebra: Masayoshi Nagata
- IV Group Theory: Nagayoshi Iwahori
- V Number Theory: Takayoshi Mitsui
- VI Euclidean and Projective Geometry: Itiro Tamura
- VII Differential Geometry: Morio Obata, Shigeru Iitaka, Itiro Tamura
- VIII Algebraic Geometry: Shigeru Iitaka
- IX Topology: Itiro Tamura
- X Analysis: Sigeru Mizohata, Kiyosi Itô
- XI Complex Analysis: Yukio Kusunoki, Shigeru Iitaka
- XII Functional Analysis: Hikosaburo Komatsu
- XIII Differential, Integral, and Functional Equations: Tosihusa Kimura, Sigeru Mizohata
- XIV Special Functions: Sin Hitotumatu
- XV Numerical Analysis: Masaya Yamaguti
- XVI Computer Science and Combinatorics: Sin Hitotumatu
- XVII Probability Theory: Kiyosi Itô
- XVIII Statistics: Kei Takeuchi
- XIX Mathematical Programming and Operations Research: Shigeru Furuya
- XX Mechanics and Theoretical Physics: Huzihiro Araki
- XXI History of Mathematics: Shôkichi Iyanaga

Appendices: Sin Hitotumatu

Before the actual process of compilation started, the editorial committee had met several times, and two meetings of all the subject-area editors had been called. Furthermore, editors for each area consulted with other experts in their fields as they selected the titles of articles to be included. In areas where remarkable development had taken place, such as differential geometry, functional analysis, probability theory, and applied mathematics, extensive revision and insertion of many new articles were proposed by the respective editors. For this reason, the original articles were thoroughly reorganized and systematized. We resolved to keep the whole work in one volume, even though a number of new articles have had to be added.

The selection of articles and of their respective authors was finally completed in the spring of 1980, and 197 colleagues were asked to write the articles. The names of these contributors and those of the previous editions are listed elsewhere in this volume. To all of the authors we express our sincere gratitude.

Editing of the entire manuscript has been carried out since the summer of 1982, and we are deeply indebted to the following colleagues for their painstaking efforts in checking cross

Preface to the Third Japanese Edition

references and in proofreading: Nobuyosi Motohashi (Foundations, Set Theory), Takeo Yokonuma (Algebra, Group Theory), Takayoshi Mitsui (Number Theory), Tetsuro Kawasaki (Geometry, Topology), Shigeru Iitaka, Isao Wakabayashi (Algebraic Geometry), Morio Obata, Koichi Ogiue, Osamu Kobayashi (Differential Geometry), Seizô Ito, Hisashi Okamoto (Analysis), Hiroaki Aikawa, Makoto Ohtsuka (Computer Analysis), Hikosaburo Komatsu, Akihiko Miyachi (Functional Analysis), Kazuo Okamoto, Daisuke Fujiwara (Differential Equations), Sin Hitotumatu (Special Functions), Teruo Ushijima (Numerical Analysis), Hideo Wada (Computer Science), Yasunori Okabe (Probability Theory), Mituaki Huzii, Yoshihiro Yajima (Statistics), Shigeru Furuya (Mathematical Programming), Koichi Nakamura (Theoretical Physics), Shûichi Okamoto (History of Mathematics), Kosaku Okutsu (History of Mathematics, Number Theory).

On those occasions when it became necessary to rapidly revise manuscripts in order to unify the presentation, we were forced to go through the revision without consulting the authors of the manuscripts. I am responsible for all such revisions and hereby express my apologies to the authors concerned.

As for the indexes, we received assistance from Takeo Yokonuma, Koichi Yano, Hiroaki Aikawa, and Hisashi Okamoto in all aspects of the work, which lasted for two years, through the final proofreading. Preliminary work on the Name Index was carried out by staff members of the University of Tokyo, and Seizô Ito supervised its final compilation. We also asked many other colleagues, and in particular Nobuyuki Ikeda and Huzihiro Araki, to participate in the preparation of the Name Index, using resources available at different universities. To all of these people goes our sincere gratitude for their assistance.

Last August, when the completion of the work was drawing near, it became necessary for me to leave Japan for some time, and this made it imperative that I entrust Shigeru Iitaka with responsibility for supervising the work at the final stage of editing. I am most grateful to Iitaka for having agreed to take over this responsibility and for having brought the work to completion under the pressure of time.

From the beginning of this project, we have received an unlimited amount of assistance from the members of the Dictionary Department of Iwanami Shoten, Publishers. Messrs. Ikutaro Sasaki, Hiroto Ushida, Kazuhiko Uetake, and Nagao Sato in particular, have made supreme efforts and have come up fre-

quently with innovative ideas to make this dictionary polished and perfect. To them and also to those at Dai-Nippon Printing Co., who typeset with the use of computers the entire text, including the complicated mathematical formulas, and who have cooperated with us fully in the process of editing the indexes, goes our deep gratitude.

Kiyosi Itô
October 1985

Preface to the First English Edition

The first and second editions of *Iwanami Sūgaku Ziten* (in Japanese) were published, respectively, in April 1954 and June 1968 by Iwanami Shoten, Publishers, Tokyo. Beginning in the late 1950s, a number of unsuccessful attempts were made to arrange for translating the *Sūgaku Ziten* into European languages. Finally an agreement for an English translation was made between The MIT Press and the Mathematical Society of Japan in July 1968. The discussions were carried on first by Professor Kōsaku Yosida, then president of the Mathematical Society of Japan, and later by Yukiyo Kawada, who succeeded him in April 1968. Throughout these initial negotiations, which lasted from 1966 to 1968, we received the kindest assistance from Dr. Gordon Walker, Executive Director of the American Mathematical Society, and from Professors W. T. Martin and Shizuo Kakutani.

The agreement for the project was shortly followed by the establishment of a committee for the English edition of *Sūgaku Ziten* within the Mathematical Society of Japan, with the following membership: Professors Yasuo Akizuki, Shigeru Furuya, Sin Hito-tumatu, Masuo Hukuhara, Isao Imai, Shōkichi Iyanaga, Yukiyo Kawada, Kunihiro Kodaira, Atuo Komatu, Hirokichi Kudō, Shōji Maehara, Yukio Mimura, Kiyoshi Noshiro, Shigeo Sasaki, Shoji Ura, Nobuo Yoneda, and Kōsaku Yosida. This committee requested the original authors of the articles and other members of the Society to translate the work. A list of translators will be found at the end of this work.

In November 1968, an advisory committee for the project was formed with the following membership: Professor Edwin Hewitt (chairman), Dr. Sydney H. Gould, Professor Shizuo Kakutani, Professor Kenneth O. May, and Professor Isaac Namioka.

As the translating began, we were immediately faced with problems concerning unification of terminology and style, some of which were inherent in the differences between the structures of our two languages—for example, the fact that the Japanese language makes no distinction between singular and plural forms of nouns.

In August 1969, Professor Hewitt kindly arranged a meeting at the University of Washington, Seattle, that included the members of the Japanese and American committees and a representative of The MIT Press. It was agreed during this meeting that the transla-

tion should be faithful, with only a minimum number of changes, such as the correction of mathematical errors; whereas the references to each article might be augmented considerably for the convenience of Western readers. Professor Kenneth O. May volunteered to review the entire translated manuscript, and Professors Isaac Namioka and Shizuo Kakutani, who are proficient in both Japanese and English, proposed to read through some of the manuscript of the translated articles. It was also agreed that the Systematic List of Articles should appear in French, German, and Russian, as well as in English.

We owe very much to the American committee: Professor Hewitt organized the whole work, and Professor May revised the entire manuscript and gave us important advice concerning the appendices, according to which we deleted some of the numerical tables which may be easily found in readily accessible Western books. Professor Namioka reviewed a great part of the manuscript, transmitting his views to Professor May, who forwarded them to us with his comments. All of this assistance helped us greatly in making our final decisions. Professor Kakutani gave us very detailed and important advice on the choice of reference works.

We were also assisted concerning English terminology and reference books by the following Japanese mathematicians working in American universities: Tadatoshi Akiba, Professors Kiyosi Itô, Tatsuji Kambayashi, Tosio Kato, Teruhisa Matsusaka, Katsumi Nomizu, Ichiro Satake, Michio Suzuki, and Gaisi Takeuti.

The Mathematical Society of Japan established the following double reviewing system: group A with its twenty subgroups, each headed by the members listed below, reviewed their respective subjects; while group B reviewed the whole manuscript, mainly from the linguistic standpoint.

Group A

1. Foundations of mathematics: Shôji Maehara
2. Set theory: Atuo Komatu and Shôji Maehara
3. Algebra: Akira Hattori, Masayoshi Nagata, and Hideyuki Matsumura
4. Group theory: Shingo Murakami, Mitsuo Sugiura, and Reiji Takahashi
5. Number theory: Yuki-yosi Kawada and Tomio Kubota
6. Geometry, 7. Differential geometry: Shôkichi Iyanaga, Shigeo Sasaki, and Kentaro Yano
8. Algebraic geometry: Yasuo Akizuki and Kunihiko Kodaira
9. Topology: Atuo Komatu
10. Real analysis: Sin Hitotumatu, Shunji Kametani, and Shigeo Yano

11. Complex analysis: Kiyoshi Noshiro
12. Functional analysis: Yukio Mimura and Kôzaku Yosida
13. Differential equations: Masuo Hukuhara and Sigeru Mizohata
14. Special functions: Sin Hitotumatu
15. Numerical analysis, 16. Probability theory: Kiyosi Itô
17. Statistics: Hirokichi Kudô
18. Information theory: Tosio Kitagawa and Hirofumi Uzawa
19. Theoretical physics: Isao Imai and Kazuhiko Nishijima
20. History of mathematics: Tamotsu Murata Group B

Kenichi Iyanaga and Mitsuyo Iyanaga

Professor Sin Hitotumatu also assisted us in translating the titles of Japanese books given in the references and the explanations attached to the lists of formulas and numerical tables in the appendices. We are also grateful for the generous cooperation offered to us by our colleagues in the Department of Mathematics, Faculty of Science, University of Tokyo: Hiroshi Fujita, Shigeru Furuya, Akio Hattori, Seizô Itô, Nagayoshi Iwahori, Tosihusa Kimura, Kunihiko Kodaira, Iikosaburo Komatsu, Akihiro Nozaki, and Itiro Tamura. We are indebted as well to Professors Walter L. Bailey of the University of Chicago and Yuji Ito of Brown University for many valuable consultations concerning both mathematical and linguistic questions.

In translating the Systematic List of Articles into French, German, and Russian, we were assisted by Professor Hideya Matsumoto in Paris, Professor Emanuel Sperner in Hamburg, Professor Katsuhiro Chiba in Tokyo, and Professor Arkadii Maltsev in Moscow.

We began to send the manuscript to The MIT Press in March 1970 and finished sending it in July 1972. The manuscript was edited there, then sent to Professors May, Namioka, and Kakutani, and finally was sent back to us with their comments and questions. All of the references were carefully checked by Laura Platt.

Iwanami Shoten, Publishers, have always been cooperative with us. In the office of the Mathematical Society of Japan, Yôko Endo, Reiko Nagase, and Chieko Sagawa helped us with their efficient secretarial work.

The fruition of this project was made possible only by the gracious assistance offered to us by many people, including those already mentioned. We should like to express our most sincere gratitude to all those who have helped us so kindly.

Shôkichi Iyanaga, Yuki-yosi Kawada
August 1973

Addition made in January 1976

After the procedures described above, the whole manuscript of this Encyclopedia was sent to The MIT Press in August 1973. It was, however, toward the end of November 1975 that the final decision was made by The MIT Press to send the manuscript to composition in early 1976 in order that the work be published in 1977.

At the same time, we were asked to review and update the manuscript up to the end of February 1976. We are now making our best effort to this effect with the kind help, especially from the linguistic viewpoint, of Dr. E. J. Brody.

In so doing, we have noticed that perhaps too much emphasis has been given to results obtained by Japanese mathematicians and that there are still many things in this book which should be improved.

We hope that ongoing revisions will be carried out in subsequent editions.

Preface to the Second Japanese Edition

Seven and a half years have passed since the revised and augmented edition of *Iwanami Sūgaku Ziten* was published. The nature and purpose of this book remain the same as described in the preface to the first edition: It is an encyclopedic dictionary with articles of medium length aimed at presenting the whole of mathematics in a lucid system, giving exact definitions of important terms in both pure and applied mathematics, and describing the present state of research in each field, together with historical background and some perspectives for the future. However, mathematical science is in rapid motion, and the "present state of research" changes constantly. The present updated second edition has been published to remedy this situation as far as possible.

The main points of revision are as follows:

(1) On the Articles and the Size of the Encyclopedia: From the articles of the last edition, we have removed those whose importance has diminished recently (e.g., Geometry of Triangles), while we have added new articles in domains of growing importance (e.g., Categories and Functors; K-Theory). Many articles concerning applied mathematics in the first edition were short; in this edition, they have been combined into articles of medium length to save space and to systematize the presentation. The number of articles, 593 in the first edition, has thus diminished to 436. We have made every effort to keep the size of the encyclopedia as it was, but the substantial augmentation of content has necessarily brought about an enlargement of about 30%.

(2) On the Text: When the title of an article has remained the same as in the first edition, we have reviewed the whole text and revised whenever necessary. Especially for the fundamental ideas, we have endeavored to give thorough explanations. In the first edition we gave English, French, and German translations of article titles; in the present edition, we have also added Russian. The bibliographies at the ends of articles have been updated.

(3) On Terminology: In previous editions we endeavored to unify the terminology of the whole encyclopedia so that the reader would have no difficulties with cross-references. Here we have done this once again with the hope of attaining results more perfect than before.

(4) On the Appendices: The appendices were designed to supplement the text efficiently. Some overlapping of the appendices with the text found in previous editions has been removed. Also deleted in this edition are elemen-

tary formulas in analytic geometry and tables of statistical distributions, which can be easily found in other books. However, we have added some formulas in topology, the theory of probability, and statistics, as well as tables of characters of finite groups, etc.

(5) On the Indexes: Important terms are listed multiply in the indexes to facilitate finding, e.g., the term *transcendental singularity* appears under both *transcendental* and *singularity*. Both names in the text and those in the references are included in the Name Index of this edition. The numbers of items in the Index of Mathematical Terms in Japanese and in European Languages and in the Name Index in this edition are 17740, 10124, and 2438, compared with 8254, 8070, and 1279, respectively, in the previous edition.

The compilation of this edition was organized as follows. In the spring of 1964 we began to select the titles of articles with the aid of the following colleagues: in set theory and foundations of mathematics, Shôji Machara; in algebra and number theory, Yasuo Akizuki, Yukiyo Kawada; in differential geometry, theory of Lie groups, and topology, Yozo Matsushima, Atuo Komatu; in analysis, Masuo Hukuhara, Kôzaku Yosida, Shunji Kametani, Sin Hitotumatu; in probability theory, statistics, and mathematics for programming, Kiyosi Itô, Hirokichi Kudô, and Shigeru Furuya; in theoretical physics, Isao Imai; and for the appendices, Sin Hitotumatu. I have participated in compiling the articles on geometry and the history of mathematics. Kawada and Hitotumatu undertook the responsibility of putting the volume in order.

The work of selecting titles was completed in the summer of 1964. We then asked 173 colleagues to contribute articles. The names of these contributors and those of the previous editions are listed elsewhere. To all of them goes our most sincere gratitude.

In editing the manuscript, we were assisted by the following colleagues in addition to those mentioned already: in set theory and foundations of mathematics, Setsuya Seki and Tsurane Iwamura; in algebra and number theory, Masayosi Nagata, Akira Hattori, Hideyuki Matsumura, Ichiro Satake, Tikao Tatzawa; in geometry, theory of Lie groups, and topology, Singo Murakami, Hideki Ozeki, Noboru Tanaka, Kiiti Morita, Hiroshi Toda, Minoru Nakaoka, Masahiro Sugawara, Shôrô Araki; in analysis, Kiyoshi Noshiro, Yûsaku Komatu, Seizo Ito, Hiroshi Fujita, Shige-Toshi Kuroda, Sigeru Mizohata, Masaya Yamaguti, Tosiya Saito, Tosihusa Kimura, Masahiro Iwano; in probability theory, statistics, and mathematics of programming,

Nobuyuki Ikeda, Tadashi Ueno, Masashi Okamoto, Haruki Morimoto, Kei Takeuchi, Goro Ishii, Tokitake Kusama, Hukukane Nikaido, Toshio Kitagawa; and in theoretical physics, Ryogo Kubo, Hironari Miyazawa, Yoshihide Kozai.

After the summer of 1965, we entered into the period of finer technical editing, in which we were assisted by the following colleagues: in algebra, Keijiro Yamazaki, Shin-ichiro Ihara, Takeshi Kondo; in geometry, Tadashi Nagano, Mitsuo Sugiura, Ichiro Tamura, Kiyoshi Katase; in analysis, Nobuyuki Suita, Kotaro Oikawa, Kenkiti Kasahara, Tosinobu Muramatsu, Hikosaburo Komatsu, Setuzô Yosida, Hiroshi Tanaka; and in history, Tamotsu Murata.

We were also assisted by Katsuhiko Chiba in the Russian-language translation of the article titles, and by Osamu Kôta and Kiyoshi Katase in the indexing.

Proof sheets began appearing in the spring of 1966. In proofreading, Kaoru Sekino, Osamu Kôta, Kiyoshi Katase, and Teruo Ushijima helped us, as well as Mrs. Rieko Fujisaki. Miss Yoko Endo worked with all of us throughout the entire revision at the office of the Mathematical Society of Japan. She helped us especially in looking for and checking references and preparing the Name Index.

Yukiyo Kawada supervised the whole work, succeeding me in the role I had played in the compilation of the first and augmented editions. Sin Hitotumatu collaborated with him throughout, especially on the appendices. The second and the third proof sheets of the text were read by Kawada; the fourth proof by Hitotumatu; the proof sheets of appendices by both Kawada and Hitotumatu.

The Editorial Committee of the Mathematical Society of Japan asked me to write this preface. Having edited the previous editions and realizing full well the difficulty of the task, I would like to express my particular gratitude to Kawada. In the Dictionary Department of Iwanami Shoten, Publishers, Messrs. Hiroshi Horie, Tetsuo Misaka, Shigeaki Kobayashi, and Toshio Kouda were very cooperative in their collaboration with us. To them and also to those who typeset and printed this book at Dai-Nippon Printing Co. and Shaken Co. goes our gratitude.

S. Iyanaga
March 1968

Preface to the Revised and Augmented Japanese Edition

Six years have passed since the publication of the first edition of this encyclopedia. This revised and augmented edition incorporates the achievement of these years. It contains, together with the correction of errors found in the first edition, some new articles such as Abelian Varieties, Automata, Sheaves, Homological Algebra, Information Theory, and also supplements to articles in the first edition such as Complex Multiplication, Computers, and Manifolds. These additional items render the new edition 93 pages longer than the previous one. Each article has been thoroughly revised, and the indexes have been completely rewritten.

We were assisted by the following colleagues in selecting articles, writing, and proofreading: In set theory and foundations of mathematics, Sigeatsu Kuroda, Setsuya Seki; in algebra and number theory, Tadao Tannaka, Tsuneo Tamagawa; in real analysis, Shunji Kametani, Kôzoku Yosida; in function theory, Kiyoshi Noshiro, Shin Hitotumatu; in theory of differential and functional equations, Masuo Hukuhara, Masahiro Iwano, Ken Yamanaka; in functional analysis, Kôzoku Yosida, Seizô Itô; in geometry, Shigeo Sasaki, Nagayoshi Iwahori; in topology, Atuo Komatu, Itiro Tamura, Nobuo Yoneda; in theory of probability, Kiyosi Itô, Seizô Itô; in statistics, Toshio Kitagawa, Sigeiti Moriguti, Tatsuo Kawata; in applied mathematics, Sigeiti Moriguti; and in mechanics and theoretical physics, Takahiko Yamanouchi, Isao Imai. The revision and augmentation of the articles concerning the history of mathematics was done by myself. Miles. Yôko Tao, Eiko Miyagawa, and Mutsuko Nogami worked in the office of the Society.

The names of authors who contributed to the completion of this edition have been added to the original list of contributors.

The project of editing this edition started in the summer of 1958. We acknowledge our deep gratitude to all those who have collaborated with us since that time.

Preface to the First Japanese Edition

This encyclopedia, *Iwanami Sûgaku Ziten*, was compiled by the Mathematical Society of Japan at the request of the Iwanami Shoten, Publishers, who have hitherto published a series of scientific dictionaries such as *Iwanami Rikagaku-Ziten* (*Iwanami Encyclopedia of Physics and Chemistry*) and *Iwanami Tetugaku-Ziten* (*Iwanami Encyclopedia of Philosophy*). As mentioned in the prefaces to these volumes, the importance of such encyclopedias in clarifying the present state of each science is obvious if we observe the rapid pace of contemporary research. Mathematics is also in rapid motion. As a fundamental part of exact science, it serves as a basis of all science and technology. It also retains its close contact with philosophy. Therefore, the significance of having an encyclopedia of mathematics cannot be overemphasized.

Mathematics have made remarkable progress in the 20th century. As for the situation toward the end of the 19th century, we quote the following passage from the article Mathematics in the 19th Century of this encyclopedia: "Toward the end of [the 19th] century, the subjects of mathematical research became highly differentiated. Branches split into more specialized areas of study, while unexpected relations were found between previously unconnected fields. The situation became so complicated that it was difficult to view mathematics as a whole. It was in these circumstances that in 1898, at the suggestion of Franz Meyer and under the sponsorship of the Academies of Göttingen, Berlin, and Vienna, a project was initiated to compile an encyclopedia of the mathematical sciences. Entitled the *Enzyklopädie der mathematischen Wissenschaften*, it was completed in 20 years...."

One of the characteristics of 20th-century mathematics is the conscious utilization of the axiomatic method and of general concepts such as sets and mappings, which serve as foundations of different theories. Indeed, mathematics is being reorganized on the basis of topology and algebra. One such example of reorganization is found in Bourbaki's *Éléments de mathématique*; some fifteen volumes of this series have been published since 1939, and more are coming. This encyclopedia, with its limited size, cannot contain proofs for theorems. However, we intend to present a lucid view of the totality of mathematics, including its historical background and future possibilities.

Each article of this encyclopedia is of medium length—sufficiently short to permit

the reader to find exact definitions of notions, and sufficiently long to contain explanations clarifying how important concepts in the same field are related to each other. The problem of choosing adequate titles required some deliberation. The Systematic List of Articles, classified according to specific fields, shows those we have chosen. The Index of Terms contains detailed references for each notion. The appendices, including formulas and tables, supplement the text, and will be particularly useful for applied mathematicians.

The project of compiling this encyclopedia was proposed in the spring of 1947 by the Steering Committee of the Mathematical Society of Japan. It was promptly adopted, and the selection of articles in specific fields was started by the sectional committees of the Society. After seven years, our encyclopedia is finally appearing. We shall not give a detailed description of how our work proceeded through all these years. We list simply the names of those who assisted us greatly and to whom we should like to express our deep gratitude.

The president of the Society at the start of this project was the late Professor Tadahiko Kubota; but our work has been supported also by Professors Teiji Takagi, Zyoiti Suetuna, and Masatsugu Tsuji as well as by other leading members of the Society.

At the stage of selecting articles, we were assisted by the following colleagues: in history and the foundations of mathematics, Sigekatu Kuroda, Motokiti Kondo; in algebra and number theory, Kenjiro Shoda, Tadasi Nakayama, Masao Sugawara, Yukiyoji Kawada, Kenkichi Iwasawa; in geometry, Kentaro Yano, Asajiro Ichida; in function theory, Kiyoshi Noshiro, Yûsaku Komatu; in the theory of differential and functional equations, Masuo Hukuhara, Shigeru Furuya; in topology, Atuo Komatu, Ryoji Shizuma; in functional analysis, Yukio Mimura, Shizuo Kakutani, Kôzaku Yosida; in the theory of probability and statistics, Tatsuo Kawata, Toshio Kitagawa, Junjiro Ogawa; and in applied mathematics, Ayao Amemiya, Isao Imai, Kunihiko Kodaira, Shigeiti Moriguti.

We asked 190 colleagues to contribute articles, which were collected in 1949. Since then we have spent an unexpectedly long time editing them. Terminology had to be unified throughout the encyclopedia so that the reader would have no trouble with cross-references. Repetitions had to be eliminated and gaps filled. Part of the manuscript thus had to be rewritten a number of times. We have made out utmost effort in this editing work, but we are not completely without apprehension that our result has still left something to be desired.

For any shortcomings in the work, I take complete responsibility, as I have acted as the editor-in-chief. Also, since we have rewritten the manuscript, as already mentioned, we have refrained from printing the name of the original author of each article; for this, I must request the understanding of the contributors.

In the stage of editing and proofreading, we were assisted by the following colleagues: Yukio Mimura, Yukiyoji Kawada, Kazuo Matsuzaka, Sin Hitotumatu, Setsuo Fukutomi, Setsuya Seki, Shoji Irie, Shigeo Sasaki, Tatsuo Kawata, Sigekatu Kuroda, Yûsaku Komatu, Ayao Amemiya, Isao Imai, Tosio Kato, Tsurane Iwamura, Morikuni Goto, Kôzaku Yosida, Jirô Tamura, Yasuo Akizuki, Kiyoshi Noshiro, Motosaburo Masuyama, Sigeiti Moriguti, Osamu Kôta, Nobuo Yoneda, Tsuneo Tamagawa, Jun-ichi Hano; and more particularly, in the foundations of mathematics, Sigekatu Kuroda, Tsurane Iwamura; in algebra and number theory, Kazuo Matsuzaka, Yukiyoji Kawada; in algebraic geometry, Yakuo Akizuki; in real analysis, Tatsuo Kawata; in complex analysis, Yûsaku Komatu, Sin Hitotumatu, Jirô Tamura; in functional analysis, Kôzaku Yosida; in topology, Setsuo Fukutomi, Nobuo Yoneda; in the theory of probability and statistics, Motosaburo Masuyama, Sigeiti Moriguti; and in applied mathematics, Ayao Amemiya, Isao Imai, Tosio Kato, Sigeiti Moriguti.

The portraits of Abel and Riemann were kindly loaned to us by Torataro Shimomura.

The formulas in the appendices were compiled by Isao Imai, Sin Hitotumatu, and Sigeiti Moriguti; the Subject Index (in Japanese and European languages) by Osamu Kôta and Mrs. Hiroko Ide; the Name Index and Comments on Journals and Serials by Setsuo Fukutomi. Setsuo Fukutomi has taken an active part in our work ever since 1948 and given much effort to collecting and rewriting the manuscript and to unifying terminology. The editorial staff of Iwanami Shoten, Publishers, has always been cooperative. Without their generous support, this encyclopedia could never have been published.

I should like to express my sincere gratitude to all those who have collaborated with us directly or indirectly.

S. Iyanaga
March 1954

Introduction

The text of this Encyclopedic Dictionary consists of 450 *articles* arranged alphabetically, beginning with 1 Abel and ending with 450 Zeta Functions. Most of these articles are divided into *sections*, indicated by A, B, C, ..., AA, BB, Cross-references to articles, e.g., to the second article, are of the form: (\rightarrow 2 Abelian Groups) or (\rightarrow 2 Abelian Groups A), according as the whole article or a specific section is being referred to. Citations in the indexes are also given in terms of article and section numbers.

Key terms accompanied by their definitions in the text are printed in boldface. All of these terms are found in the Subject Index at the end of the volume.

The sign [†] means that the term preceded by it can be found in the index. A list of special notations used throughout the work (with explanations of their meanings) appears after the appendices.

A Systematic List of Articles, showing the general structure of the work, will be found on p. 1857 (vol. IV). The number in parentheses after each article title refers to this systematic classification into subject areas; e.g., "Abelian Varieties (VIII.5)" means that the article on Abelian varieties is the fifth article in Section VIII of the systematic list.

Books and articles in journals are cited in the text by numbers in brackets: [1], [2], At the end of each article there is a section of references in which, for books, the name of the author or authors, title, name of the publisher, year of publication, and the number of the edition are given; for journals, the name of the author, title of the article, name of the journal, and the volume numbers and inclusive page numbers are given in this order. (The names of journals and publishers are abbreviated as indicated in the lists at the end of the work.)

The Cyrillic alphabet is transliterated as follows:

Cyrillic Alphabet	Transliteration		
А	а	(a)	a
Б	б	(be)	b
В	в	(ve)	v
Г	г	(ge)	g
Д	д	(de)	d
Е	е	(ye)	e

A

1 (XXI.12) Abel, Niels Henrik

Niels Henrik Abel (August 5, 1802–April 6, 1829) was born a son of a poor pastor in the hamlet of Findö in Norway. In 1822, he entered the University of Christiania; however, he studied mathematics almost entirely on his own. He was recognized as a promising student by his senior, Holmboe, and after graduation he studied abroad in Berlin and Paris. In Berlin he met and was aided by A. Crelle, the founder of the *Journal für die Reine und Angewandte Mathematik*, and participated in the founding of this journal. Although he did brilliant work in Paris, he did not gain the fame he deserved. He returned to Norway in May 1827, but, unable to find a job, he was obliged to fight poverty while continuing his research. He died at twenty-six of tuberculosis.

His best-known works are the result that algebraic equations of order five or above cannot generally be solved algebraically, the result that \dagger Abelian equations can be solved algebraically, the theory of \dagger binomial series and of series in general, the theory of \dagger elliptic functions and more generally of \dagger algebraic functions, the introduction of \dagger Abelian integrals, and the establishment of \dagger Abel's theorem. His work in both algebra and analysis, written in a style conducive to easy comprehension, reached the highest level of attainment of his time.

2 (IV.2) Abelian Groups

A. General Remarks

A \dagger group G is called an **Abelian group** (or **commutative group**) if G satisfies the commutative law $ab = ba$ for all $a, b \in G$. In this article, G always denotes an Abelian group. Every \dagger subgroup of G is a \dagger normal subgroup, and all the elements of finite order in G form a subgroup

T , for which the \dagger factor group G/T has no elements of finite order except the identity e . T is called the (**maximal**) **torsion subgroup** of G . If $G = T$, then the Abelian group G is called a **torsion group** (or **periodic group**). On the other hand, if $T = \{e\}$, then G is called **torsion-free**; if $T \neq G$, $T \neq \{e\}$, then G is called **mixed**. If the order of every element of a torsion group G is a power of a fixed prime number p , then G is called an **Abelian p -group** (or **primary Abelian group**). An Abelian torsion group is the \dagger direct sum of primary Abelian groups. Thus the study of torsion groups is reduced to that of primary Abelian groups.

B. Finite Abelian Groups

The following fundamental theorem on finite Abelian groups was established by L. Kronecker, G. Frobenius, and L. Stickelberger in the 1870s. An Abelian group G of order p^n , where p is a prime number, is a direct product of \dagger cyclic subgroups Z_1, \dots, Z_r : $G = Z_1 \times \dots \times Z_r$. If Z_i is of order p^{n_i} , then $n = n_1 + \dots + n_r$, and we can assume that $n_i \geq n_{i+1}$. A direct product decomposition of G , as above, is not unique, but n_1, \dots, n_r are determined uniquely by G . The system $\{p^{n_1}, \dots, p^{n_r}\}$ or $\{n_1, \dots, n_r\}$ is called the system of **invariants** (or **type**) of G , and a system of \dagger generators $\{z_1, \dots, z_r\}$ of Z_1, \dots, Z_r is called a **basis** of G . An Abelian group of type (p, p, \dots, p) is called an **elementary Abelian group**. The decomposition of a finite Abelian group into a \dagger direct sum of subsets (not necessarily of subgroups) was considered by G. Hajós (1942) and applied successfully to a problem of number theory (\rightarrow 151 Finite Groups).

C. Finitely Generated Abelian Groups

The theory of \dagger finitely generated Abelian groups, i.e., Abelian groups generated by a finite number of elements, is as old as that of finite Abelian groups. The direct product of \dagger infinite cyclic groups is called a **free Abelian group**. A finitely generated Abelian group G is the direct product of a finite Abelian group and a free Abelian group. The finite factor is the **torsion subgroup** of G . The free factor of the group G is not necessarily unique; however, the number of infinite cyclic factors of the free factor is uniquely determined and is called the **rank** of G . Two finitely generated Abelian groups are isomorphic if they have isomorphic maximal torsion subgroups and the same rank. This theory can be extended to the theory of \dagger modules over a \dagger principal ideal domain (\rightarrow 67 Commutative Rings K).

D. Torsion Groups

The structure of Abelian p -groups is relatively well known, compared with other infinitely generated Abelian torsion groups. In the 1920s, H. Prüfer made the first important contribution to the study of Abelian p -groups, and H. Ulm and L. Zippin completed the theory for countable groups in the 1930s. The uncountable case was first treated by L. Kulikov in the 1940s, but the study of this case is still in progress.

An Abelian p -group $G \neq \{e\}$ is called **divisible** (or **complete**) if for any $a \in G$ there is an element $x \in G$ satisfying $x^p = a$. A divisible group is a \dagger direct sum of **Abelian groups of type p^∞** (Prüfer). Here a group of type p^∞ is isomorphic to the \dagger multiplicative group of all the p^n th roots of unity ($n = 1, 2, \dots$) in the complex number field. Let G be any Abelian p -group. The maximal divisible subgroup V of G is a direct product factor of G : $G = V \times R$, where R has no divisible subgroups. An Abelian p -group without a divisible subgroup is called a **reduced Abelian group**.

An element x of an Abelian p -group G is said to have **infinite height** if for any n there is an element $y_n \in G$ satisfying $x = y_n^{p^n}$. The elements of infinite height form a subgroup G^1 of G . If $G^1 = \{e\}$ and G is countable, then G is decomposed uniquely into the direct sum of cyclic groups. This assertion fails if the hypothesis of countability is dropped. By \dagger transfinite induction we can define G^β as follows. If β is an \dagger isolated ordinal number, then $G^\beta = (G^{\beta-1})^1$; if β is a \dagger limit ordinal number, then $G^\beta = \bigcap_{\alpha < \beta} G^\alpha$. For the least ordinal number τ such that $G^\tau = G^{\tau+1}$, G^τ is the maximal divisible subgroup of G . If G is reduced, then $G^\tau = \{e\}$. We call τ the **type** of an Abelian p -group G . For $\alpha < \tau$, $\bar{G}^\alpha = G^\alpha / G^{\alpha+1}$ is called the **Ulm factor** of G , and the sequence $\bar{G}^0, \dots, \bar{G}^\alpha, \dots$ ($\alpha < \tau$) is called the **sequence of Ulm factors** of G . Each Ulm factor \bar{G}^α has no element of infinite height, and if $\alpha < \tau - 1$, then \bar{G}^α has an element of arbitrarily large order. Let τ be a countable ordinal number; assume that for any ordinal number $\alpha < \tau$ there is given a countable Abelian p -group A_α such that A_α has no element of infinite height, and that for $\alpha \neq \tau - 1$ A_α has an element of arbitrarily large order. Then there is a reduced countable Abelian p -group which is of type τ with a sequence of Ulm factors isomorphic to $A_0, A_1, \dots, A_\alpha, \dots$ ($\alpha < \tau$) (Zippin). Two reduced countable Abelian p -groups A and B are isomorphic if they have the same type τ ; and for any $\alpha < \tau$ the Ulm factors \bar{A}^α and \bar{B}^α are isomorphic. The assertion fails if the hypothesis of countability is dropped.

E. Torsion-Free Groups

In Abelian groups, the group operation is often written $a + b$, using the additive notation; an additively written group, called an **additive group**, is generally assumed to be Abelian. In the rest of this article we consider exclusively additive Abelian groups, of which the additive group \mathbf{Z} of rational integers is the most primitive example. In such a group the identity element is called the **zero element** and is denoted by 0; the inverse of a is denoted by $-a$, and we write $a + (-b) = a - b$. The direct sum of additive groups A_λ ($\lambda \in \Lambda$) is called a **free additive group** if each A_λ is isomorphic to \mathbf{Z} . An additive group G is regarded as a \dagger module over the \dagger ring \mathbf{Z} , to which the notion of linear independence is applicable (\rightarrow 277 Modules). Elements a_1, \dots, a_r of G are **linearly dependent** if there are integers n_1, \dots, n_r , not all of which are zero such that $n_1 a_1 + \dots + n_r a_r = 0$. Those that are not linearly dependent are termed **linearly independent**. An infinite set of elements of G is called linearly independent if the elements of any finite subset are linearly independent. If there are N elements of G that are linearly independent, but if any $N + 1$ elements of G are linearly dependent, then N is called the **rank** of G . Such a system of N linearly independent elements is called a **maximal independent system**. A torsion-free additive group G is not necessarily free if G is not finitely generated.

The first important work on torsion-free additive groups was done by F. W. Levi (1917). A. G. Kurosh (1937) completed the theory in the case of finite rank. In the general case little is known, and I. Kaplansky, J. Rotman, and others are continuing the investigation.

The additive group \mathbf{Q} of rational numbers is of rank 1, and conversely any additive group of rank 1 is isomorphic to some subgroup of \mathbf{Q} . An additive group G is called **divisible** (or **complete**) if for any $a \in G$ and for any integer n there is an element $x_n \in G$ such that $nx_n = a$. A divisible torsion-free additive group is isomorphic to a direct sum of some copies of \mathbf{Q} . For any torsion-free additive group G there is a divisible torsion-free additive group containing G . A minimal additive group F among these groups is uniquely determined up to isomorphism and has the rational number field \mathbf{Q} as an \dagger operator domain. Let $\mathbf{Q}^{(p)} = \{a/b \mid (a, b) = 1, p \nmid b\}$ be the ring of p -integers in \mathbf{Q} , and let G_p be the smallest $\mathbf{Q}^{(p)}$ -subgroup of F containing G . Let \mathbf{Q}_p be the $\dagger p$ -adic number field and \mathbf{Z}_p the ring of $\dagger p$ -adic integers. Extending the operator domain \mathbf{Q} to \mathbf{Q}_p we obtain naturally a \mathbf{Q}_p -module F_p from F . Let \bar{G}_p be the natural closure of G_p in F_p . Then \bar{G}_p has \mathbf{Z}_p as an

operator domain and thus becomes a \mathbb{Z}_p -module. A \mathbb{Z}_p -module of rank N is isomorphic to the direct sum of κ_p copies of \mathbb{Q}_p and $N - \kappa_p$ copies of \mathbb{Z}_p : $G_p \cong \sum_n \mathbb{Q}_p v_n + \sum_m \mathbb{Z}_p w_m$ ($n = 1, \dots, \kappa_p$; $m = 1, \dots, N - \kappa_p$). Here κ_p is called the p -rank of G . As the invariants of G , Kurosh gives the rank, the p -ranks for all primes p , and a certain equivalence class of the sequence of the matrices \mathfrak{M}_p . Here p ranges over all primes, and \mathfrak{M}_p is the matrix of coefficients when the elements of a maximal independent system of F are written as linear combinations of (v_n, w_m) .

F. General Abelian Groups

An Abelian group is, in general, an extension of a torsion group by a torsion-free group. A torsion group T is called **bounded** if there is an integer n such that $t^n = 1$ for all $t \in T$. Suppose there is a torsion group T . Then T is a direct summand of an Abelian group G which contains T as its maximal torsion subgroup if and only if T is the direct product of a divisible group and a bounded group (R. Baer and S. Fomin).

G. Characters

A **character** χ of an Abelian group G is a function which assigns to each $a \in G$ a complex number $\chi(a)$ of absolute value 1 and satisfies $\chi(ab) = \chi(a)\chi(b)$ for all $a, b \in G$. The product $\chi = \chi_1 \chi_2$ of two characters χ_1 and χ_2 is defined by $\chi(a) = \chi_1(a)\chi_2(a)$, and χ is also a character of G . Thus all the characters of G form an Abelian group $C(G)$, which is called the **character group** of G . The identity element of the character group is the **identity character** (or **principal character**) χ such that $\chi(a) = 1$ for all $a \in G$. If G is finite, then $G \cong C(G)$. This implies the duality $G = C[C(G)]$. This fact was extended by L. S. Pontryagin to locally compact topological Abelian groups (\rightarrow 422 Topological Abelian Groups B–D). For additive Abelian groups with operator domains \rightarrow 277 Modules.

3 (VIII.5) Abelian Varieties

A. History

Except for C. F. Gauss, whose work on this subject saw the light many years after his death, N. H. Abel was the first to consider algebraic functions as functions of complex variables and to discover double periods of elliptic functions such as $x = x(u)$, which is the inverse function of an elliptic integral

$$u = \int^x \frac{dx}{\sqrt{f_4(x)}},$$

where $f_4(x)$ is a polynomial in x of degree 4. C. G. Jacobi expressed elliptic functions explicitly as ratios of theta series. As a natural generalization of elliptic functions, which are Abelian functions of genus 1, Jacobi and his successors studied the inverse function of the hyperelliptic integral, or more generally, the inverse function of the Abelian integral. By investigating hyperelliptic integrals of the first kind of genus 2,

$$\int^{x_1} \frac{dx_1}{\sqrt{f_6(x_1)}}, \quad \int^{x_2} \frac{x_2 dx_2}{\sqrt{f_6(x_2)}},$$

where $f_6(x)$ is a polynomial of degree 6 in x , Jacobi obtained multiple-valued functions with quadruple periods. He then discovered the remarkable fact that if we consider sums of two integrals

$$u_1 = \int^{x_1} \frac{dx_1}{\sqrt{f_6(x_1)}} + \int^{x_2} \frac{dx_2}{\sqrt{f_6(x_2)}},$$

$$u_2 = \int^{x_1} \frac{x_1 dx_1}{\sqrt{f_6(x_1)}} + \int^{x_2} \frac{x_2 dx_2}{\sqrt{f_6(x_2)}},$$

the elementary symmetric functions $s_1 = x_1 + x_2$ and $s_2 = x_1 x_2$ of x_1 and x_2 are single-valued functions of u_1 and u_2 with quadruple periods. He also conjectured that these functions s_1 and s_2 might be expressed explicitly in terms of theta series of u_1 and u_2 ; this conjecture was later confirmed by J. G. Rosenhain and A. Göpel.

In the latter half of the 19th century, the general theory of Abelian functions was established. The central subject was Jacobi's inverse problem (\rightarrow Section L), which is a natural generalization of the above results. B. Riemann solved this problem by expressing elementary Abelian functions (\rightarrow Section M) as rational functions of theta functions.

The theory of functions with multiple periods was developed further by H. Poincaré, G. Frobenius, and E. Picard. In the 20th cen-

tury, the importance of the theories of Abelian functions and Abelian varieties has become more obvious with the development of the theory of functions of several complex variables and algebraic geometry. In particular, problems intimately related to number theory have given rise to the development of a purely algebraic theory of Abelian varieties. Valuable contributions have been made by S. Lefschetz, C. L. Siegel (*Siegel modular forms), A. Weil (algebraic theory of Abelian varieties, systematization of the theory of theta functions), and by D. Mumford (*moduli theory, algebraic theory of theta functions).

B. Algebraic Theory

When a \dagger group variety is \dagger complete as a variety, the group law is commutative; such a group variety is called an **Abelian variety** (\rightarrow 12 Algebraic Varieties H.). Let B be a subvariety of an Abelian variety A , and assume that B is a subgroup of A as an abstract group. Then B has the structure of an Abelian variety whose law of composition is induced by that of A , and B is called an **Abelian subvariety** of A . More generally, when an algebraic subset \mathfrak{B} is a subgroup of A , then the component B of \mathfrak{B} containing the identity element is an Abelian subvariety, and \mathfrak{B} is a union of B and a finite number of cosets of B . When A is defined over a field k , then any Abelian subvariety of A is defined over a finite \dagger separable extension of k (W. L. Chow's theorem). An Abelian variety A is called **simple** if A has no Abelian subvarieties other than A itself and 0.

Every \dagger rational mapping of an algebraic variety V into an Abelian variety is defined at each simple point of V . This implies that an Abelian variety is \dagger absolutely minimal.

C. Homomorphisms

A rational mapping of an Abelian variety A into an Abelian variety B is called a **rational homomorphism** (or simply **homomorphism**) if f is a group homomorphism. Let F be a rational mapping of A into B ; then F can be uniquely expressed as follows: $F(x) = F_0(x) + F(0)$ ($x \in A$), where F_0 is a homomorphism and $F(0)$ is the image of the unit element 0 of A . Hence the structure of an Abelian variety (as a group variety) is uniquely determined by the underlying algebraic-variety structure.

When a rational homomorphism f is birational, f is called a **birational isomorphism** (or simply **isomorphism**). It is clear that a rational isomorphism is an abstract isomorphism, but the converse is not necessarily true. Let A, B

be two Abelian varieties. We say that A is **isogenous** to B if the dimension of A is equal to that of B and there exists a surjective homomorphism of A onto B , or equivalently, if there exists a surjective homomorphism of A onto B whose kernel is finite. The relation of isogeny is an equivalence relation. For an Abelian variety A and an Abelian subvariety X of A there is an Abelian subvariety Y of A such that the natural homomorphism $X \times Y \rightarrow A: (x, y) \rightarrow x + y$ is an isogeny (**Poincaré's complete reducibility theorem**). In particular, every Abelian variety is isogenous to a product of simple Abelian varieties that are determined uniquely up to isogeny and order.

Let A, B be two Abelian varieties; we denote by $\text{Hom}(A, B)$ the additive group of rational homomorphisms of A into B . When a rational homomorphism λ is surjective, then the **degree** $v(\lambda)$ of λ is defined by $\lambda(A) = v(\lambda)B$ as \dagger algebraic cycles. If λ is an isogeny, then $v(\lambda) \neq 0$, and the order of the kernel $\{t \mid t \in A, \lambda t = 0\}$ is at most $v(\lambda)$ and equal to $v(\lambda)$ if and only if λ is \dagger separable. The additive group $\text{Hom}(A, B)$ is shown to be free of rank $\leq 4 \dim A \cdot \dim B$ by the l -adic representation (\rightarrow Section E). If $A = B$, then $\text{Hom}(A, A)$ has a ring structure; it is called the **ring of endomorphisms** (or **endomorphism ring**) of A and is denoted by $\mathfrak{U}(A)$. The tensor product $\mathfrak{U}_0(A) = \mathfrak{U}(A) \otimes \mathbf{Q}$, where \mathbf{Q} is the field of rational numbers, is an \dagger associative algebra over \mathbf{Q} . If A is simple, then $\mathfrak{U}_0(A)$ is a \dagger division algebra. More generally, $\mathfrak{U}_0(A)$ is isomorphic to a direct product of some \dagger total matrix algebras over division algebras; thus $\mathfrak{U}_0(A)$ is \dagger semisimple. In particular, if A is 1-dimensional (in other words, if A is an \dagger elliptic curve), the types of $\mathfrak{U}_0(A)$ are well known; when the characteristic $p = 0$, then $\mathfrak{U}_0(A)$ is either the field of rational numbers or an \dagger imaginary quadratic field. When $p > 0$, aside from these two fields, we have a \dagger quaternion algebra over \mathbf{Q} as a possible type of $\mathfrak{U}_0(A)$.

Let k be a finite field with q elements. An algebraic integer is called a **Weil number** for q if every conjugate of it has absolute value $\sqrt[q]{q}$. If A is an Abelian variety defined and simple over k , the q th power endomorphism of $A: x \rightarrow x^q$ determines a conjugacy class of Weil numbers for q , as Weil showed (\rightarrow 450 Zeta Functions). Moreover, we have the following classification theorem (J. Tate, T. Honda): There is a one-to-one correspondence between the set of all k -isogeny classes of k -simple Abelian varieties over k and the set of all conjugacy classes of Weil numbers for q . Tate also determined the structure of the division algebra $\mathfrak{U}_0(A)$ over \mathbf{Q} , which is described in terms of the decomposition of the q th power endomorphism into prime ideals.

D. Divisors

Let \mathfrak{G} be the additive group of \dagger divisors on an Abelian variety A and \mathfrak{G}_a be the subgroup of divisors that are \dagger algebraically equivalent to 0. Then the factor group $\mathfrak{G}/\mathfrak{G}_a$ has no \dagger torsion part; this implies that for an Abelian variety \dagger numerical equivalence coincides with \dagger algebraic equivalence. We denote this relation by \equiv . Given an element a of A , the translation $T_a: A \ni x \rightarrow x+a \in A$ gives a \dagger birational transformation, which is everywhere \dagger biregular, on the underlying variety of A ; we denote by X_a the image of a divisor X on A . Then $X \equiv 0$ if and only if X_a is \dagger linearly equivalent to X for each point a of A . The \dagger Albanese variety of an Abelian variety A is A itself, and the \dagger Picard variety \hat{A} of A is isogenous to A . In particular, for the \dagger Jacobian variety J of an algebraic curve, \hat{J} is isomorphic to J itself. The Picard variety $\hat{\hat{A}}$ of \hat{A} is isomorphic to A (**duality theorem**). Let X be a divisor on A ; the mapping $a \rightarrow$ the \dagger linear equivalence class of the divisor $X_a - X$, $a \in A$, is a rational homomorphism of A into \hat{A} , and we denote it by φ_X . If $\varphi_X = 0$, then $X \equiv 0$, and vice versa; hence we have an additive map of $\mathfrak{G}/\mathfrak{G}_a$ into $\text{Hom}(A, \hat{A})$. If φ_X is surjective, we say that X is **nondegenerate**. A \dagger positive divisor X is nondegenerate if and only if X is \dagger ample, and then nX is \dagger very ample for $n \geq 3$. There always exist positive nondegenerate divisors on an Abelian variety; therefore an Abelian variety is a \dagger projective variety. For a given divisor X on A , we can find n suitable points u_1, \dots, u_n , where n is the dimension of A , so that the \dagger intersection product $X_{u_1} \cdot \dots \cdot X_{u_n}$ is defined. We denote by $(X^{(n)})$ the \dagger degree of the zero cycle $X_{u_1} \cdot \dots \cdot X_{u_n}$. If X is positive nondegenerate, then the dimension $l(X)$ of the \dagger defining module of the \dagger complete linear system determined by X is equal to $(X^{(n)})/n!$ (**Poincaré's theorem**). Furthermore, the degree $v(\varphi_X)$ of φ_X , where X is any divisor on A , is given by the formula $v(\varphi_X) = ((X^{(n)})/n!)^2$ (**Frobenius's theorem**).

For a nondegenerate divisor X on A there is a unique integer $i = i(X)$, $0 \leq i \leq \dim A$, called the **index** of X , such that $H^p(A, \mathcal{O}(X)) = 0$ for $p \neq i$ and $H^i(A, \mathcal{O}(X)) \neq 0$. We have $i(-X) = \dim A - i(X)$ and $i(X) = 0$ if and only if X is ample.

E. l -adic Representations

Let A be an Abelian variety of dimension n . For a given prime number l , let $\mathfrak{G}_l(A)$ denote the group of points on A whose order is a power of l . If l is different from the characteristic of the base field of A , then the group $\mathfrak{G}_l(A)$ is isomorphic to the direct product of $2n$

factor groups $\mathbf{Q}_l/\mathbf{Z}_l$, where \mathbf{Q}_l is the field of l -adic numbers and \mathbf{Z}_l is the group of l -adic integers (\rightarrow 439 Valuations). We call such an isomorphism the **l -adic coordinate system** of $\mathfrak{G}_l(A)$. Now let λ be a rational homomorphism of A into an Abelian variety B of dimension m . Then we can see that λ induces a homomorphism of $\mathfrak{G}_l(A)$ into $\mathfrak{G}_l(B)$. This shows that by placing l -adic coordinate systems on $\mathfrak{G}_l(A)$ and $\mathfrak{G}_l(B)$ respectively, we get a matrix representation $M_l(\lambda)$ of λ with $2m$ rows and $2n$ columns. The representation $\lambda \rightarrow M_l(\lambda)$ is faithful, and $M_l(\lambda)$ is called the **l -adic representation** of λ . When $A = B$, then $\lambda \rightarrow M_l(\lambda)$ is a faithful representation of the ring of endomorphisms $\mathfrak{A}(A)$. This representation can be naturally extended to the representation of the algebra $\mathfrak{A}_0(A)$; the characteristic polynomial of the l -adic representation $M_l(\lambda)$ (where λ is an element of $\mathfrak{A}_0(A)$) is a polynomial with coefficients in \mathbf{Q} . Moreover, the polynomial does not depend on the choice of the prime number l . When $\lambda \in \mathfrak{A}(A)$, then $v(\lambda)$ is equal to $\det M_l(\lambda)$. The trace of $M_l(\lambda)$ is usually written as $\sigma(\lambda)$.

Let λ be a rational homomorphism of A into B and Y be a divisor on B . Then by the correspondence $\text{cl}(Y) \rightarrow \text{cl}(\lambda^{-1}(Y))$, we obtain a rational homomorphism of \hat{B} into \hat{A} , called the **transpose** of λ and denoted by ${}^t\lambda$, where cl means the linear equivalence class (\rightarrow 16 Algebraic Varieties M). If X is a nondegenerate divisor on A , then the composition map $\beta: \hat{A} \rightarrow A$ of ${}^t\varphi_X: \hat{A} \rightarrow \hat{\hat{A}}$ and the canonical isomorphism $\hat{\hat{A}} \rightarrow A$ satisfy the equality $\beta \circ \varphi_X = v(\varphi_X)\delta$ ($\delta =$ the identity mapping of A). We denote by φ_X^{-1} the element $(1/v(\varphi_X))\beta$ in $\text{Hom}(\hat{A}, A) \otimes \mathbf{Q}$. The correspondence $\alpha \rightarrow \alpha'$, $\alpha' = \varphi_X^{-1} \circ {}^t\alpha \circ \varphi_X$ ($\alpha \in \mathfrak{A}_0(A)$) is an \dagger involution of $\mathfrak{A}_0(A)$ and is of order 1 or 2. If $\alpha \neq 0$, then $\sigma(\alpha' \circ \alpha) > 0$ (**Castelnuovo's lemma**). A. Weil was the first to recognize the importance of this theorem in connection with \dagger Riemann's hypothesis on \dagger congruence zeta functions.

F. Differential Forms

A \dagger differential form ω on an Abelian variety A of dimension n is called **invariant** if $T_a^*\omega = \omega$ for every point $a \in A$, where T_a is the translation by a (\rightarrow Section D). The differential form \dagger of the first kind is invariant, and conversely, every invariant differential form is of the first kind. Let K be the \dagger universal domain and $K(A)$ be the \dagger function field of A . The set of the linear differential forms of the first kind on A is a linear space over K of dimension n , and its basis becomes a basis over $K(A)$ of the linear space consisting of all linear differential forms on A . An **invariant derivation** on A is a derivation D in $K(A)$ satisfying $(Df) \circ T_a = D(f \circ T_a)$

for any element f of $K(A)$ and every point a of A . For a linear differential form $\omega = \sum f_i du_i$ and a derivation D , we put $\langle \omega, D \rangle = \sum f_i Du_i$. Then $\langle \omega, D \rangle$ is a bilinear form in ω and D . A derivation D is invariant if and only if $\langle \omega, D \rangle$ is a constant function for every invariant linear differential form ω . Similarly, a linear differential form ω is invariant if and only if $\langle \omega, D \rangle$ is a constant function for every invariant derivation D . The linear space of invariant linear differential forms and that of invariant derivations are dual to each other with respect to the bilinear form $\langle \omega, D \rangle$.

Now consider the case when the characteristic p of the universal domain is positive. The automorphism $a \rightarrow a^p$, $a \in K$, of the universal domain K induces a group isomorphism of A ; we denote by A^p the image of A and by x^p the image of a point x of A . The image A^p is an Abelian variety, and the group isomorphism $\pi: x \rightarrow x^p$, $x \in A$, is an isogeny of A onto A^p . Let B be another Abelian variety and let λ be an isogeny of A onto B . If there is an isogeny $\mu: B \rightarrow A^p$ such that $\pi = \mu \circ \lambda$, then we say that λ is of **height 1**. The function field $K(B)$ of B can be considered as a subfield of the function field $K(A)$ of A by the mapping λ . If λ is of height 1 and $v(\lambda) = p$, there exists an invariant derivation D of $K(A)$ with the constant field $K(B)$, uniquely determined up to constants. Moreover, we can choose D so that $D^p = D$ or $D^p = 0$. In the first case λ is said to be of type (i_1) ; in the second case it is said to be of type (i_2) . An isogeny whose degree is a prime different from the characteristic p is said to be of type (s_1) , and a separable isogeny whose degree is p is said to be of type (s_2) . Any isogeny can be written as a product of isogenies of these four types.

G. Polarized Abelian Varieties

Let X be a divisor on an Abelian variety A ; we denote by \mathfrak{X} the class of divisors X' such that $mX \equiv m'X'$ for suitably chosen positive integers m, m' . When the class \mathfrak{X} contains positive nondegenerate divisors, we say that \mathfrak{X} determines a **polarization** on A , and the couple (A, \mathfrak{X}) is called a **polarized Abelian variety**. In particular, if A is a \dagger Jacobian variety whose polarization \mathfrak{X} is determined by a theta divisor, we call (A, \mathfrak{X}) the **canonically polarized Jacobian variety**. If an endomorphism α of A keeps the polarization invariant, i.e., if the class determined by $\alpha^{-1}(X)$ coincides with the class \mathfrak{X} , then α is called an **endomorphism** of the polarized Abelian variety (A, \mathfrak{X}) . In particular, if α is an automorphism of A , then we say that α is an **automorphism** of (A, \mathfrak{X}) . The group of all automorphisms of a polarized

Abelian variety is finite. In particular, the group of automorphisms of a canonically polarized Jacobian variety is finite. Hence follows the famous theorem concerning the finiteness of the group of automorphisms of an \dagger algebraic curve of genus not less than 2.

On the other hand, the algebraic equivalence class of a nondegenerate divisor is called an **inhomogeneous polarization**. (The above polarization is then sometimes called a homogeneous polarization.) An inhomogeneous polarization X determines an isogeny $\varphi_X: A \rightarrow \hat{A}$ uniquely. If φ_X is an isomorphism, the polarization is called **principal**. An endomorphism of an inhomogeneously polarized Abelian variety can be defined similarly.

H. Analytic Theory

For the rest of this article we take the complex number field \mathbb{C} as the universal domain, and in this case we can utilize analytic and topological methods.

Let \mathbb{C}^n be an n -dimensional vector space over \mathbb{C} . In a natural way, the space \mathbb{C}^n becomes a $2n$ -dimensional vector space \mathbb{R}^{2n} over the real field \mathbb{R} , and the mapping $J: z \rightarrow \sqrt{-1}z$, $z \in \mathbb{C}^n$, is an \mathbb{R} -linear automorphism of \mathbb{R}^{2n} such that $J^2 = -1$. Conversely, if for an even-dimensional \mathbb{R} -vector space \mathbb{R}^{2n} such a mapping J is given, then by putting $(a + \sqrt{-1}b)x = ax + bJx$ ($x \in \mathbb{R}^{2n}$; $a, b \in \mathbb{R}$), we can introduce an n -dimensional complex linear structure into \mathbb{R}^{2n} . We then say that J determines a **complex structure** on \mathbb{R}^{2n} ; we denote by $\mathbb{C}^n = (\mathbb{R}^{2n}, J)$ the space having the complex structure determined by J . Let $\omega_1, \dots, \omega_{2n}$ be $2n$ \mathbb{R} linearly independent points on $\mathbb{C}^n = (\mathbb{R}^{2n}, J)$. Then the \dagger lattice \mathbb{D} generated by these points is discrete, and the factor group $\mathbb{T}^n = \mathbb{C}^n / \mathbb{D}$ is a **complex torus** of dimension n . We fix a basis of \mathbb{C}^n and introduce a complex coordinate system on \mathbb{C}^n . Utilizing the basis $\omega_1, \dots, \omega_{2n}$ of \mathbb{R}^{2n} , we also introduce a real coordinate system on \mathbb{R}^{2n} . We then obtain an $n \times 2n$ matrix $\Omega = (\omega_{ij})$, where the $(\omega_{1i}, \dots, \omega_{ni})$ are the complex coordinates of ω_i ; the matrix Ω is called the **period matrix** of \mathbb{T}^n . Let (z_1, \dots, z_n) be the complex coordinates of a point $z \in \mathbb{C}^n$ and (x_1, \dots, x_{2n}) be the real coordinates. Then we have $\dagger(z_1, \dots, z_n) = \Omega \dagger(x_1, \dots, x_{2n})$. If we let the same symbol J stand for the representation matrix of the linear transformation J with respect to the basis $\omega_1, \dots, \omega_{2n}$, then we have $\sqrt{-1}\Omega = \Omega J$. The underlying real Lie group of \mathbb{T}^n is a $2n$ -dimensional (real) \dagger torus group $(\mathbb{R}/\mathbb{Z})^{2n}$. Hence the \dagger Poincaré polynomial of \mathbb{T}^n is $(1+x)^{2n}$. Any \dagger Hermitian metric on \mathbb{C}^n (as a vector space) induces a \dagger flat \dagger Kähler metric; hence the

Hodge numbers (\rightarrow Kähler Manifolds C) are $h^{p,q} = \binom{n}{p} \binom{n}{q}$.

I. Theta Functions

A holomorphic function $f(z)$ on $C^n = (R^n, J)$ is called a **theta function** if for every $d \in D$ we have $f(z+d) = f(z) \exp(l_d(z) + c_d)$, where $l_d(z)$ is a linear form on C^n which, as for c_d , depends on d . The set of zeros of a theta function f , which we write as (f) , determines an analytic divisor on T^n . Conversely, for every effective analytic divisor X on T^n , there exists a theta function f such that $(f) = X$. With respect to the real coordinate system x_1, \dots, x_{2n} determined by the basis $\omega_1, \dots, \omega_{2n}$, we can find $2n \times 2n$ matrices A, A_0 and a $1 \times 2n$ matrix b , with elements in C , such that the **transformation formula** $f(x+a) = f(x) \exp(2\pi\sqrt{-1}(aAx + \frac{1}{2}aA_0a + ba))$ (where $A \equiv A_0 \pmod{Z}$, $A_0 = A_0$) holds for every $1 \times 2n$ matrix a whose elements are rational integers. Moreover, if we put $E = A - {}^1A$, then E is an alternating matrix whose elements are rational integers, and $S = EJ$ is a positive semidefinite symmetric matrix. Conversely, if there exists such an alternating matrix E we can find a theta function. (There does exist, however, a complex torus on which no theta function exists other than trivial ones, i.e., ones of the form $\exp(\varphi(z))$, where $\varphi(z)$ is a polynomial of degree at most 2.)

A theta function f is called **nondegenerate** if it cannot be a function of $n-1$ complex variables, and f is nondegenerate if and only if the matrix $S = EJ$ is positive definite. A complex torus has the structure of an Abelian variety if and only if there exists a nondegenerate theta function, i.e., if and only if there exists an alternating matrix E whose elements are rational integers such that EJ is a positive definite symmetric matrix. The latter condition is satisfied if and only if there exists an alternating matrix E whose elements are rational integers such that $\Omega {}^1E^{-1} \Omega = 0$, $\sqrt{-1} \Omega {}^1E^{-1} \Omega > 0$ (positive definite Hermitian matrix). In particular, a period matrix Ω satisfying these conditions is called a **Riemann matrix**, and the rational matrix ${}^1E^{-1}$ is called the **principal matrix** belonging to Ω .

Determining a polarization on an Abelian variety can be reduced to designating a class of principal matrices obtained from a given

from f is invertible. For a given principal matrix ${}^1E^{-1}$, we can choose suitable coordinate systems of C^n and D so that $\Omega = (I_n, F)$ and $E = \begin{pmatrix} 0 & \Delta \\ -\Delta & 0 \end{pmatrix}$, where I_n is a unit matrix and Δ is a diagonal matrix whose elements are elementary divisors of E . In these situations, ΔF is symmetric and its imaginary part positive definite, i.e., ΔF is a point of the Siegel upper half-space \mathfrak{S}_n . Thus to the polarized Abelian variety (where the polarization is determined by ${}^1E^{-1}$) there corresponds a point of \mathfrak{S}_n . This gives a one-to-one correspondence between the isomorphism classes of Abelian varieties inhomogeneously polarized by a principal matrix with given elementary divisors and the points of the factor space $\mathfrak{S}_n/\Gamma_n(\Delta)$, where $\Gamma_n(\Delta)$ is a subgroup that is commensurable to the Siegel modular group of degree n and operates on \mathfrak{S}_n discontinuously. The case of principal polarization corresponds to the case when $\Delta = I_n$, and then $\Gamma_n(\Delta)$ is the Siegel modular group itself. $\mathfrak{S}_n/\Gamma_n(\Delta)$ is the coarse moduli space of Abelian varieties, polarized as above; the projective embedding of $\mathfrak{S}_n/\Gamma_n(\Delta)$ is given by means of Siegel modular forms.

J. Abelian Functions

Meromorphic periodic functions on C^n with periods $\omega_1, \dots, \omega_{2n}$ (i.e., meromorphic functions on $T = C^n/D$, $D = Z\omega_1 \oplus \dots \oplus Z\omega_{2n}$) are called **Abelian functions** with periods D (or on T). The quotient of two theta functions having the same periods and the same transformation formulas is an Abelian function, and conversely any Abelian function can be written as such. All Abelian functions on T form a field $C(T)$ called the **Abelian function field**. If T has the structure of an Abelian variety, then $C(T)$ coincides with the field of rational functions on T . In general, for any complex torus T there are an Abelian variety T' (possibly of dim 0) and a surjective homomorphism $\lambda: T \rightarrow T'$ which induces an isomorphism $\lambda^*: C(T') \simeq C(T)$. Such a pair $(T', \lambda: T \rightarrow T')$ is unique up to isomorphism, and is called the **algebraic reduction** of T .

K. Homomorphisms

Let $C^{n_i} = (R^{2n_i}, J_i)$ ($i = 1, 2$) be complex linear spaces, D_1, D_2 be lattices in R^{2n_1}, R^{2n_2} respectively.

$T^n = C^n/D$, and let f be a theta function such that $(f) = X$. Then the divisor X is nondegenerate if and only if the theta function f is nondegenerate, and the latter statement holds if and only if the alternating matrix E obtained

$i = 1, 2$. If a C -linear mapping $\Lambda: C^{n_1} \rightarrow C^{n_2}$ satisfies $\Lambda(D_1) \subset D_2$, then Λ induces a complex analytic homomorphism of $T_1 = C^{n_1}/D_1$ to $T_2 = C^{n_2}/D_2$. Conversely, any complex analytic homomorphism of T_1 to T_2 is ob-

tained in this way. Let \mathbf{T}_1 and \mathbf{T}_2 be Abelian varieties, and let $\Omega_1 = (\omega_1^{(1)}, \dots, \omega_{2n_1}^{(1)})$ and $\Omega_2 = (\omega_1^{(2)}, \dots, \omega_{2n_2}^{(2)})$ be their Riemann matrices. Then for a homomorphism $\lambda: \mathbf{T}_1 \rightarrow \mathbf{T}_2$, we can find a representation matrix $W(\lambda)$ with complex coefficients; and with respect to the real coordinate systems $(\omega_1^{(1)}, \dots, \omega_{2n_1}^{(1)})$ and $(\omega_1^{(2)}, \dots, \omega_{2n_2}^{(2)})$, we can find a representation matrix $M(\lambda)$ with coefficients in \mathbf{Z} such that $W(\lambda)\Omega_1 = \Omega_2 M(\lambda)$. Conversely, if for a complex matrix W there is a matrix M , with coefficients in \mathbf{Z} , satisfying the relation given above, then W gives a homomorphism of \mathbf{T}_1 to \mathbf{T}_2 . The above equation is called **Hurwitz's relation**. The notion of l -adic coordinate system, which is valid for a general characteristic, corresponds to that of the lattice group, and the l -adic representation $M_l(\lambda)$ of λ is the abstraction of the integral representation $M(\lambda)$.

L. Abelian Integrals

Let \mathfrak{R} be a compact \dagger Riemann surface of genus $g \geq 1$ (\rightarrow 11 Algebraic Functions) and let ω be a sum of \dagger Abelian differentials of the first kind or of the second kind. Then the \dagger period of ω along a cycle γ depends only on the \dagger homology class of γ . The set of all differentials of the first kind forms a complex linear space of dimension g ; we denote it by \mathfrak{D}_0 . Let P be a point and P_0 a fixed point of \mathfrak{R} ; then we denote by $u(P)$ the vector integral $(\int_{P_0}^P \omega_1, \dots, \int_{P_0}^P \omega_g)$, where $(\omega_1, \dots, \omega_g)$ is a basis of \mathfrak{D}_0 and the path from P_0 to P is common to every integral. The correspondence $P \rightarrow u(P)$ is not a single-valued mapping; the totality of differences of values of $u(P)$ coincides with the group \mathbf{D} consisting of periods $(\int_\gamma \omega_1, \dots, \int_\gamma \omega_g)$, where γ varies over all cycles. Let a set of cycles $\{\gamma_1, \dots, \gamma_{2g}\}$ be a basis of the homology group, with coefficients in \mathbf{Z} ; then $2g$ column vectors of the $g \times 2g$ matrix $\Omega = (\omega_{ij})$, $\omega_{ij} = \int_{\gamma_j} \omega_i$, are linearly independent over \mathbf{R} . Since the group \mathbf{D} coincides with the set of linear combinations, with coefficients in \mathbf{Z} , of column vectors of Ω , this \mathbf{D} is a \dagger lattice of rank $2g$, and the matrix Ω is a period matrix of the complex torus $\mathbf{T}^g = \mathbf{C}^g/\mathbf{D}$ of dimension g .

For a basis of the homology group with coefficients in \mathbf{Z} , we take \dagger normal sections $\alpha_1, \dots, \alpha_g, \alpha_{g+1}, \dots, \alpha_{2g}$ of \mathfrak{R} , and let the same symbol Ω stand for the period matrix (ω_{ij}) , $\omega_{ij} = \int_{\alpha_j} \omega_i$; then we have

$$\Omega E^* \Omega = 0, \quad \sqrt{-1} \Omega E^* \bar{\Omega} > 0$$

(positive definite Hermitian matrix), where

$$E = \begin{pmatrix} 0 & I_g \\ -I_g & 0 \end{pmatrix} \quad (\text{with } I_g \text{ the unit matrix}).$$

This implies that E is a principal matrix be-

longing to Ω ; we call the equality and inequality just given **Riemann's period relation** and **Riemann's period inequality**, respectively. Furthermore, we can choose a suitable basis of \mathfrak{D}_0 so that the period matrix Ω is of the form (I_g, F) with $F \in \mathfrak{S}_g$ (\rightarrow Section I). We consider the function $\mathfrak{g}(u)$, $u = (u_1, \dots, u_g)$, defined by an infinite series

$$\mathfrak{g}(u) = \sum_m \exp(2\pi \sqrt{-1} (\mathbf{m}^* u + \frac{1}{2} \mathbf{m}^* F \mathbf{m})),$$

where the sum is taken over all row vectors $\mathbf{m} = (m_1, \dots, m_g)$ with coefficients in \mathbf{Z} . If u is in a bounded region, then the series for $\mathfrak{g}(u)$ is uniformly and absolutely convergent. Hence $\mathfrak{g}(u)$ is a holomorphic function of u . This is a theta function corresponding to the principal matrix $E = \begin{pmatrix} 0 & I_g \\ -I_g & 0 \end{pmatrix}$ and is called the

Riemann theta function. As $\mathfrak{g}(u)$ is nondegenerate, the complex torus $\mathbf{T}^g = \mathbf{C}^g/\mathbf{D}$ has the structure of an Abelian variety. If we regard the Riemann surface \mathfrak{R} as an algebraic curve, this Abelian variety \mathbf{T}^g is precisely the Jacobian variety of the curve \mathfrak{R} . The collection of zeros of $\mathfrak{g}(u)$, a divisor on \mathbf{T}^g , defines the canonical polarization on the Jacobian variety (\rightarrow Section G).

The correspondence $P \rightarrow u(P)$, $p \in \mathfrak{R}$ induces a well-defined mapping φ of \mathfrak{R} into $\mathbf{T}^g = \mathbf{C}^g/\mathbf{D}$. Moreover, if we set $\varphi(A) = \sum_{j=1}^r \varphi(P_j) - \sum_{j=1}^r \varphi(Q_j)$ for any divisor $A = P_1 \dots P_r / Q_1 \dots Q_r$ of degree 0, then $\varphi(A)$ is a point on $\mathbf{T}^g = \mathbf{C}^g/\mathbf{D}$, which is represented by the vector $(\sum_{j=1}^r \int_{Q_j}^{P_j} \omega_1, \dots, \sum_{j=1}^r \int_{Q_j}^{P_j} \omega_g)$ of \mathbf{C}^g , and the mapping $A \rightarrow \varphi(A)$ is a homomorphism of the group \mathfrak{G}_0 of divisors of degree 0 onto $\mathbf{T}^g = \mathbf{C}^g/\mathbf{D}$. The kernel of this homomorphism coincides with the group \mathfrak{G}_1 of \dagger principal divisors (**Abel's theorem**). Hence a divisor $A = P_1 \dots P_r / Q_1 \dots Q_r$ of degree 0 is a divisor of some function if and only if we have $\sum_{j=1}^r \int_{Q_j}^{P_j} \omega_i \equiv 0 \pmod{\mathbf{D}}$ ($i = 1, \dots, g$), or equivalently, the left-hand side is 0 for a suitable path.

Given g fixed points P_1, \dots, P_g on \mathfrak{R} and given (u_1, \dots, u_g) as any vector of \mathbf{C}^g , the problem of finding g points Q_1, \dots, Q_g satisfying relations $\sum_{j=1}^g \int_{P_j}^{Q_j} \omega_i \equiv u_i \pmod{\mathbf{D}}$, $i = 1, \dots, g$, is called **Jacobi's inverse problem**. To solve the problem, we take a divisor A of degree 0 such that the class $\varphi(A) \pmod{\mathbf{D}}$ is represented by (u_1, \dots, u_g) ; then, by virtue of the \dagger Riemann-Roch theorem, there exists a divisor $Q_1 \dots Q_g$ satisfying

$$A \equiv Q_1 \dots Q_g / P_1 \dots P_g \pmod{\mathfrak{G}_1}.$$

Abel's theorem implies that the set of points $\{Q_1, \dots, Q_g\}$ is a solution of Jacobi's problem. Moreover, for general (u_1, \dots, u_g) , the solution is unique; i.e., there exists a subvariety \mathfrak{X} of dimension $g-2$ on \mathbf{C}^g such that the solution is

unique up to order if and only if (u_1, \dots, u_g) does not lie on $\tilde{\mathfrak{X}}$. In particular, if every point P_i coincides with the fixed point P_0 that appeared in the definition of $u(P)$, the subvariety on $\mathbf{T}^g = \mathbf{C}^g/\mathbf{D}$ determined by $\tilde{\mathfrak{X}}$ is obtained in the following way: Let $W_1 + \dots + W_{2g-2}$ be a canonical divisor on \mathfrak{R} , and put $c = \varphi(W_1) + \dots + \varphi(W_{2g-2})$. Then the locus of points $c - \varphi(R_1) - \dots - \varphi(R_{g-2})$ (where $g-2$ points R_1, \dots, R_{g-2} are taken independently over all points of \mathfrak{R}) is the desired subvariety.

In terms of the theory of complex manifolds the above result can be rewritten as follows: Let $S^g(\mathfrak{R})$ be the symmetric product of \mathfrak{R} and $\tilde{\mathfrak{X}}$ the subvariety of $\mathbf{T}^g = \mathbf{C}^g/\mathbf{D}$ induced from $\tilde{\mathfrak{X}}$. Then the holomorphic map $S^g(\varphi): S^g(\mathfrak{R}) \rightarrow \mathbf{T}^g$ induced from $\varphi: \mathfrak{R} \rightarrow \mathbf{T}^g$ is bimeromorphic and isomorphic outside that $\tilde{\mathfrak{X}}$ whose elements correspond to effective divisor classes of degree g contained in canonical divisors on \mathfrak{R} .

M. Elementary Abelian Functions

Let z be a nonconstant meromorphic function on \mathfrak{R} . Then for any $u = (u_1, \dots, u_g) \in \mathbf{C}^g$ that does not lie on $\tilde{\mathfrak{X}}$, there exist g points Q_1, \dots, Q_g (uniquely determined up to order) as the solution of Jacobi's problem. Therefore the elementary symmetric functions

$$s_1(u; z) = \sum_{j=1}^g z(Q_j),$$

$$s_2(u; z) = \sum_{i < j} z(Q_i)z(Q_j), \dots, s_g(u; z) = \prod_{j=1}^g z(Q_j)$$

are well defined if u lies outside the variety $\tilde{\mathfrak{X}}$ of dimension $g-2$. Each function $s_i(u; z)$, regarded as a function of u , can be extended uniquely to an Abelian function in the whole space \mathbf{C}^g ; the function is denoted by the same symbol $s_i(u; z)$. The Abelian functions $s_1(u; z), \dots, s_g(u; z)$ are called the **elementary Abelian functions** obtained from z .

Now let K be the field of Abelian functions on \mathbf{C}^g/\mathbf{D} and k the field of meromorphic functions on \mathfrak{R} ; then the dimension of K over \mathbf{C} is g , and $[K: \mathbf{C}(s_1(u; z), \dots, s_g(u; z))] = r^g$, where r is the degree of the function z that is given by $[k: \mathbf{C}(z)]$. Moreover, if we take any function w such that $k = \mathbf{C}(z, w)$, then we have

$$K = \mathbf{C}(s_1(u; z), \dots, s_g(u; z); s_1(u; w), \dots, s_g(u; w)),$$

where $s_i(u; w), \dots, s_g(u; w)$ are the elementary Abelian functions obtained from w .

We can write any elementary Abelian function as a rational function of Riemann theta functions; therefore any Abelian function can be written as a rational function of Riemann theta functions. Furthermore, if u and v are variable vectors, then $s_i(u+v; z)$ can be repre-

sented as an algebraic function of $s_1(u; z), \dots, s_g(u; z), s_1(v; z), \dots, s_g(v; z)$; i.e., we can choose a suitable polynomial $H_i(Z; X_1, \dots, X_g; Y_1, \dots, Y_g)$ with coefficients in \mathbf{C} so that $H_i(s_i(u+v; z); s_1(u; z), \dots, s_g(u; z); s_1(v; z), \dots, s_g(v; z)) = 0$. This **algebraic addition formula** with respect to the elementary Abelian functions $s_i(u; z)$, $i = 1, \dots, g$, is a function-theoretic interpretation of the fact that the addition map $X \times X \rightarrow X: (x, y) \rightarrow x + y$ is a t morphism of algebraic varieties.

As the study of t Abelian integrals of the first kind led us to the theory of Jacobian varieties, t Abelian integrals of the second and the third kind give rise to the theory of t generalized Jacobian varieties (\rightarrow 9 Algebraic Curves).

The theory of Abelian varieties has significant applications to number theory, as shown by the following examples: the theory of t unramified Abelian extensions with respect to a function field of several variables defined over a finite field (S. Lang), the theory of heights of points on an Abelian variety (Weil, A. Néron, J. Tate), and the theory of complex multiplication (\rightarrow 73 Complex Multiplication) in the case of higher dimensions (Y. Taniyama, G. Shimura).

N. Some Recent Results

(1) Level Structure, Moduli of Abelian

Varieties. Let A be an Abelian variety over k of dimension g and n a positive integer which the characteristic of k does not divide. A **level n structure** on A is defined to be a set of $2g$ points $\sigma_1, \dots, \sigma_{2g}$ on A which form a basis for the group of points of order n on A .

Let $A(g, d, n; k)$ be the set of triples: (i) an Abelian variety A over k of dimension g , (ii) an inhomogeneous polarization X on A with $v(\varphi_X) = d^2$, and (iii) a level n structure $\sigma_1, \dots, \sigma_{2g}$ of A , all up to isomorphisms. Similarly we can define $A(g, d, n; S)$ for Abelian schemes over a scheme S . The correspondence $S \rightarrow A(g, d, n; S)$ defines a functor $\mathcal{A}(g, d, n)$.

D. Mumford has shown that there exists the t coarse moduli scheme $A(g, d, n)$ quasi-projective over $\text{Spec}(\mathbf{Z}[1/n])$, and that it is even fine if $n \geq 3$ [6]. He used the technique of t Hilbert schemes and t stable points (\rightarrow 16 Algebraic Varieties). One of the key steps of his proof is to show that for an embedding $\phi: A \rightarrow \mathbf{P}^m$ of degree r (i.e., the degree of $\phi(A)$ in \mathbf{P}^m) over an algebraically closed field k and a positive integer n such that $\text{char}(k)$ does not divide n and $n > \sqrt{(m+1)r}$, the point $(\phi(x_i))_{i=1, \dots, n^{2g}}$ in $(\mathbf{P}^m)^{n^{2g}}$ is stable with respect to the action of $\text{PGL}(m)$, where the x_i are the points of order n on A (with an arbitrary order). Mumford

later showed another method of constructing the moduli of polarized Abelian varieties by using algebraic theta constants [7].

(2) Néron Minimal Models, Good and Stable

Reduction. Let R be a discrete valuation ring with residue field k and quotient field K . For an Abelian variety A over K , there exists a smooth group scheme \mathcal{A} of finite type over $S = \text{Spec}(R)$, called the **Néron minimal model** of A , such that for every scheme S' smooth over S there is a canonical isomorphism

$$\text{Hom}_S(S', \mathcal{A}) \cong \text{Hom}_K(S'_K, A),$$

where S'_K is the pullback of S' by $\text{Spec}(K) \rightarrow \text{Spec}(R)$ (A. Néron, M. Raynaud). In particular, we have $\mathcal{A}_K \cong A$. Denote by A_0 the fiber of \mathcal{A} over the closed point of S .

If \mathcal{A} is proper over S , we say that A has a **good reduction** at R . If the connected component A_0^0 of A_0 containing 0 has no unipotent radical (or equivalently, A_0^0 is an extension of an Abelian variety by an ℓ -algebraic torus over a finite algebraic extension of k), we say that A has a **stable reduction**. If there is a finite separable extension K' of K with a prolongation R' of R to K' such that $A \times_K K'$ has good (stable) reduction, we say that A has a **potential good (stable) reduction** at R . Let K_s be a separable closure of K and \bar{R} a prolongation of R to K_s . For a prime number $l \neq \text{char}(k)$, we have a canonical homomorphism $\rho: \text{Gal}(K_s/K) \rightarrow \text{Aut}(\mathcal{G}_l(A))$, called a monodromy. Then A has potential good reduction if and only if the image of the ℓ -inertia group $I(\bar{R})$ by ρ is a finite group (J.-P. Serre and Tate). Every Abelian variety A over K has potential stable reduction at R (**stable reduction theorem**, A. Grothendieck [16]).

(3) Graded Ring of Theta Functions. If f is a theta function with a period system \mathbf{D} , f^n is also a theta function with the same period system for every positive n . We denote by S_n the vector space of the theta functions with the period system \mathbf{D} subject to the same transformation law as f^n . If we denote by X the effective divisor on $\mathbf{T} = \mathbf{C}^g/\mathbf{D}$ defined by f , then S_n can be naturally considered as the ℓ -defining module of the ℓ -complete linear system of nX , and the dimension of $S_n (= l(nX))$ is equal to the product of the nonzero diagonal elements of $n\Delta$ (\rightarrow Section I) (Frobenius). If $g \in S_m$ and $h \in S_n$, then $gh \in S_{m+n}$; hence $S = \bigoplus_{n \geq 0} S_n$ is a ℓ -graded ring, which is normal and finitely generated. For $m \geq 2$ and $n \geq 3$, the product map $S_m \times S_n \rightarrow S_{m+n}$ is surjective (D. Mumford, S. Koizumi). If the elementary divisors of E can be divided by an integer ≥ 4 , the kernel of the natural graded mapping $S(S_1) \rightarrow S$ (where

3 Ref.

Abelian Varieties

$S(S_1)$ denotes the ℓ -symmetric algebra over S_1) is generated by the quadratic relations (i.e., the part of degree 2) for sufficiently large degrees (Mumford). Geometrically this means that if $X = (f)$, $f \in S_1$, is nondegenerate, then, with the projective embedding $i: \mathbf{T} \rightarrow \mathbf{P}^N$ defined by the complete linear system of X , $i(\mathbf{T})$ is an intersection of quadrics in \mathbf{P}^N containing $i(\mathbf{T})$.

Mumford has developed a theory of algebraic theta functions that also works for the positive characteristic case [7] and has proved the above results in general.

4 (V.5) Additive Number Theory

A. General Remarks

Let \mathbf{N} be the set of natural numbers, and let A, B, \dots be subsets of \mathbf{N} . The sum $C = A + B$ is defined as the set $\{c | c \in A, c \in B, \text{ or } c = a + b, a \in A, b \in B\}$. A finite sum of subsets of \mathbf{N} is defined similarly. If \mathbf{N} is the sum $A + \dots + A$ (r times), then we say that A is a **basis of order r in \mathbf{N}** . Let $A(x)$ denote the number of integers in A that do not exceed x . The **density** of A is defined as $\inf A(x)/x$. If $A(n) \geq \alpha n$, $B(n) \geq \beta n$ ($0 < \alpha, \beta < 1$) for all $n \in \mathbf{N}$, then we have $(A+B)(n) \geq (\min(1, \alpha + \beta))n$. This result was stated by E. Landau (1937) without proof; A. J. Khinchin had given a proof (1932) for the case $\alpha = \beta$, and H. B. Mann (1942) and E. Artin and P. Scherk (1943) succeeded in proving the statement for the general case. Suppose that the densities of A and B are, respectively, α and 0. If B is a basis of finite order in \mathbf{N} , then the density of $A + B$ is greater than that of A (Khinchin and P. Erdős, 1936). Let P be the set of all prime numbers. Though the density of P is 0, the density of $P + P$ is positive (L. G. Shnirel'man, 1930). Hence P is a basis of finite order in \mathbf{N} ; in other words, there exists a positive integer r such that every natural number can be expressed as a sum of at most r primes. Though the density of the set Q of the k th powers of natural numbers is 0, there exists a positive integer $s(k)$ such that the sum $Q + \dots$

$+ Q$ ($s(k)$ times) is a set of positive density. L. K. Hua (1956) gave a simple proof of this fact, based on Yu. V. Linnik's idea. It follows, therefore, that any natural number n can be expressed as a sum $n = a_1^k + \dots + a_r^k$, where $a_i \in \mathbf{N}$, $t \geq s(k)$. This result had already been shown by D. Hilbert (1909).

An ancient method of finding prime numbers is 'Eratosthenes' sieve. V. Brun (1920) devised a new sieve method to express an arbitrary integer n as the sum of two integers $n = a + b$, where the number of prime factors of a and b is as small as possible. This method was improved by H. A. Rademacher (1924), Landau (1931), A. Bustab (1937), and others. Among these the method found by A. Selberg (1952) is notable (\rightarrow 123 Distribution of Prime Numbers E).

B. Farey Sequences

Let τ be a positive integer. We arrange in increasing order the set of all positive irreducible fractions lying between 0 and 1 whose denominators do not exceed τ . This sequence is called the **Farey sequence** of order τ . For example, the Farey sequence of order 5 consists of

$$0, \frac{1}{5}, \frac{1}{4}, \frac{1}{3}, \frac{2}{5}, \frac{1}{2}, \frac{3}{5}, \frac{2}{3}, \frac{3}{4}, \frac{4}{5}, 1.$$

A necessary and sufficient condition that a fraction a/b be directly followed by a fraction c/d in the Farey sequence of order n is $b + d \geq n + 1$, $bc - ad = 1$. In this case the fraction $(a + c)/(b + d)$ is called the **mediant** of a/b and c/d . Interpolating the Farey sequence of order n with such mediants $(a + c)/(b + d)$ satisfying $b + d = n + 1$, we obtain the Farey sequence of order $n + 1$.

Let a/q be a fraction in the Farey sequence of order τ , and $a'/q', a''/q''$ be adjacent members of a/q in the sequence such that $a'/q' < a/q < a''/q''$. The interval $[(a' + a)/(q' + q), (a + a'')/(q + q'')]$ is known as the **Farey arc** surrounding a/q . In particular, if $a/q = 0/1$, then we set $[-1/n, 1/n]$ to be the Farey arc surrounding 0/1, where $n = [\tau] + 1$ ($[\]$ is the Gauss symbol). We can thus decompose the interval $[-1/n, 1 - 1/n]$ into a disjoint union of Farey arcs. If α is contained in the Farey arc surrounding a/q , then $|\alpha - a/q| < 1/q\tau$. Therefore, for a given $\tau \geq 1$ and a real α , we can prove the existence of a/q such that

$$(|a|, q) = 1, \quad 0 < q \leq \tau, \quad |\alpha - a/q| < 1/q\tau.$$

Let $f(\zeta) = \sum_{n=0}^{\infty} a_n \zeta^n$ be a power series which is convergent in the disk $|\zeta| \leq 1$. Then, by Cauchy's integral formula,

$$a_n = \frac{1}{2\pi i} \int_{|\zeta|=1} \frac{f(\zeta)}{\zeta^{n+1}} d\zeta = \int_0^1 f(e^{2\pi i \alpha}) e^{-2\pi i n \alpha} d\alpha.$$

To estimate such an integral, we sometimes utilize the decomposition of the interval $[0, 1]$ into a disjoint union of Farey arcs as mentioned above. This method is called the **circle method**, and the subdivision of the interval is known as the **Farey dissection**.

Given a positive number c , a Farey arc around a/q is usually called a **major arc** (or **basic interval**) if q does not exceed the given bound c ; otherwise, it is called a **minor arc** (or **supplementary interval**). Usually, the principal part of the previously mentioned integral is derived from the integral over the major arcs, and the residual part is provided by the integral over the minor arcs.

C. Goldbach's Problem

Goldbach's problem is found in letters (1742) he exchanged with L. Euler. In them he stated that every positive integer can be expressed as the sum of primes. More precisely, he conjectured that any even integer not smaller than 6 can be expressed as the sum of two odd primes and that any odd integer not smaller than 9 can be expressed as the sum of three odd primes.

I. M. Vinogradov (1937) proved that every sufficiently large odd integer can be expressed as the sum of three primes. Let N be a sufficiently large odd integer. If we write

$$A(q, N) = \frac{\mu(q)}{\varphi^3(q)} \sum_{\substack{1 \leq a \leq q \\ (a, q)=1}} \exp\left(-2\pi i \frac{a}{q} N\right),$$

then the series $S(N) = \sum_{q=1}^{\infty} A(q, N)$ is absolutely convergent and is equal to

$$\prod_p \left(1 + \frac{1}{(p-1)^3}\right) \prod_{p|N} \left(1 - \frac{1}{p^2 - 3p + 3}\right).$$

It is known that $S(N) > 6/\pi^2$ for all N . If we denote by $r(N)$ the number of solutions of $N = p_1 + p_2 + p_3$, then $r(N) \sim (N^2/2(\log N)^3) \cdot S(N)$. To prove this, Vinogradov used the circle method. He employed the \dagger prime number theorem for arithmetic progressions to estimate the integrals over the major arcs and devised an ingenious method to estimate the series $\sum_{p \leq N} \exp(2\pi i \alpha p)$ in the computation of the integrals on the minor arcs. A finite or infinite sum of exponential functions such as this is called a **trigonometric sum**. More generally, we consider trigonometric sums of several variables. Vinogradov provided detailed remarks and calculations [6].

In the case of even integers, the problem is still unsolved, although J. G. van der Corput, T. Estermann, and N. G. Chudanov proved

4 D

Additive Number Theory

simultaneously (1938) that almost all even integers (i.e., except a set of density 0) can be expressed as the sum of two primes. For these problems, Linnik (1946) and Chudanov (1947) introduced function-theoretic methods. They obtained the density theorem concerning the zeros of L -series, and A. Zulauf (1952) continued along the same lines. These methods had been suggested by G. H. Hardy and J. E. Littlewood (c. 1919), although they had assumed that the \dagger extended Riemann hypothesis held.

We denote by P_j a number having at most j prime factors counted with their multiplicity. Using his sieve method, Brun (1919) proved that every sufficiently large even integer $2n$ can be expressed in the form $2n = P_9 + P_9$. Rademacher (1924) improved this result and obtained $2n = P_7 + P_7$. Applying his new sieve method to this problem, Selberg (1950) proved that $2n = P_2 + P_3$. On the other hand, using the \dagger large sieve, A. Rényi proved that $2n = P_1 + P_k$ for some k . Afterwards, combining Richert's sieve with a large sieve, Chen Jing-Run (1973) proved that $2n = P_1 + P_2$ for large $2n$ [11].

D. Polygonal Numbers

Let m be an integer greater than 3, and let $a_1 = 1$, $a_{n+1} - a_n = (m-2)n + 1$ ($n = 1, 2, \dots$). The sequence $\{a_n\}$ forms the system of **polygonal numbers of order m** . The general term of $\{a_n\}$ is given by $n + \frac{1}{2}(m-2)(n^2 - n)$ ($n = 1, 2, \dots$). Such a_n are said to be **triangular numbers** if $m = 3$, **square numbers** if $m = 4$, and **pentagonal numbers** if $m = 5$.

P. Fermat (1636) stated that every natural number can be expressed as the sum of m polygonal numbers of order m . This conjecture was proved by A. M. Legendre (1798) for $m = 3$, by J. L. Lagrange (1772) for $m = 4$, and by A. L. Cauchy (1813) for the general case. With regard to Lagrange's result, Legendre noticed that in order that a positive integer n be expressed as the sum of three squares, it is necessary and sufficient that n not be of the form $4^a(8m+7)$.

Given a positive integer n , the number of integral solutions of the equation $x_1^2 + x_2^2 + \dots + x_s^2 = n$ is denoted by $r_s(n)$. For example, $r_2(5) = 8$. The \dagger generating function $\sum_{n=1}^{\infty} r_2(n)n^{-s}$ can be expressed as $\sum_{m,n=-\infty}^{+\infty} (m^2 + n^2)^{-s}$, where the term corresponding to $m = n = 0$ is omitted; the function is equal to $4\zeta_K(s)$, where $\zeta_K(s)$ is the \dagger Dedekind zeta function of the Gaussian number field $K = \mathbf{Q}(\sqrt{-1})$. The equation $4\zeta_K(s) = 4\zeta(s)L(s, \chi)$ (where $\chi(n) = (-4/n)$) leads to

$$r_2(n) = 4 \sum'_{m|n} (-1)^{(m-1)/2},$$

where \sum' means the sum over all odd factors m of n . This result was obtained by C. G. J. Jacobi (1829). He also obtained the following formula:

$$r_4(n) = 8 \sum'_{m|n, 4 \nmid m} m,$$

where \sum' means the sum over all divisors m of n not divisible by 4 (Hardy and E. M. Wright, C. L. Siegel, 1964). Let $q = \exp(2\pi i\tau)$ ($\text{Im } \tau > 0$), and

$$f(q) = 1 + \sum_{n=1}^{\infty} r_s(n)q^n \\ = (1 + 2q + 2q^4 + 2q^9 + \dots)^s.$$

Hardy (1920) considered the variation of $f(q)$ for $q = a \exp(2\pi i h/k)$ (with $0 < a < 1$) as $a \rightarrow 1$; he obtained

$$f(q) \sim \pi^{s/2} \left(\frac{S_{h,k}}{k} \right)^s \log \left(\frac{1}{a} \right)^{-s/2},$$

where $S_{h,k} = \sum_{j=1}^k \exp(2\pi i(h/k)j^2)$. Furthermore, he constructed the **singular series**

$$\rho_s(n) = \frac{\pi^{s/2} n^{(s/2)-1}}{\Gamma(s/2)} \sum_{k=1}^{\infty} A_k, \quad A_1 = 1,$$

$$A_k = k^{-s} \sum_{\substack{1 \leq h \leq k \\ (h,k)=1}} (S_{h,k})^s \exp \left(-2\pi i \frac{h}{k} n \right),$$

and showed that $r_s(n) = \rho_s(n)$ for $s = 5, 6, 7$, and 8. P. T. Bateman (1951) proved the same equation for $s = 3$ and 4. If $s \geq 9$ then $r_s(n) = \rho_s(n) + O(n^{s/4})$ (Hardy, Littlewood, and S. Ramanujan, c. 1919). The detailed exposition of this result is in the notes of A. Z. Walfisz (1952) and Rademacher [4]. H. D. Kloostermann (1926) and Estermann (1962) studied the equation $ax_1^2 + bx_2^2 + cx_3^2 + dx_4^2 = n$, which led to a new field of study concerning the \dagger Kloostermann sum. For instance, estimates such as

$$\left| \sum_{x=1}^{p-1} \exp \left(2\pi i \frac{cx + d/x}{p} \right) \right| \leq 2\sqrt{p}$$

are obtained by using the theory of zeta functions in algebraic function fields in one variable (A. Weil, 1948) (\rightarrow 450 Zeta Functions).

E. Waring's Problem

The first formulation of **Waring's problem** is found in E. Waring, *Meditationes algebraicae* (1770), in which he discusses the problem of expressing an arbitrary positive integer as the sum of at most nine cubes or as the sum of at most nineteen biquadratics. Hilbert proved (\rightarrow Section A) that there exists a positive integer $s(k)$ such that, for any integer N , the equation

$$x_1^k + x_2^k + \dots + x_s^k = N$$

has a nonnegative integral solution if $s \geq s(k)$. We denote by $g(k)$ the least value of $s(k)$, and by $G(k)$ the least value of $s(k)$ for which the equation is solvable with at most finitely many exceptions of N . Research concerning $g(k)$ and $G(k)$ received its initial impetus from the circle method considered by Hardy and Littlewood, and it underwent considerable development in the works of H. Weyl and Vinogradov.

Let $r_s(N)$ be the number of solutions of the above equation. We then have

$$r_s(N) = \int_0^1 \left(\sum_{x \leq N^{1/k}} \exp(2\pi i \alpha x^k) \right)^s \times \exp(-2\pi i N \alpha) d\alpha.$$

If we make the Farey dissection, translating the interval $[0, 1]$ slightly, then the main term of $r_s(N)$ is provided by the integrals over major arcs, and the residual term is derived from the integrals over minor arcs. Let p be a prime, and let $M(N, p^l)$ denote the number of solutions of the congruence equation

$$x_1^k + x_2^k + \dots + x_s^k \equiv N \pmod{p^l}.$$

Then $\lim_{l \rightarrow \infty} M(N, p^l)/p^{l(s-1)} = \chi_p(N)$ is not zero, and the infinite product $\prod_p \chi_p(N) = S(N)$ converges for $s \geq 4k$, where $S(N)$ is larger than a positive constant which is determined independently of the choice of N . On the other hand, let

$$S(a, q) = \sum_{x=0}^{q-1} \exp \left(2\pi i \frac{a}{q} x^k \right),$$

$$A(q, N) = q^{-s} \sum_{\substack{1 \leq a \leq q \\ (a, q)=1}} S(a, q)^s \exp \left(-2\pi i \frac{a}{q} N \right).$$

Then $\sum_{q=1}^{\infty} A(q, N)$ is absolutely convergent, and the sum is equal to $S(N)$. According to Hua (1959) we have

$$r_s(N) \sim S(N) \frac{\Gamma(1 + 1/k)^s}{\Gamma(s/k)} N^{s/k-1},$$

provided that $s \geq 2k^2(2 \log k + \log \log k + c)$. Next, if we denote by $V(N, \delta)$ the volume of the closed region satisfying $N \leq x_1^k + x_2^k + \dots + x_s^k \leq N + \delta$ in the s -dimensional Euclidean space, then $\lim_{\delta \rightarrow 0} V(N, \delta)/\delta = \chi_{\infty}(N)$ exists and is equal to $(\Gamma(1 + 1/k)^s / \Gamma(s/k)) N^{s/k-1}$. Hence we can show that the principal part of $r_s(N)$ is equal to the infinite product $\prod_p \chi_p(N)$, where p runs over all finite and infinite prime spots in \mathbf{Q} . This is a generalization of the singular series studied by Hardy.

With regard to $g(k)$, there are studies by L. E. Dickson (1936) and others. It is easy to see that $g(k) \geq 2k + (3/2)^k - 2$ and that $G(k) \geq k + 1$. It has been shown that $g(3) = 9$, $G(3) \leq 7$ (G. L. Watson, Linnik, 1947) and that $g(4) \leq 37$, $G(4) = 16$ (H. Davenport, 1939). More generally, Vinogradov (1959) proved that

$$G(k) \leq 2k \log k + 4k \log \log k + 2k \log \log \log k + ck.$$

To prove this, Vinogradov (1934) introduced the following integral, which is closely related to the prime number theorem:

$$I(P) = \int_0^1 \dots \int_0^1 \left| \sum_{x \leq P} \exp(2\pi i(\alpha_1 x + \alpha_2 x^2 + \dots + \alpha_k x^k)) \right|^{2s} d\alpha_1 \dots d\alpha_k.$$

Hua (1949) improved Vinogradov's result and proved that if $s \geq \frac{1}{4}k(k+1) + lk$, then

$$I(P) \leq (5s)^{5sl} (\log P)^{2l} P^{2s-k(k+1)/2+\delta},$$

where $\delta = \frac{1}{2}k(k+1)(1-1/k)^{l-1}$. Concerning $I(P)$, another notable approach was made by A. A. Karacuba and N. M. Korobov (1963). Further investigation proved that $I(P) = c_1 c_2 P^{2s-k(k+1)/2} + o(P^{2s-k(k+1)/2})$ if $s \geq ck^2 \log k$ (Vinogradov, Hua, 1959). The result is called the **Vinogradov mean value theorem**.

There are many variations and generalizations of this theorem. Vinogradov and Hua (1944) studied the problem of representing an arbitrary N as $N = p_1^k + p_2^k + \dots + p_s^k$ (with p_i prime). Hua (1937) and others also considered the problem of representing N as $N = f(x_1) + f(x_2) + \dots + f(x_s)$, where $f(x)$ is a given polynomial. Also, let

$$C(x_1, x_2, \dots, x_n) = \sum_{i=1}^n \sum_{j=1}^n \sum_{k=1}^n C_{ijk} x_i x_j x_k$$

be a homogeneous polynomial of degree 3 with integral coefficients. Davenport (1963) proved that if $n \geq 16$, then the equation $C(x_1, x_2, \dots, x_n) = 0$ has at least one nontrivial integral solution. There are further developments of the theory of representations of integers by forms in many variables by V. A. Tartakovskii, H. Davenport, B. J. Birch, and D. J. Lewis.

F. Additive Problems in an Algebraic Number Field

Siegel (1922) considered the generalization of Hardy's square sum problem to the case of an algebraic number field. He later (1945) studied the generalized Waring's problem in an algebraic number field K of finite degree: Let I be the principal order of K , and let J_k be the subring of I generated by the k th powers of integers in K . It is easily seen that the index $(I:J_k)$ is finite. Hence our concern regarding $s(k)$ must be restricted to integers contained in J_k . Another question is how to extend the Farey dissection to an algebraic number field. Siegel succeeded in solving these difficulties.

4 Ref.

Additive Number Theory

His ingenuity is seen in his way of dealing with the minor arcs, which provided a stimulus to the research of T. Mitsui (1960).

A generalization of Goldbach's problem to the case of an algebraic number field was obtained by Mitsui (1960) and O. Körner (1961).

As another extension of the Vinogradov three primes theorem, Mitsui (1971) proved the following theorem: Let K be an algebraic number field of degree n . Let C be the principal ideal class generated by a totally positive number in K , and P be the set of prime ideals of degree 1 contained in C . Let N be a positive integer and $I_s(N)$ be the number of representations of N as the sum of the norms of s prime ideals belonging to P ,

$$I_s(N) = \sum_{N = N_{p_1} + \dots + N_{p_s}} 1, \quad p_i \in P \quad (1 \leq i \leq s).$$

If N is sufficiently large and $s \geq 3$, we have the asymptotic formula

$$I_s(N) = A_s S(N) \frac{N^{s-1}}{(\log N)^s} + O\left(\frac{N^{s-1} \log \log N}{(\log N)^{s+1}} \right),$$

where A_s is a positive constant depending on s and K independent of N , and $S(N)$ denotes the singular series. If $s \equiv N \pmod{2D}$, where D is the discriminant of K , then $S(N) \geq c > 0$, where c is a constant. Later this problem was extended by Mitsui and T. Tatzuza (1981).

5 (XVII.9) Additive Processes

A. General Remarks

The study of sums of \dagger independent random variables has been one of the main topics in modern probability theory (\rightarrow 250 Limit Theorems in Probability Theory). Combining the ideas of this study with the consideration of \dagger stochastic processes with continuous time parameter, we get the notion of additive processes.

B. Definitions and Fundamental Properties

A real-valued \dagger stochastic process $\{X_t\}_{0 \leq t < \infty}$, denoted by $X(t)$ ($0 \leq t < \infty$) for the rest of this article, where for simplicity we assume that $X(0)=0$, is called an **additive process** (or **process with independent increments**) if for any $t_0 < t_1 < \dots < t_n$, $X(t_i) - X(t_{i-1})$ ($i=1, 2, \dots, n$) are \dagger independent. An additive process is essentially the same as a \dagger spatially homogeneous \dagger Markov process (i.e., a Markov process on \mathbf{R}^1 that is invariant under translations). When, for any $h>0$ and $t>s$, $X(t+h) - X(s+h)$ and $X(t) - X(s)$ have the same law, i.e., the distribution law of $X(t) - X(s)$ depends only on $t-s$, we call the additive process $X(t)$ **temporally homogeneous**. This is essentially the same notion as a temporally and spatially homogeneous Markov process.

Let $X(t)$ be a given additive process. If $f(t)$ is a function of t only, then clearly $Y(t) = X(t) - f(t)$ is also an additive process, and we can choose $f(t)$ in such a way that for every $t>0$ and for every sequence $s_n \uparrow t$ ($s_n \downarrow t$), $Y(s_n)$ converges with probability one. Here, $\lim Y(s_n)$ is independent of a particular choice of s_n , and we denote it by $Y(t-) (=Y(t+))$. We call such $Y(t)$ a **central process** and also say that $Y(t)$ is obtained from $X(t)$ by **centering**. This $f(t)$ is given, for example, by the condition $E(\arctan(X(t) - f(t))) = 0$.

Let $Y(t)$ be a centered additive process. Then $Y(t-) = Y(t) = Y(t+)$ for all $t>0$, except on an at most countable t -set S , and $t \in S$ is called a **fixed point of discontinuity** of $Y(t)$. Then $Y_1(t) = \lim_{n \rightarrow \infty} U_n(t)$ exists with probability 1, where

$$U_n(t) = \sum_{\substack{0 \leq i \leq n \\ s_i < t}} (Y(s_i+) - Y(s_i-)) \\ + Y(t) - Y(t-) - C_t^n,$$

C_t^n being a constant determined by $E(\arctan U_n(t)) = 0$, and $S = \{s_j\}$ ($j=1, 2, \dots$). $Y_2(t) = Y(t) - Y_1(t)$ is a centered additive process without any fixed point of discontinuity. Furthermore, $Y_1(t)$ and $Y_2(t)$ are independent. Thus we have a decomposition of $Y(t)$: $Y(t) = Y_1(t) + Y_2(t)$, where $Y_1(t)$ and $Y_2(t)$ are mutually independent additive processes. The structure of $Y_1(t)$ is simple, and it is not worthwhile to study its behavior in more detail. On the other hand, since $Y_2(t)$ is a centered additive process without any fixed point of discontinuity, it is an additive process that is \dagger continuous in probability. Let $\tilde{Y}_2(t)$ be a \dagger separable modification of $Y_2(t)$. Then the discontinuities of almost all sample functions of $\tilde{Y}_2(t)$ are of the first kind. If we set $Y_2^*(t) = \tilde{Y}_2(t+)$, $Y_2^*(t)$ is a \dagger modification of $Y_2(t)$, and almost all sample functions of $Y_2^*(t)$ are right continuous and have a left-hand limit at every t . In the study of the process $Y_2(t)$, it is always convenient to take such a modification. Thus we give the following general definition: An additive process is called a **Lévy process** if it is continuous in probability and almost all sample functions are right continuous and have a left-hand limit at every $t \in [0, \infty)$ [3, 9].

The notions of additive processes and Lévy processes can also be considered for \mathbf{R}^N -valued processes.

C. Additive Processes and Infinitely Divisible Distributions

Let $X(t)$ be a Lévy process and Φ_{st} ($s < t$) be the \dagger distribution of $X(t) - X(s)$. Then Φ_{st} is an \dagger infinitely divisible distribution (\rightarrow 341 Probability Measures G). Conversely, for a given infinitely divisible distribution Φ we can construct an essentially unique temporally homogeneous Lévy process $X(t)$ such that Φ coincides with the distribution of $X(1)$. If $X(t)$ is temporally homogeneous, the \dagger characteristic function $\varphi_{st}(z) = E(e^{iz(X(t) - X(s))})$ of the distribution Φ_{st} is given in the form $\varphi_{st} = \exp((t-s)\psi(z))$; hence the law of the process $X(t)$ is completely determined by the function $\psi(z)$. By the \dagger Lévy-Khinchin canonical form, $\psi(z)$ is

written in the form

$$\psi(z) = imz - \frac{v}{2}z^2 + \int_{-\infty}^{\infty} \left(e^{izu} - 1 - \frac{izu}{1+u^2} \right) n(du), \quad (1)$$

where $m, v \in \mathbf{R}$, $v \geq 0$, and $n(du)$ is a nonnegative measure on $\mathbf{R} - \{0\}$ such that $\int_{-\infty}^{\infty} \frac{u^2}{1+u^2} n(du) < \infty$. These m, v , and $n(du)$ are uniquely determined by $\psi(z)$.

D. Basic Additive Processes

Wiener Process. When almost all sample functions of a Lévy process $X(t)$ are continuous, the distribution of $X(t) - X(s)$ is a \dagger normal distribution. If, further, $X(t)$ is temporally homogeneous, $\psi(z)$ has the form $\psi(z) = imz - \frac{1}{2}vz^2$. In particular, if $m = 0$ and $v = 1$, then $X(t)$ is called a **Wiener process** or **Brownian motion**. This stochastic process was introduced by N. Wiener (1923) as a mathematical model for the random movement of colloidal particles first observed by a British botanist, R. Brown. This is one of the most fundamental and important stochastic processes in modern probability theory (\rightarrow 45 Brownian Motion).

Poisson Processes. When almost all sample functions of a Lévy process are increasing step functions with only jumps of size 1, the distribution of $X(t) - X(s)$ is a \dagger Poisson distribution. If, further, $X(t)$ is temporally homogeneous, $\psi(z)$ in (1) has the form $\psi(z) = \lambda(e^{iz} - 1)$ ($\lambda > 0$), and $X(t)$ is called a **Poisson process**. Let $X(t)$ be a Poisson process, and let $T_0, T_0 + T_1, T_0 + T_1 + T_2, \dots$ be successive jumping times of a sample function $X(t)$. Then T_0, T_1, T_2, \dots is a sequence of mutually independent random variables with the common exponential distribution $P(T \in dt) = \lambda e^{-\lambda t} dt$. Conversely, given such a sequence $\{T_n\}$, if we define $X(t) = \inf\{n | T_0 + T_1 + \dots + T_n > t\}$, then $X(t)$ is a Poisson process. Thus, for example, the number of telephone calls at a switchboard is a Poisson process when the intervals between successive calls can be regarded as independent and having a common exponential distribution.

E. The Structure of the General Lévy Process [8, 9]

In this section we restrict ourselves for simplicity to temporally homogeneous Lévy processes. As we noted, the probability law of the process $X(t)$ is determined by the function $\psi(z)$. The Lévy-Khinchin formula (1) in a

5 E

Additive Processes

certain sense shows that ψ is a combination of a Wiener process and Poisson processes. This fact can be seen more clearly from the **Lévy-Itô theorem**, which states that the sample function of $X(t)$ itself can be expressed as a composite of those of a Wiener process and Poisson processes. The Lévy-Itô theorem actually implies formula (1) and, moreover, clarifies its probabilistic meaning.

The Lévy-Itô theorem can be summarized as follows: Let U be a Borel subset of \mathbf{R} which has a positive distance from the origin, and let $N(t, U)$ be the number of s such that $X(s) - X(s-) \in U$, $s \leq t$. Then $N(t, U)$ is a Poisson process. The expectation $E(N(t, U))$ can be written in the form $tn(U)$, where $n(U)$ defines a nonnegative Borel measure on $\mathbf{R} - \{0\}$; furthermore, it satisfies

$$\int_{-\infty}^{\infty} \frac{u^2}{1+u^2} n(du) < \infty.$$

Next, we set

$$\begin{aligned} S_\varepsilon(t) &= \int_{|u| > \varepsilon} u N(t, du) \\ &= \sum_{\substack{s \leq t \\ |X(s) - X(s-)| \geq \varepsilon}} (X(s) - X(s-)). \end{aligned}$$

Generally, $S_\varepsilon(t)$ diverges as $\varepsilon \downarrow 0$. However, with probability one, a centered process

$$\bar{S}_\varepsilon(t) = S_\varepsilon(t) - t \int_{|u| > \varepsilon} \frac{u}{1+u^2} n(du)$$

converges uniformly in t on every finite interval as $\varepsilon \downarrow 0$. Furthermore, $X(t) - \lim_{\varepsilon \downarrow 0} \bar{S}_\varepsilon(t)$ is continuous with probability one. However, a Lévy process $X(t)$ of which almost all sample functions are continuous has the form $mt + \sqrt{v} B(t)$, where $m, v \geq 0$ are constants and $B(t)$ is a Wiener process. Hence we have

$$\begin{aligned} X(t) &= mt + \sqrt{v} B(t) \\ &+ \lim_{\varepsilon \downarrow 0} \int_{|u| > \varepsilon} \left(u N(t, du) - \frac{u}{1+u^2} tn(du) \right). \end{aligned} \quad (2)$$

Furthermore, we can show that if

$$U_1, U_2, \dots, U_n$$

are disjoint, then

$$B(t), N(t, U_1), N(t, U_2), \dots, N(t, U_n)$$

are mutually independent Lévy processes. In particular, in (2) the terms are mutually independent. The m, v , and $n(du)$ in (2) correspond, of course, to those in (1). Conversely, given m, v , and $n(du)$, we can construct $B(t)$ and $N(t, U)$ with the properties above, and then (2) defines a Lévy process which corresponds to $\psi(z)$ given by (1). The measure $n(du)$ is called the **Lévy measure** of $X(t)$.

F. Examples of Lévy Processes

Compound Poisson Processes. A temporally homogeneous Lévy process is called a **compound Poisson process** if almost all sample functions are step functions, namely, if $\psi(z)$ in (1) is given by

$$\psi(z) = \int_{-\infty}^{\infty} (e^{izu} - 1)n(du),$$

$$\lambda = \int_{-\infty}^{\infty} n(du) < \infty.$$

If we set $\Phi(du) = (1/\lambda)n(du)$, then $\Phi(du)$ is a probability distribution on \mathbf{R} . Φ is the distribution of the size of jumps when they occur. A compound Poisson process is constructed in the following way: Let $T_0, T_1, T_2, \dots; U_1, U_2, \dots$ be mutually independent random variables such that

$$P(T_n \in dt) = \lambda e^{-\lambda t} dt, \quad t > 0,$$

$$P(U_n \in du) = \Phi(du),$$

and let

$$N(t) = U_1 + U_2 + \dots + U_{N(t)},$$

where

$$n = \inf\{n | T_0 + T_1 + \dots + T_n > t\}.$$

Then $X(t)$ is a compound Poisson process. Thus the number of jumps of $X(t)$ follows a Poisson process, and the size of each jump obeys the distribution Φ .

Stable Processes. A temporally homogeneous Lévy process $X(t)$ is called a **stable process** if for every $a > 0$ we can find $b > 0$ and c real such that the processes $X_1(t) = X(at)$ and $X_2(t) = bX(t) + ct$ are equivalent in law. It is called a **strictly stable process** if in the above c can be chosen to be 0. $X(t)$ is a stable process (resp. a strictly stable process) if and only if the corresponding infinitely divisible distribution is a † quasistable distribution (resp. † stable distribution). The † exponent α ($0 < \alpha \leq 2$) of the quasistable distribution is called the **exponent** (or **index**) of the stable process. $\psi(z)$ in (1) corresponding to a stable process is given as follows:

$$\psi(z) = imz + C_+ \int_0^{\infty} (e^{izu} - 1) \frac{du}{u^{1+\alpha}}$$

$$+ C_- \int_{-\infty}^0 (e^{izu} - 1) \frac{du}{|u|^{1+\alpha}}, \quad 0 < \alpha < 1,$$

$$\psi(z) = imz + C_+ \int_0^{\infty} \left(e^{izu} - 1 - \frac{izu}{1+u^2} \right) \frac{du}{u^2}$$

$$+ C_- \int_{-\infty}^0 \left(e^{izu} - 1 - \frac{izu}{1+u^2} \right) \frac{du}{|u|^2}, \quad \alpha = 1,$$

$$\psi(z) = imz + C_+ \int_0^{\infty} (e^{izu} - 1 - izu) \frac{du}{u^{1+\alpha}}$$

$$+ C_- \int_{-\infty}^0 (e^{izu} - 1 - izu) \frac{du}{|u|^{1+\alpha}}, \quad 1 < \alpha < 2,$$

$$\psi(z) = imz - \frac{v}{2} z^2, \quad \alpha = 2.$$

Here m, C_+, C_- , and v are real constants such that $C_+ \geq 0, C_- \geq 0$ with $C_+ + C_- > 0$ and $v > 0$. $\psi(z)$ corresponds to a strictly stable process if and only if $m=0$ when $\alpha \neq 1$ and $C_+ = C_-$ when $\alpha = 1$. The above $\psi(z)$ is also expressed as follows:

(i) if $0 < \alpha \leq 2, \alpha \neq 1$, then

$$\psi(z) = imz - c_0 |z|^{\alpha} \left(1 - i\beta \tan \frac{\pi\alpha}{2} \frac{z}{|z|} \right),$$

where

$$c_0 = \frac{v}{2} \quad \text{if } \alpha = 2$$

and

$$c_0 = -(C_+ + C_-) \Gamma(-\alpha) \cos \frac{\pi\alpha}{2},$$

$$\beta = \frac{C_+ - C_-}{C_+ + C_-} \quad \text{if } \alpha \neq 2;$$

(ii) if $\alpha = 1$, then

$$\psi(z) = i\gamma z - c_0 |z| \left(1 + i\frac{2}{\pi} \beta \frac{z}{|z|} \log |z| \right),$$

where

$$\gamma = m + a(C_+ + C_-)$$

$$\left(a = \int_0^{\infty} \left(\sin u - \frac{u}{1+u^2} \right) \frac{du}{u^2} \right),$$

$$c_0 = \frac{\pi}{2} (C_+ - C_-), \quad \beta = \frac{C_+ - C_-}{C_+ + C_-}.$$

When $\alpha = 2$, it is thus essentially a Wiener process: $X(t) = mt + \sqrt{v} B(t)$, where $B(t)$ is a Wiener process. When $\alpha = 1$, it is called a **Cauchy process**, a **symmetric Cauchy process** if $m=0$ and $C_+ = C_-$ or equivalently $\gamma = \beta = 0$, or an **asymmetric Cauchy process** if $\beta \neq 0$. Generally it is called a **symmetric stable process** if $m=0$ and $C_+ = C_-$ or $\alpha = 2$ and $m=0$. In particular, for the symmetric Cauchy process corresponding to $\psi(z) = -|z|$, we have

$$P(X(t) < x) = \frac{1}{\pi} \int_{-\infty}^x \frac{t}{t^2 + y^2} dy.$$

Next, when $0 < \alpha < 1$ and $m = C_- = 0$, almost all sample functions of $X(t)$ are purely discontinuous increasing functions (i.e., sums of positive jumps). In this case, $X(t)$ is called a **one-sided stable process of the exponent α** (or **subordinator of the exponent α**). Now, if $X(t)$ is

a symmetric stable process of the exponent β ($0 < \beta \leq 2$) and $Y(t)$ is a subordinator of the exponent α which is independent of $X(t)$, then $Z(t) = X(Y(t))$ is a symmetric stable process of the exponent $\alpha\beta$. This operation is called a **subordination** and is closely related to the theory of fractional powers of infinitesimal generators of semigroups (\rightarrow 261 Markov Processes) [2].

A stable process $X(t)$ is defined in a similar way when $X(t)$ takes values in an N -dimensional space \mathbf{R}^N . In particular, if $X(t)$ is a symmetric stable process of the exponent α ($0 < \alpha \leq 2$) given by

$$E(e^{i(z, X(t))}) = e^{-t|z|^\alpha}, \quad z \in \mathbf{R}^N,$$

then for every bounded measurable function $f(x)$ with compact support, we have

$$\begin{aligned} E\left(\int_0^\infty f(x + X(t)) dt\right) \\ = \frac{\Gamma((N-\alpha)/2)}{2^\alpha \pi^{N/2} \Gamma(\alpha/2)} \int_{\mathbf{R}^N} |x-y|^{\alpha-N} f(y) dy. \end{aligned}$$

The right-hand side is the \dagger Riesz potential of order α (\rightarrow 338 Potential Theory). This fact is a generalization of a well-known relation between Brownian motion and Newtonian potential (\rightarrow 45 Brownian Motion), and through this relation we can study several properties of sample functions and also compute various quantities related to stable processes [1].

G. Sample Path Properties of Lévy Processes

Let $X(t)$ be a temporally homogeneous Lévy process. For a Borel set B in \mathbf{R} , the hitting time σ_B is defined by

$$\sigma_B = \inf\{t > 0 \mid X(t) \in B\}.$$

Recurrence. $X(t)$ is called **recurrent** if $\sigma_B < \infty$ a.s. for every nonempty open set B . Otherwise it is called **transient**. $X(t)$ is recurrent if and

only if $\int_{-1}^1 \operatorname{Re} \frac{1}{-\psi(z)} dz = \infty$ (Port and Stone, Ornstein). If, in particular, $E(X(1))$ exists, it is recurrent if and only if $E(X(1)) = 0$. When $X(t)$ is a stable process, it is recurrent if and only if $\alpha > 1$, or $\alpha = 1$ and $\beta = 0$.

Hitting Probabilities for Single Points. If $B = \{a\}$, σ_B is denoted by σ_a . $0 \in \mathbf{R}$ is said to be **regular** for $X(t)$ if $\sigma_0 = 0$ a.s. Set $C = \{x \in \mathbf{R} \mid P(\sigma_x < \infty) > 0\}$. The following result is due to Kesten [10]:

- (i) If $v \neq 0$, then $C = \mathbf{R}$ and 0 is regular;
- (ii) If $v = 0$ and $\int_{-1}^1 |u| n(du) = \infty$, then either $C = \mathbf{R}$ and 0 is regular, or $C = \emptyset$ and 0 is not

regular according to whether $\int_{\mathbf{R}} \operatorname{Re} \frac{1}{\lambda - \psi(z)} dz < \infty$ for all $\lambda > 0$ or $= \infty$ for some $\lambda > 0$;

(iii) If $v = 0$ and $\int_{-1}^1 |u| n(du) < \infty$, then the following four cases are possible, where $a = m - \int_{\mathbf{R}} u(1+u^2)^{-1} n(du)$ and $S(n)$ is the support of the Lévy measure n :

- (a) $C = \emptyset$ when $a = 0$,
- (b) $C = (0, \infty)$ when $a > 0$ and $S(n) \subset (0, \infty)$,
- (c) $C = (-\infty, 0)$ when $a < 0$ and $S(n) \subset (-\infty, 0)$, and
- (d) $C = \mathbf{R}$ in the remaining case.

For further properties of sample functions \rightarrow [4].

H. Generalization of Additive Processes

A temporally homogeneous Lévy process is, as we have seen, essentially a temporally homogeneous Markov process on \mathbf{R} which is homogeneous in space (i.e., invariant under translations of the space). Thus, on a homogeneous space when homogeneity in space makes sense, we can generalize the notion of additive processes. Let M be a \dagger homogeneous space with transformation group G . A temporally homogeneous Markov process $X(t)$ is called an **invariant Markov process**, (or **homogeneous Markov process**) if its system of \dagger transition probabilities $\{P(t, x, E)\}$ satisfies $P(t, x, E) = P(t, gx, gE)$ for all $g \in G$. Thus an additive process is exactly an invariant Markov process on \mathbf{R}^N when G is the group of translations. G. A. Hunt determined all invariant Markov processes when M is a \dagger Lie group or a factor space of a Lie group [6].

Let G be a Lie group and $\Lambda = \Lambda(G)$ be the (left-invariant) \dagger Lie algebra of G . Let $G_c = G \cup \{\omega\}$ be a \dagger one-point compactification of G , and C be the set of all continuous functions on G_c . We can define $Y(f) (Y \in \Lambda, f \in C)$ as usual by

$$Y(f) = \lim_{t \downarrow 0} \frac{R_{\eta(t)} f - f}{t},$$

$$\eta(t) = \exp t Y, \quad R_\sigma f(\tau) = f(\tau\sigma),$$

when the limit exists uniformly. Let $C_2 = \{f \in C \mid Y(Xf) \text{ exists for every } X, Y \in \Lambda\}$. Let X_1, X_2, \dots, X_d be a basis of $\Lambda(G)$, and let x_1, x_2, \dots, x_d be functions in C_2 such that $x_i(e) = 0$ and $X_i(x_j)(e) = \delta_{ij}$ ($i, j = 1, 2, \dots, d$; e is the unit element of G). Take a neighborhood of e , and define a function $\varphi(g) = \sum_{i=1}^d x_i^2(g)$ for g contained in the neighborhood, and extend this function to G_c in such a way that $\varphi \in C_2$ and $\varphi \geq k > 0$ ($k = \text{constant}$) outside of the neighborhood of e . Then $g \in G$ defines a transformation of G_c by $\tau_g \sigma = g\sigma$, $\tau_g \omega = \omega$, and in this way G_c is supplied with the structure of a \dagger homogeneous space with the transformation

group G . Now let $X(t)$ be an invariant Markov process on G_c which is \dagger continuous in probability. Then the \dagger semigroup T_t (which is a \dagger strongly continuous semigroup on C) of the process $X(t)$ is characterized as follows: The domain of the infinitesimal generator A of T_t contains C_2 , and for $f \in C_2$

$$\begin{aligned} Af(\tau) = & \sum_{i=1}^d a_i(X_i f)(\tau) + \sum_{i,j=1}^d a_{ij} X_i(X_j f)(\tau) \\ & + \int_{G_c - \{e\}} \left\{ f(\tau\sigma) - f(\tau) \right. \\ & \left. - \sum_{i=1}^d X_i f(\tau) \cdot x_i(\sigma) \right\} n(d\sigma), \end{aligned}$$

where a_i, a_{ij} are real numbers ($i, j = 1, 2, \dots, d$) such that (a_{ij}) is a symmetric nonnegative definite matrix, and $n(d\sigma)$ is a nonnegative measure on $G_c - \{e\}$ such that $\int_{G_c - \{e\}} \varphi(\sigma) n(d\sigma) < \infty$. Conversely, given such a_i, a_{ij} and $n(d\sigma)$, there exists one and only one invariant Markov process on G_c whose infinitesimal generator is given as above.

A similar result is obtained when M is a factor space of a Lie group by its compact subgroup. Furthermore, for more concrete homogeneous spaces such as spheres or Lobachevskii spaces (more generally, \dagger symmetric Riemannian spaces) the canonical form of the invariant Markov processes and infinitely divisible laws is obtained by making use of harmonic analysis [5].

6 (III.20) Adeles and Ideles

A. Introduction

The concept of idele was first introduced by C. Chevalley (*J. Math. Pures Appl.*, (9) 15 (1936); *Ann. Math.*, (2) 41 (1940)), for \dagger algebraic number fields. Later on, this concept and the allied concept of adele were defined for \dagger simple algebras and also for \dagger algebraic groups over algebraic number fields, and the two concepts became important in the arithmetical theory of these objects. We shall first explain the general concept of restricted direct product, by means of which adeles and ideles will be defined.

B. Restricted Direct Product

Let I be an index set. Suppose we are given, for each $p \in I$, a \dagger locally compact group G_p , and for each p except for a given finite set, say p_1, p_2, \dots, p_r , a compact open subgroup U_p of G_p . Let G be the subgroup of the direct product $\prod_{p \in I} G_p$ consisting of elements (g_p) whose G_p -components g_p lie in U_p , except for a finite number of p . Put $U = \prod_{i=1}^r G_{p_i} \times \prod_{p \neq p_i} U_p$. Then U is a locally compact group with respect to the \dagger product topology. The group G can be supplied naturally with a topology with respect to which G is a locally compact group and the quotient space G/U is discrete. The group G together with this topology is called the **restricted direct product** of $\{G_p\}$ with respect to $\{U_p\}$.

C. Adeles and Ideles

Let k be an \dagger algebraic number field of finite degree and I be the totality of finite and infinite \dagger prime divisors of k . For each $p \in I$ we denote by k_p and k_p^* the \dagger completion of k with respect to p and the multiplicative group of nonzero elements of k_p , respectively. Furthermore, for each finite prime divisor p , we denote by \mathfrak{o}_p and u_p the ring of $\dagger p$ -adic integers

of k and the multiplicative group of \dagger units of \mathfrak{o}_p , respectively.

(1) Since \mathfrak{o}_p is a compact open subgroup of k_p as an additive group, we can construct the restricted direct product \mathbf{A}_k of $\{k_p\}$ with respect to $\{\mathfrak{o}_p\}$. Then \mathbf{A}_k is a locally compact ring with respect to the componentwise ring operations. We call \mathbf{A}_k the **adele ring** (or **ring of valuation vectors**) of k , and an element of \mathbf{A}_k an **adele** (or **valuation vector**) of k . The element of the direct product $\prod_p k_p$ whose p -component is a fixed element of k for all p is an adele. We call such an adele a **principal adele**. Since \mathfrak{o}_p is a compact open subgroup of k_p^\times for each finite prime p , we can construct the restricted direct product \mathbf{J}_k of $\{k_p^\times\}$ with respect to $\{\mathfrak{o}_p\}$. We call \mathbf{J}_k the **idele group** of k and an element of \mathbf{J}_k an **idele** of k . The element of the direct product $\prod_p k_p^\times$ whose p -component is a fixed element of k for all p is an idele. We call such an idele a **principal idele**. Each element b of \mathbf{J}_k induces an automorphism f_b of the additive group \mathbf{A}_k defined by $f_b(a) = b \cdot a$ ($a \in \mathbf{A}_k$). Thus \mathbf{J}_k can be regarded as a subgroup of the automorphism group $\text{Aut}(\mathbf{A}_k)$ of the additive group \mathbf{A}_k . The topology of \mathbf{J}_k coincides with the relative topology of \mathbf{J}_k as a subgroup of $\text{Aut}(\mathbf{A}_k)$. We note, however, that the topology of \mathbf{J}_k is different from the relative topology of \mathbf{J}_k as a subspace of \mathbf{A}_k , and the former is stronger than the latter. Finally, for a \dagger function field in one variable over a \dagger finite field, the adele ring and the idele group can be defined similarly.

(2) Let \mathfrak{R} be a \dagger normal simple algebra over k and \mathfrak{O} be a \dagger maximal order of \mathfrak{R} . For each $p \in I$ put $\mathfrak{R}_p = \mathfrak{R} \otimes_k k_p$, and for each finite prime divisor p put $\mathfrak{O}_p = \mathfrak{o}_p \cdot \mathfrak{O}$. Then \mathfrak{O}_p is a compact open additive subgroup of \mathfrak{R}_p . By the adele ring $\mathbf{A}_{\mathfrak{R}}$ of \mathfrak{R} we mean the restricted direct product of $\{\mathfrak{R}_p\}$ with respect to $\{\mathfrak{O}_p\}$. Let \mathfrak{R}_p^\times and \mathfrak{U}_p be the multiplicative group of nonzero divisors of \mathfrak{R}_p and the multiplicative group of the units of \mathfrak{O}_p , respectively. (\mathfrak{U}_p can be defined only if p is a finite prime divisor.) By the idele group $\mathbf{J}_{\mathfrak{R}}$ of \mathfrak{R} we mean the restricted direct product of $\{\mathfrak{R}_p^\times\}$ with respect to $\{\mathfrak{U}_p\}$. The notion of principal adele (or idele) of \mathfrak{R} can be defined similarly, as in (1). The structures, as topological groups, of $\mathbf{A}_{\mathfrak{R}}$ and $\mathbf{J}_{\mathfrak{R}}$ do not depend on the choice of a maximal order \mathfrak{O} . The adele ring \mathbf{A}_k and the idele group \mathbf{J}_k described in (1) are special cases of $\mathbf{A}_{\mathfrak{R}}$ and $\mathbf{J}_{\mathfrak{R}}$, respectively.

(3) Let G be a linear \dagger algebraic group defined over k , and let G_p be the set of k_p - \dagger rational points of the group for each $p \in I$. For each finite prime divisor p , let U_p be the set of elements α of G_p such that the coordinates of both α and α^{-1} are p -adic integers. We can then construct the restricted direct product of

$\{G_p\}$ with respect to $\{U_p\}$, which is called the **idele group** (or **adele group**) of G .

In the following section we focus on describing the fundamental properties of adeles and ideles of an algebraic number field k . We shall start, however, by observing more generally those adeles and ideles of a normal simple algebra \mathfrak{R} over k . (For the properties of the adele group of algebraic groups \rightarrow [7], 13 Algebraic Groups.)

D. The Structures of the Adele Ring and Idele Group

Let \mathfrak{R} be a normal simple algebra over an algebraic number field of finite degree k . We identify the totality of principal adeles of \mathfrak{R} (principal ideles of \mathfrak{R}) with $\mathfrak{R}(\mathfrak{R}^\times)$, and denote it by the same letter $\mathfrak{R}(\mathfrak{R}^\times)$. Then $\mathfrak{R}(\mathfrak{R}^\times)$ is a discrete subgroup of $\mathbf{A}_{\mathfrak{R}}(\mathbf{J}_{\mathfrak{R}})$. The quotient group $\mathbf{A}_{\mathfrak{R}}/\mathfrak{R}$ is compact. Denoting by $|\alpha_p|_p$ ($\alpha_p \in k_p$) and $N_p(\alpha_p)$ ($\alpha_p \in \mathfrak{R}_p$) the \dagger normalized valuation of k_p and the \dagger reduced norm from \mathfrak{R}_p to k_p , respectively, we define, for $a \in \mathbf{J}_{\mathfrak{R}}$, a positive number: $V(a) = \prod_{p \in I} |N_p(\alpha_p)|_p$, where $a = (\alpha_p)$. We call $V(a)$ the **volume** of a . If a is a principal idele, we have $V(a) = 1$ by the \dagger product formula on valuations. Denote by $\mathbf{J}_{\mathfrak{R}}^0$ the set of ideles a with $V(a) = 1$ and put $\mathbf{C}_{\mathfrak{R}}^0 = \mathbf{J}_{\mathfrak{R}}^0/\mathfrak{R}^\times$. Then $\mathbf{C}_{\mathfrak{R}}^0$ has finite volume with respect to the \dagger Haar measure of $\mathbf{J}_{\mathfrak{R}}$. Furthermore, $\mathbf{C}_{\mathfrak{R}}^0$ is compact if and only if \mathfrak{R} is a \dagger division algebra. In particular, \mathbf{C}_k^0 is compact. Let \mathbf{Q} be the field of rational numbers. For each rational prime p , we define a character λ_p of the completion \mathbf{Q}_p of \mathbf{Q} with respect to the p -adic topology (by a character of \mathbf{Q}_p , we mean a continuous homomorphism from \mathbf{Q}_p to the 1-dimensional torus \mathbf{R}/\mathbf{Z}): If $p = p_\infty$ is the infinite prime of \mathbf{Q} , then we put $\lambda_{p_\infty}(x) \equiv -x \pmod{\mathbf{Z}}$ ($x \in \mathbf{Q}_p$). If p is finite, then we let λ_p be the composite of the following three canonical homomorphisms, namely, the one from \mathbf{Q}_p to $\mathbf{Q}_p/\mathbf{Z}_p$, the one from $\mathbf{Q}_p/\mathbf{Z}_p$ to \mathbf{Q}/\mathbf{Z} , and the one from \mathbf{Q}/\mathbf{Z} to \mathbf{R}/\mathbf{Z} . We define a character λ_p of \mathfrak{R}_p as follows: $\lambda_p = \lambda_p \circ \text{tr}(\mathfrak{R}_p/\mathbf{Q}_p)$, where p is the rational prime divisible by p and $\text{tr}(\mathfrak{R}_p/\mathbf{Q}_p)$ denotes the \dagger reduced trace from \mathfrak{R}_p to \mathbf{Q}_p . For $x, y \in \mathfrak{R}_p$, put $(x, y)_p = \exp(2\pi i \lambda_p(xy))$. Then the additive group \mathfrak{R}_p is self-dual relative to $(x, y)_p$. Furthermore, if we put $\langle a, b \rangle = \prod_p (a_p, b_p)_p$ for $a = (a_p)$ and $b = (b_p) \in \mathbf{A}_{\mathfrak{R}}$ then $\mathbf{A}_{\mathfrak{R}}$ is self-dual relative to $\langle a, b \rangle$. The \dagger annihilator of the group of principal adeles with respect to $\langle a, b \rangle$ is \mathfrak{R} . Hence it follows from \dagger Pontryagin's duality theorem that $\mathbf{A}_{\mathfrak{R}}/\mathfrak{R}$ is compact. Henceforth let $\mathfrak{R} = k$. We call the quotient group $\mathbf{C}_k = \mathbf{J}_k/k^\times$ (an element of \mathbf{C}_k) the **idele class group** of k (an **idele class**). If a character χ of \mathbf{J}_k satisfies the condition $\chi(\alpha) = 1$ for all $\alpha \in k$ (i.e.,

if χ is a character of C_k , we call such a character a **Größencharakter** (or **Hecke character**). Größencharakteren were introduced by E. Hecke as characters of a certain type of the ideal group of k (*Math. Z.*, 1 (1918), 5 (1920)), but they are essentially the same as the ones defined above [1]. Let D_k be the connected component of the identity element of C_k . Then C_k/D_k is totally disconnected and compact. Hence a Größencharakter χ is of finite order if and only if $\chi(D_k) = 1$. We can prove by class field theory that C_k/D_k is canonically isomorphic to the Galois group over k of the maximal Abelian extension of k (\rightarrow 59 Class Field Theory). For the structure of D_k , the following fact is known: Let r_1 and r_2 be the number of real infinite prime divisors and imaginary infinite prime divisors of k , respectively. Then the dual group of D_k is isomorphic to $\mathbf{R} \times \mathbf{Q}^{r_1+r_2-1} \times \mathbf{Z}^{r_2}$, where \mathbf{R} is the additive group of real numbers with the usual topology and $\mathbf{Q}(\mathbf{Z})$ is the additive group of rational numbers (rational integers) with the discrete topology. Let F be a function field in one variable over a finite field \mathbf{F}_0 . The properties of the adèle ring and idele group of F are similar to the properties of A_k and J_k , while the group C_F has a simpler structure than C_k . To explain the structure of C_F , let \tilde{F} be the maximal Abelian extension of F , \tilde{G} be the Galois group of \tilde{F}/F , and G_F be the subgroup of \tilde{G} consisting of the elements σ such that $\sigma(\alpha) = \alpha^{q^n}$ for all $\alpha \in \bar{\mathbf{F}}_0$ (= the algebraic closure of \mathbf{F}_0), where q is the number of elements of the finite field \mathbf{F}_0 and n is a given rational integer. Also, let G_F^0 be the subgroup of G_F consisting of the elements inducing the identity map on $\bar{\mathbf{F}}_0$. G_F^0 is a compact group with respect to the Krull topology. G_F can be naturally supplied with a topology such that the group G_F is a locally compact group and the quotient group G_F/G_F^0 is discrete. Then class field theory implies that G_F is isomorphic to C_F as a topological group.

The following characterization of the adèle ring of a number field or function field in one variable over a finite field is the work of K. Iwasawa (*Ann. Math.*, (2) 57 (1953)). Let A be a semisimple commutative and locally compact topological ring with unity 1. Assume that A is neither discrete nor compact, and moreover that A contains a discrete subfield $k \ni 1$ and A/k is compact. Then k is an algebraic number field or a function field in one variable over a finite field, and A is isomorphic to the adèle ring of k as a topological ring.

E. Ideles and Cohomology

Let K be a Galois extension of finite degree of an algebraic number field k , and \mathfrak{G} be the

Galois group of the extension K/k . \mathfrak{G} operates naturally on the idele group J_K and the idele class group C_K of K . The structures of the cohomology groups of \mathfrak{G} with the coefficient groups J_K and C_K were investigated by G. Hochschild, T. Nakayama, E. Artin, J. Tate, and others. In particular, we have $H^1(\mathfrak{G}, C_K) = \{0\}$ and $H^2(\mathfrak{G}, C_K) \cong \mathbf{Z}/n\mathbf{Z}$ (cyclic group of order n), where $n = [K:k]$. These facts play an important role in one of the proofs of class field theory (\rightarrow [3]; 59 Class Field Theory). Furthermore, A. Weil introduced the so-called **Weil group**, which is a group extension of a certain type of C_K by \mathfrak{G} . He defined the most general L -functions, which include both Artin L -functions and Hecke L -functions with Größencharakteren (\rightarrow [2]; 450 Zeta Functions).

F. Fourier Analysis on the Adele Group

Dedekind zeta functions and Hecke L -functions are meromorphic on the whole complex plane and satisfy functional equations of certain types. This can be proved by methods of Fourier analysis on the adèle group A_k (Artin, Iwasawa, Tate [1, 8, 9]). For a continuous complex-valued function $\varphi(a)$ on A_k satisfying suitable conditions, we define the Fourier transform of $\varphi(a)$ as follows:

$$\hat{\varphi}(a) = \int_{A_k} \varphi(b) \langle a, b \rangle db,$$

where db denotes the Haar measure on A_k . By normalizing db suitably and applying Poisson's summation formula, we get, for each idele a of k ,

$$\sum_{\alpha \in k} \varphi(a\alpha) = V(a)^{-1} \sum_{\alpha \in k} \hat{\varphi}(a^{-1}\alpha).$$

This is called the **Θ -formula**. Consider the following integral on J_k :

$$\xi(s) = \int_{J_k} V(a)^s \chi(a) \varphi(a) d^*a,$$

where d^*a denotes the Haar measure on J_k , s is a complex number, and χ is a Größencharakter of k , namely, a character of C_k . This integral converges if $s > 1$, and by using the Θ -formula one can show that $\xi(s)$ is meromorphic on the whole complex plane and satisfies a functional equation of a certain type. When the function φ is of special type, then the above integral can be explicitly expressed as the product of L -functions, Γ -functions, and exponential functions. This method of expressing L -functions by integrals on J_k and applying the Θ -formula can be applied to investigate Hey zeta functions and L -functions of various types defined for a simple algebra (\rightarrow

450 Zeta Functions) (G. Fujisaki [6]; T. Tamagawa, *Ann. Math.*, 77 (1963)).

7 (VI.15) Affine Geometry

A. Construction of Affine Spaces

An affine space A is constructed as follows: Let V be a \dagger vector space over a \dagger field K , and let A be a nonempty set. For any vector $\mathbf{a} \in V$ and any element p of A , suppose that an addition $p + \mathbf{a} \in A$ is defined so as to satisfy the following three conditions: (i) $p + \mathbf{0} = p$ ($\mathbf{0}$ being a zero vector); (ii) $(p + \mathbf{a}) + \mathbf{b} = p + (\mathbf{a} + \mathbf{b})$ ($\mathbf{a}, \mathbf{b} \in V$); and (iii) for any $q \in A$ there exists a unique vector $\mathbf{a} \in V$ such that $q = p + \mathbf{a}$. (Condition (i) follows from (ii) and (iii).) Then we call A an **affine space**, V the **standard vector space** of A , and K the **coefficient field** of A . Each element of A is called a **point**.

If we fix an arbitrary point $o \in A$, there is a one-to-one correspondence between A and V given by the mapping sending $p \in A$ to $\mathbf{a} \in V$ such that $p = o + \mathbf{a}$. Such an element \mathbf{a} of V is called a **position vector** of p with the **initial point** o and is denoted by \overrightarrow{op} . We say that $r + 1$

7 B

Affine Geometry

points p_α ($0 \leq \alpha \leq r$) of A are **independent** if r vectors $\mathbf{a}_i = \overrightarrow{p_0 p_i}$ ($1 \leq i \leq r$) are linearly independent in V ; otherwise, they are said to be **dependent**. This definition of dependence of points p_α is independent of the choice of the initial point among them. If V is of dimension n , we say that A is of **dimension** n , $\dim A = n$; in this case, we sometimes write A^n instead of A and V^n instead of V . The affine space A is of dimension n if and only if the maximum number of independent points in A is $n + 1$.

Next, for any vector subspace V^k of V^n and an arbitrary point $p \in A^n$, we put $A_p^k = \{q \in A^n \mid q = p + \mathbf{x}, \mathbf{x} \in V^k\}$ and call it a **subspace** of A^n . It is an affine space of dimension k : Conversely, every subset of A^n that is an affine space under the affine space structure of A can be expressed in this form. A^1 , A^2 , and A^{n-1} in A^n are called a **line**, **plane**, and **hyperplane**, respectively. A set that consists of only one point is also considered as a subspace A^0 . For subspaces A^r and A^s of A^n , we denote by $A^r \cap A^s$ the **intersection** (i.e., the set-theoretic intersection) of A^r and A^s , and by $A^r \cup A^s$ the **join** of A^r and A^s (i.e., the intersection of all subspaces that contain both A^r and A^s). Then $A^r \cap A^s$ is the affine space of highest dimension contained in A^r and A^s , and $A^r \cup A^s$ is the affine space of lowest dimension that contains A^r and A^s . If $r + 1$ points are given in A^n , there always exists a subspace A^r that contains all these points. In particular, if the points are independent, then such an A^r is unique. Moreover, if $A^r \cap A^s \neq \emptyset$ (\emptyset is the empty set), then we have $r + s = \dim(A^r \cup A^s) + \dim(A^r \cap A^s)$. This is called the **dimension theorem** (or **intersection theorem**) of affine geometry.

Next suppose that $r + 1$ points p_α ($0 \leq \alpha \leq r$) in A^n are independent, and put $p_{r+1} = p_0$. Let q_α be an arbitrary point on $p_\alpha \cup p_{\alpha+1}$ that differs from p_α and $p_{\alpha+1}$. If λ^α are elements of K such that $\lambda^\alpha \cdot \overrightarrow{p_\alpha q_\alpha} = \overrightarrow{q_\alpha p_{\alpha+1}}$, then q_0, \dots, q_r are dependent if and only if $\lambda^0 \lambda^1 \dots \lambda^r = (-1)^{r+1}$. And if $r \geq 2$ and $\sigma_\alpha = q_\alpha \cup p_{\alpha+2} \cup \dots \cup p_{\alpha+r}$ ($p_{i+r} = p_{i-1}$ if $i \geq 1$), then $\sigma_0, \dots, \sigma_r$ have a point in common if and only if $\lambda^0 \lambda^1 \dots \lambda^r = 1$. The former is called **Menelaus's theorem**, and the latter **Ceva's theorem**.

The set $L(A)$ of all subspaces (including \emptyset considered as an affine space of dimension -1) constitutes a \dagger lattice with respect to the inclusion relation.

B. Parallelism in Affine Spaces

Let A^r and A^s be subspaces of A^n . We say that A^r and A^s are **parallel in the wider sense** if either of the following conditions holds:

- (i) $A^r \supset A^s$ or $A^s \supset A^r$; or (ii) $A^r \cap A^s = \emptyset$ and $\dim(A^r \cup A^s) \leq r + s$. Next, let A^r and

B^r be subspaces of A^n of the same dimension. If A^r and B^r coincide, or $A^r \cap B^r = \emptyset$ and $\dim(A^r \cup B^r) = r + 1$, then they are said to be **parallel in the narrower sense** (or simply **parallel**), and we denote the relation by $A^r \parallel B^r$. If $r = s = 1$, the definitions of parallelism in the narrower sense and wider sense are equivalent. If $r > 1$, parallelism in the narrower sense implies parallelism in the wider sense. For two sets (a_α) and (b_α) ($0 \leq \alpha \leq r$) of $r + 1$ independent points, let V^r and W^r be vector spaces with bases $\overrightarrow{a_0 a_i}$ and $\overrightarrow{b_0 b_i}$ ($1 \leq i \leq r$), respectively. Then $A^r = a_0 \cup \dots \cup a_r$ and $B^r = b_0 \cup \dots \cup b_r$ are parallel if and only if $V^r = W^r$; and for an arbitrary point p , there exists a unique r -dimensional subspace that is parallel to A^r and passes through point p . If A^r and B^s are parallel in the wider sense, then there exist subspaces A^t and B^t ($t \geq 1$) of A^r and B^s that are parallel to each other. Moreover, if neither A^r nor B^s is contained in the other and if t is the largest integer with the property just given, then we have $t = r + s + 1 - \dim(A^r \cup B^s)$.

Parallelism between subspaces of A^n is an equivalence relation. Specifically, the equivalence class of a 1-dimensional subspace A^1 is called a **point at infinity** and is denoted by A_∞^0 . Given a subspace A^r of A^n , the set of points at infinity A_∞^0 represented by lines A^1 contained in A^r is denoted by A_∞^{r-1} ; we have $A^r \parallel B^r$ if and only if $A_\infty^{r-1} = B_\infty^{r-1}$. A_∞^{r-1} is called a **space at infinity**. In particular, the set A_∞^{n-1} is called the **hyperplane at infinity**. The set-theoretic sum $A^n \cup A_\infty^{n-1} = \bar{A}^n$ is supplied with the structure of a \dagger projective space; the "points" in \bar{A}^n are elements of \bar{A}^n , and the "lines" in \bar{A}^n are $A^1 \cup A_\infty^0$ and A_∞^1 .

C. Coordinates of Affine Spaces

If we fix a point o in A^n and a basis $\{e_1, \dots, e_n\}$ of the standard vector space V^n , then any point p in A^n is uniquely expressed as

$$p = o + \sum_{i=1}^n x^i \cdot e_i, \quad x^i \in K. \quad (1)$$

The system $\mathfrak{F} = (o; e_1, \dots, e_n)$ is called an **affine frame** (simply the **frame**) of A^n ; the point o is called its **origin**, and e_i is called the i th **unit vector**. The mapping sending p to (x^1, \dots, x^n) gives a \dagger bijection of A^n to K^n ; we call (x^1, \dots, x^n) **affine coordinates** of p with respect to \mathfrak{F} , and x^i the i th **affine coordinate**. In particular, if K is a topological field (e.g., the real number field \mathbf{R} or the complex number field \mathbf{C}), this bijection $A^n \rightarrow K^n$ induces a topology of A^n , which can be shown to be independent of the choice of \mathfrak{F} . For the remainder of this article, by "coordinates" we mean affine coordinates unless otherwise stated. Putting

$a_i = o + e_i$ ($1 \leq i \leq n$), we sometimes call $(o; a_1, \dots, a_n)$ an affine frame. Further, putting $l_i = o \cup a_i$, $\pi_i = o \cup a_1 \cup \dots \cup a_{i-1} \cup a_{i+1} \cup \dots \cup a_n$, we call a_i , l_i , and π_i the i th **unit point**, the i th **coordinate axis**, and the i th **coordinate hyperplane**, respectively.

Assume that subspaces A^r and A^s ($r, s > 0, r + s = n$) are not parallel in the wider sense. For a point p of A^n , denote by $A^r(p)$ the subspace that passes through p and is parallel to A^r , and put $q = A^r(p) \cap A^s$. A mapping $\varphi: A^n \rightarrow A^s$ defined by $\varphi(p) = q$ is called a **parallel projection** on A^s with respect to A^r . In particular, if $A^r = \pi_i$ and $A^s = l_i$ ($r = n - 1, s = 1$), we write $\varphi(p) = p_i$. Then the i th coordinate x^i of p is an element of K such that $\overrightarrow{op_i} = x^i \overrightarrow{oa_i}$. Hence such coordinates are also called **parallel coordinates** (or **Cartesian coordinates**).

Suppose that we are given $r + 1$ points b_0, \dots, b_r of A^n and $r + 1$ elements $\lambda^0, \dots, \lambda^r$ of K such that $\sum_{\alpha=0}^r \lambda^\alpha = 1$. We fix a point o of A^n . If a point p in A^n satisfies $\overrightarrow{op} = \sum_{\alpha=0}^r \lambda^\alpha \overrightarrow{ob_\alpha}$, then $\overrightarrow{b_0 p} = \sum_{i=1}^r \lambda^i \overrightarrow{b_0 b_i}$; hence p is contained in the subspace $b_0 \cup \dots \cup b_r$. Conversely, if a point p is contained in the latter subspace, then there exists a system $(\lambda^0, \dots, \lambda^r)$ such that

$$\overrightarrow{op} = \sum_{\alpha=0}^r \lambda^\alpha \overrightarrow{ob_\alpha} \quad \text{and} \quad \sum_{\alpha=0}^r \lambda^\alpha = 1.$$

The system $(\lambda^0, \dots, \lambda^r)$ has a geometric meaning since we also have $\overrightarrow{o'p} = \sum_{\alpha=0}^r \lambda^\alpha \overrightarrow{o'b_\alpha}$ if we replace the point o by any other point o' of A^n . The elements $\lambda^0, \dots, \lambda^r$ are called **barycentric coordinates** of p with respect to $\{b_0, \dots, b_r\}$. In particular, if $\{b_0, \dots, b_r\}$ are independent, then the barycentric coordinates $(\lambda^0, \dots, \lambda^r)$ are uniquely determined by the point p on $b_0 \cup \dots \cup b_r$. Furthermore, let (y^1, \dots, y^n) be affine coordinates of p with respect to an affine frame \mathfrak{F} , and let $(x_\alpha^1, \dots, x_\alpha^n)$ be affine coordinates of b_α ($\alpha = 0, \dots, r$). Then p belongs to the subspace $A^r = b_0 \cup \dots \cup b_r$ if and only if $y^i = \sum_{\alpha=0}^r \lambda^\alpha x_\alpha^i$ ($i = 1, \dots, n$). In this case we say that the system of the linear equations $y^i = \sum \lambda^\alpha x_\alpha^i$ ($\sum \lambda^\alpha = 1$) gives a **parametric representation** of the subspace A^r (by parameters λ^α). Specifically, if $r = n - 1$, the solvability of the system of equations $y^i = \sum_{\alpha=0}^{n-1} \lambda^\alpha x_\alpha^i$ ($i = 1, \dots, n$), $1 = \sum \lambda^\alpha$ implies the equation $\sum_{i=1}^n y^i \mu_i = \mu_0$ for some nontrivial constants μ_0, \dots, μ_n . Hence the latter equation represents the hyperplane $\pi = A^{n-1}$. If a point p has barycentric coordinates $\lambda^0 = \lambda^1 = \dots = \lambda^r = (r + 1)^{-1}$ with respect to $\{b_0, \dots, b_r\}$, it is called the **barycenter** of b_0, b_1, \dots, b_r . The barycenter is uniquely determined by the set $\{b_0, \dots, b_r\}$ and is denoted by $g(b_0, \dots, b_r)$. Specifically, the barycenter of two points b_0 and b_1 is called the **midpoint** (or **middle point**) of b_0 and b_1 . If we divide $B = \{b_0, \dots, b_r\}$ into two sets of points and if g_1 and g_2 are barycenters of these two sets of points, respectively, then $g_1 \cup g_2$ passes

through the barycenter of B . More generally, a point with barycentric coordinates $(\lambda^0, \dots, \lambda^r)$ with respect to $\{b_0, \dots, b_r\}$ is called a barycenter of b_0, \dots, b_r with **weights** $\lambda^0, \dots, \lambda^r$.

D. Affine Spaces over Ordered Fields

Suppose the coefficient field K is an \dagger ordered field (e.g., the real number field \mathbf{R}). Given a hyperplane π of A^n , we take an affine frame for which π is the n th coordinate hyperplane. If we denote coordinates of points with respect to this frame by (x^1, \dots, x^n) , then the equation of π is given by $x^n = 0$. Let A_+^n and A_-^n be sets of points whose n th coordinates are positive and negative, respectively. They are called **half-spaces** of A^n divided by π . The union of π and a half-space is called a **closed half-space**. A half-space of a subspace A^r of A^n (divided by some A^{r-1} on A^r) is called a half-space of dimension r . For a point p of A^n that does not lie on π , the half-space containing p is called the **side** of p with respect to π . In particular, when $n = 1$, let p and q be two points on a line l . The closed side of q with respect to p is called the **(closed) half-line** (or **ray**) from p to q . The intersection of the closed half-lines emanating from p to q and from q to p is called the **segment** joining p and q and is denoted by \overline{pq} . Clearly $\overline{pq} = \overline{qp}$. A subset C of A^n is called a **convex set** if the segment joining two arbitrary points of C is contained in C . Each half-space of each dimension is convex. For any family C_i of convex sets, $\bigcap_i C_i$ is also convex. Therefore, for any subset D in A^n there exists a minimal convex set that contains D . It is called the **convex closure** (or **convex hull**) of D . The convex closure $C(P)$ of a finite set of points $P = \{p_0, \dots, p_k\}$ in A^n is called a **convex cell**, and $\dim(p_0 \cup \dots \cup p_k)$ is called the **dimension** of the convex cell. In particular, when p_0, \dots, p_k are independent, $C(P)$ is called a k -dimensional **simplex** with **vertices** p_0, \dots, p_k . The 1-dimensional simplex having two distinct points p and q as vertices is the segment \overline{pq} , and the vertices p and q are called **ends** of the segment. A point is regarded as a 0-dimensional simplex. Each 2-dimensional or 3-dimensional simplex is called a **triangle** or **tetrahedron**, respectively. A k -dimensional simplex S with vertices p_0, \dots, p_k is a set of points whose barycentric coordinates λ^α ($0 \leq \alpha \leq k, \sum \lambda^\alpha = 1$) with respect to the vertices satisfy $\lambda^\alpha \geq 0$. On the other hand, if we put $A^k = p_0 \cup \dots \cup p_k$ and $\pi_\alpha = p_0 \cup \dots \cup p_{\alpha-1} \cup p_{\alpha+1} \cup \dots \cup p_k$, and denote by A_α^k the side of p_α in A^k and by \bar{A}_α^k the closed side of p_α in A^k with respect to π_α , then the simplex S is given by $\bigcap_{\alpha=0}^k \bar{A}_\alpha^k$, and $\bigcap_{\alpha=0}^k A_\alpha^k$ is called an **open simplex**. A^n has the structure of a \dagger topological space in which the set of open n -

dimensional simplexes forms a \dagger base of \dagger open sets. In particular, if K is \mathbf{R} , the topology of A^n thus defined is compatible with the one that is naturally induced by the topology of \mathbf{R} . With respect to this topology, A^n is a \dagger Hausdorff space. The terms *open* and *closed* used before for n -dimensional simplexes agree with the corresponding notions with respect to this topology.

A subset of A^n is said to be **bounded** if it is contained in some simplex. A bounded set obtained through a finite process of constructing intersections and unions from a finite number of closed half-spaces is called a **polyhedron**. The points of a convex polyhedron are characterized by several linear inequalities satisfied by their coordinates. A set of points whose coordinates (x^1, \dots, x^n) satisfy $h^i \leq x^i \leq k^i$ for $k^i, h^i \in K$ is called a **parallelootope**; it is a polyhedron whose \dagger interior is called an **open parallelootope**. A simplex is a polyhedron, and polyhedra admit \dagger simplicial decompositions. A polyhedron can also be defined as the set-theoretic union of a finite number of simplexes.

Let P be a finite set of points, and let its convex closure $C(P)$ be a convex cell of dimension m . Then $C(P)$ is contained in an m -dimensional subspace A^m . The \dagger boundary of $C(P)$ in the topological space A^m is called the **boundary** of a convex cell $C(P)$. We can take a subset Q of P so that $\dim C(Q) = m - 1$ and $C(Q)$ is the intersection of the boundary of $C(P)$ and an $(m - 1)$ -dimensional subspace. Such a $C(Q)$ is called a **face** of $C(P)$, and we denote this relation by $C(P) > C(Q)$. If $C(P) > C(P_1) > \dots > C(P_s)$, then $C(P_s)$ is called an $(m - s)$ -dimensional face of $C(P)$. A 0-dimensional face is called a **vertex**, and a 1-dimensional face is called an **edge**. Suppose that $C(P) > C(Q)$ for $P = \{p_0, \dots, p_k\}$ and $Q = \{p_{i_0}, \dots, p_{i_{k-1}}\}$. Then $F = p_{i_0} \cup \dots \cup p_{i_{k-1}}$ is a hyperplane of $E = p_0 \cup \dots \cup p_k$, and $C(P)$ is contained in a closed side of E divided by F . Therefore, if $C(P)$ has d $(m - 1)$ -dimensional faces, then $C(P)$ is expressed as the intersection of d m -dimensional closed half-spaces. This shows that any convex cell is a polyhedron.

E. Affine Transformations

A mapping $\varphi: A^n \rightarrow A^m$ is an **affine mapping** if there is a linear mapping $\bar{\varphi}: V^n \rightarrow V^m$ of the standard vector spaces of A^n and A^m such that $\varphi(p + \mathbf{x}) = \varphi(p) + \bar{\varphi}(\mathbf{x})$ holds for any $p \in A^n$ and any $\mathbf{x} \in V^n$. An affine mapping of A^n into itself is called an **affine transformation** (or **affinity**) of A^n . Specifically, a bijective affine transformation is called a **regular** (or **proper**) **affine transformation**. An affine transformation φ of A^n is characterized by each one of the following

properties: (i) Let $o \in A''$ be a fixed point. Then φ is a mapping of A'' onto itself that can be expressed as

$$\varphi(o + \mathbf{x}) = o + \mathbf{a} + f(\mathbf{x}), \quad (2)$$

where \mathbf{a} is a fixed vector of V'' and f is a linear transformation of V'' . (ii) The mapping $\varphi: A'' \rightarrow A''$ is a mapping such that $\varphi(a)\varphi(b) = \lambda \cdot \varphi(p)\varphi(q)$ if $\overline{ab} = \lambda \cdot \overline{pq}$ ($\lambda \in K$). Moreover, if the characteristic of K is not equal to 2, an affine transformation is also characterized as follows: (iii) φ is a mapping that sends lines into lines and preserves the ratio of each pair of parallel segments.

The set $\mathfrak{U}(A'')$ of all regular affine transformations of A'' constitutes a group that we call the **group of affine transformations**. If the linear mapping f associated with a regular affine transformation φ is the identity mapping, then φ is called a **translation**. The set $\mathcal{T}(A'')$ of all translations is a normal subgroup of $\mathfrak{U}(A'')$ and is called the **group of translations**. The group of translations is isomorphic to V regarded as an additive group. The vector group $\mathfrak{B}(A'')$ (i.e., an additive group of a linear space) acts simply transitively on A'' . We see that $\mathfrak{U}(A'')/\mathfrak{B}(A'') \cong GL(n, K)$, where $GL(n, K)$ denotes the general linear group. The set of all regular affine transformations that leave a point o of A'' invariant constitutes a subgroup $\mathfrak{G}(A'')$ of $\mathfrak{U}(A'')$; it is called an **isotropy group** at o and is isomorphic to $GL(n, K)$. Let $\mathfrak{F} = (o; \mathbf{e}_1, \dots, \mathbf{e}_n)$ be an affine frame of A'' with origin o , and let φ be a regular affine transformation of A'' given by (2); put $\mathbf{x} = \sum x^i \mathbf{e}_i$, $\varphi(o + \mathbf{x}) = o + \sum \bar{x}^i \mathbf{e}_i$, $\mathbf{a} = \sum a^i \mathbf{e}_i$, and $f(\mathbf{e}_i) = \sum a_j^i \mathbf{e}_j$. Then φ is expressed with respect to \mathfrak{F} by the following equation:

$$\bar{x}^i = a^i + \sum_{k=1}^n a_k^i x^k, \quad \det(a_j^i) \neq 0, \quad 1 \leq i \leq n. \quad (3)$$

Conversely, a transformation that is given by (3) is a regular affine transformation. Elements of $\mathfrak{B}(A'')$ and $\mathfrak{G}(A'')$ are expressed with respect to \mathfrak{F} by

$$\bar{x}^i = x^i + a^i, \quad 1 \leq i \leq n, \quad (4)$$

and

$$\bar{x}^i = \sum_{k=1}^n a_k^i x^k, \quad \det(a_j^i) \neq 0, \quad 1 \leq i \leq n, \quad (5)$$

respectively. Hence $\mathfrak{U}(A'')$ is represented as a **semidirect product** group of $\mathfrak{B}(A'')$ and $(F)(A'')$. In particular, a regular affine transformation that is represented by $\bar{x}^i = ax^i$ ($1 \leq i \leq n$) for some $a \in K$ ($a \neq 0$) is called a **similarity** with the origin o as center.

According to F. Klein, the objects we deal with in affine geometry are the properties (parallelism, barycenters, etc.) that are invariant under regular affine transformations.

Subsets S_1 and S_2 of A'' are called **affinely congruent** if there exists a regular affine transformation φ sending S_1 onto S_2 . For a fixed k , two k -dimensional simplexes are affinely congruent. Now we fix an affine frame \mathfrak{F} in A'' and denote by x_a^i the coordinates of $n+1$ points p_a ($0 \leq a \leq n$) in A'' . Then the quantity

$$V(p_0, \dots, p_n) = \frac{1}{n!} \begin{vmatrix} 1 & 1 & \dots & 1 \\ x_0^1 & x_1^1 & \dots & x_n^1 \\ \dots & \dots & \dots & \dots \\ x_0^n & x_1^n & \dots & x_n^n \end{vmatrix} \quad (6)$$

is called the **volume** with respect to \mathfrak{F} of the n -dimensional simplex with vertices p_0, \dots, p_n . If φ is a regular affine transformation given by (3), we have $\bar{V} = \det(a_j^i) V$. Hence the ratio of volumes of two n -dimensional simplexes is independent of the choice of coordinate systems, and is invariant under regular affine transformations.

A regular affine transformation given by (3) satisfying $\det(a_j^i) = 1$ is called an **equivalent affinity**. The set of all equivalent affinities constitutes a subgroup of $\mathfrak{U}(A'')$. The geometry belonging to this group is called **affine geometry in the narrower sense**. For instance, the concept of volume is an invariant in affine geometry in the narrower sense.

F. Relation to Projective Geometry

Let \mathbf{P}^n be a projective space over a coefficient field K (\rightarrow 343 Projective Geometry). If we fix a hyperplane π_∞ in \mathbf{P}^n , then the set of projective transformations that leave π_∞ invariant constitutes a subgroup of the group of projective transformations of \mathbf{P}^n ; this subgroup is isomorphic to a group of regular affine transformations. Actually, if we use a projective frame $[a_0, a_1, \dots, a_n, u]$ such that a_0, \dots, a_n are points on π_∞ , then each projective transformation leaving π_∞ invariant is expressed by equations of the same form as (3) with respect to the inhomogeneous projective coordinates. The point set A'' complementary to π_∞ in \mathbf{P}^n is an affine space, and π_∞ coincides with the hyperplane at infinity. Moreover, two distinct lines in \mathbf{P}^n are parallel in A'' if they meet on the hyperplane at infinity. Hence, denoting by $(0, l^1, \dots, l^n)$ the homogeneous projective coordinates of the intersection of a line l in A'' and π_∞ , we call (l^1, \dots, l^n) the **direction ratio** of l . A projective transformation leaving each point of π_∞ invariant induces a translation. The principle of duality that holds in projective geometry does not hold in affine geometry. The pole of the hyperplane at infinity, with respect to a quadric hypersurface, is called the **center** of the quadric hypersurface. A regular quadric hypersurface is called **central**

or **noncentral** according as its **center** belongs to A^n or is a point at infinity. Quadric hypersurfaces in an affine space are classified in several ways, by taking account of their relations with the hyperplane at infinity (→ 78 Conic Sections, 350 Quadric Surfaces).

8 (111.1) Algebra

Though the word “algebra” usually refers to a field of mathematics as will be explained below, the word may also denote specific mathematical structures such as \dagger associative algebras, \dagger Jordan algebras, \dagger Clifford algebras, etc. The first concepts concerning “unknowns” in algebra originated in India, whence came also our decimal positional system of numeration. These ideas were introduced to Europe through Arabia in the Renaissance period. F. \dagger Viète systematized them into a symbolic method, called **algebra**, representing numbers by letters. The first problem of algebra was solving equations. Before Viète, G. Cardano and L. Ferrari had solved algebraic equations of degrees 3 and 4; the solution of equations of lower degree had been known from antiquity. The effort to solve equations of higher degree remained unresolved until the middle of the 19th Century, when N. H. \dagger Abel and E. \dagger Galois proved the nonexistence of algebraic solutions of such equations. They considered not only individual roots of these equations but also any rational transforms of their roots at the same time, and thus were led to the concept of \dagger fields. They also noticed that the problem of algebraic solution could be characterized by properties of permutation groups of the roots.

After the discovery of the Galois group, group theory and group-theoretical considerations maintained the central position in algebra for some time (→ 172 Galois Theory). These developed into the “abstract algebra” of this Century in the general atmosphere of arithmetization and of axiomatization of mathematics. At the turn of the century the monumental textbook in three volumes by H. Weber [1] was considered the standard work on algebra. Then there appeared in 1910 an epoch-making paper [2] by E. Steinitz on the abstract theory of fields.

The main objects of algebra today are \dagger algebraic systems of various kinds, such as \dagger groups, \dagger rings, \dagger fields, and \dagger modules. Another fundamental concept of algebra is that of \dagger isomorphism or of \dagger homomorphism. The collection of algebraic systems of a given kind, together with the homomorphisms among them, gives rise to the notion of \dagger category; a functor is a sort of homomorphism between categories (→ 52 Categories and Functors). These notions were first used in \dagger homological algebra, created in the 1940s by methods transferred from topology to algebra; now they are of basic significance to the whole of mathematics.

An important branch of algebra with wide applications is the theory of \dagger vector spaces, or more generally that of \dagger modules over a ring. This branch is called **linear algebra**. Homomorphisms between finitely generated modules can be represented by \dagger matrices. Another branch of algebra, called \dagger representation theory, is concerned with representations of groups or rings by matrices. The methods of modern algebra provide useful and powerful tools for the whole of mathematics, in particular for the theory of numbers and algebraic geometry.

The present development of algebra owes much to the activity of the German school in the late 1920s represented by E. Noether, E. Artin, W. Krull, and B. L. van der Waerden. The book by van der Waerden [3] has had a great impact on mathematics. N. Bourbaki [4] has been influenced by van der Waerden but gives accounts of more recent developments, particularly in linear algebra. In Japan, M. Sono, who worked at about the same period as E. Noether, was a forerunner in this field; after him, algebraists of the Kyoto School, Y. Akizuki, M. Nagata, and their followers, did notable research, especially in algebraic geometry. On the other hand, K. Shoda studied with E. Noether toward 1930 in Germany; his school includes such algebraists as T. Nakayama, K. Asano, and G. Azumaya. Finally K. Morita and his disciples have made significant contributions to homological algebra.

9 (VIII.2) Algebraic Curves

A. General Remarks

An \dagger algebraic variety of dimension 1 is called an **algebraic curve** (for analytic theory \rightarrow 11 Algebraic Functions). The theory of algebraic curves has two aspects, the geometry of 1-dimensional complex manifolds in projective spaces and the theory of function fields of transcendence degree 1 (\rightarrow 3 Abelian Varieties, 16 Algebraic Varieties). The number-theoretic study of algebraic function fields concerns the latter theory (\rightarrow 73 Complex Multiplication, 450 Zeta Functions). In this article, the geometric aspect of the theory is emphasized. We denote the \dagger universal domain by **K**.

B. Classical Results on Plane Algebraic Curves

Let $f(X, Y)$ be a polynomial of degree m in two variables X and Y . A point set in an affine two-space defined by $f(X, Y) = 0$ is called the plane algebraic curve of degree m . If we set $F(X_0, X_1, X_2) = X_0^m f(X_1/X_0, X_2/X_0)$, the homogeneous polynomial F defines an algebraic curve of degree m in a projective plane P^2 . The curve is called **irreducible** if the polynomial $f(X, Y)$ is irreducible. A curve of degree 1 is said to be a line. Some results of this section are valid only in the case where the characteristic of **K** is zero.

Let C be a plane curve defined by the equation $f(X, Y) = 0$. A point $P = (a, b)$ on C is called an **r-ple point** if $f(X + a, Y + b)$ has no term of degree $< r$ in X and Y . At an r -ple point there are r tangent straight lines (counting multiplicity). An r -ple point with $r > 1$ is

called a **multiple point** (or **singular point**). If these tangents are distinct, P is called **ordinary**. An ordinary double point is called a **node**; e.g., the origin for $X^3 + Y^3 - 3XY = 0$. An algebraic curve can be transformed into a plane curve that has only ordinary multiple points by a finite number of plane \dagger Cremona transformations (\dagger quadratic transformations of the projective plane into itself).

Let C be an irreducible plane curve of degree $m > 1$ in a projective plane. The set of all tangent lines at nonsingular points of C determines a set of points in the dual projective plane, and its closure is an algebraic curve \hat{C} , that is called the **dual curve** of C . The dual curve of \hat{C} becomes the original C . The degree m' of \hat{C} is said to be the **class** of C , which is equal to the number of tangent lines to C drawn from a general point. A nonsingular point P is called a **point of inflection** (or a **flex**) if the tangent line at P has contact of order > 2 . If C is defined by an irreducible homogeneous polynomial $F(X_0, X_1, X_2)$, the curve defined by $\det(\partial^2 F / \partial X_i \partial X_j) = 0$ is said to be the **Hessian** of C . A nonsingular point P is a point of inflection if and only if P is contained in the Hessian. A singular point P is said to be a **cusp** if C is defined by an equation $Y^2 = X^3 + \text{higher terms}$, in terms of suitable affine coordinates X and Y where $P = (0, 0)$. Whenever the singular points of C are only v nodes and y cusps, the effective genus g is given by the formula $g = (m-1)(m-2)/2 - v - y$. In addition, suppose that the dual curve has only v' nodes and y' cusps as singularities. Then C has y' points of inflection, and m' and y' are given by $m' = m(m-1) - 2v - 3y$ and $y' = 3m(m-2) - 6v - 8y$. Moreover, $m = m'(m'-1) - 2v' - 3y'$ and $y = 3m'(m'-2) - 6v' - 8y'$ hold. These formulas are called **Plücker formulas**.

For example, a nonsingular plane curve of degree 3 is an elliptic curve, i.e., $g = 1$, of class 6, which has 9 points of inflection. A nonsingular plane curve of degree 4 has, in general, 24 points of inflection and 28 bitangents. This results from the Plücker formulas.

C. Fundamental Notions

In what follows, by a curve we mean an algebraic variety of dimension 1. Let Γ be a nonsingular complete irreducible curve. An element of the free Abelian group generated by points of Γ is called a **divisor**. A divisor is written in the form $a = \sum n_i P_i$, with $n_i \in \mathbb{Z}$. The integer $n = \sum n_i$ is called the **degree** of a and is denoted by $\deg a$. The expression for a divisor a is said to be reduced if $P_i \neq P_j$ for $i \neq j$. A divisor whose reduced expression has only positive coefficients is called a **positive divisor** (or **effective**).

tive divisor, or integral divisor), and this is denoted by $\alpha \succ 0$. The group of divisors on Γ is denoted by $G(\Gamma)$, and the subgroup consisting of divisors of degree 0 is denoted by $G_0(\Gamma)$. Let P be a point of Γ . The subset of the function field $\mathbf{K}(\Gamma)$ of Γ consisting of functions regular at P forms a valuation ring R_P for a †discrete valuation of $\mathbf{K}(\Gamma)$. A prime element t of R_P is called a **local parameter** at P . Let v_P be the †normalized valuation of $\mathbf{K}(\Gamma)$ defined by R_P ; the integer $v_P(f)$ is called the **order** off at P . The point P is a **zero** off if $v_P(f) > 0$; it is a **pole** off if $v_P(f) < 0$. There are only a finite number of poles and zeros of a given function f . The divisor $\sum v_P(f)P$ is called the **divisor of the function** f and is denoted by (f) . The set of divisors of functions forms a subgroup G_f of G . Any divisor α in G_f is called a **principal divisor** (we also say that α is †linearly equivalent to zero and write $\alpha \sim 0$).

Let α be an arbitrary divisor. The set of all positive divisors that are linearly equivalent to α forms a **complete linear system** $|\alpha|$ determined by α . We set $L(\alpha) = \{f \in \mathbf{K}(\Gamma) \mid (f) + \alpha \succ 0\} \cup \{0\}$. Then $L(\alpha)$ is a finite-dimensional vector space over \mathbf{K} , and 1-dimensional subspaces of $L(\alpha)$ correspond bijectively to the elements of $|\alpha|$. We set $J(\alpha) = \dim L(\alpha)$ and $\dim |\alpha| = J(\alpha) - 1$. Then $\dim |\alpha|$ is called the **dimension** of $|\alpha|$. For any divisor α , the integer $\deg \alpha = \dim |\alpha|$ is nonnegative and bounded. The supremum g of such integers is called the **genus** of Γ . The nonnegative integer $i(\alpha) = g - \deg \alpha + \dim |\alpha|$ is called the **speciality index** of α .

Let ω be a †differential form on Γ , P be a point of Γ , and t be a local parameter at P . Then ω can be written in the form $\omega = f dt$. We now set $v_P(\omega) = v_P(f)$ and $(\omega) = \sum v_P(\omega)P$. Then (ω) is a well-defined divisor, and the class of (ω) in G/G_f is independent of the choice of ω . This divisor class is called the **canonical class**; any divisor in this class is called a **canonical divisor** (or **differential divisor**) and is denoted by \mathfrak{f} . We have $J(\mathfrak{f}) = g$, $\deg \mathfrak{f} = 2g - 2$. Given a divisor α , the index $i(\alpha)$ is equal to the number of linearly independent differentials ω such that $(\omega) \succ \alpha$, $i(\alpha) = J(\mathfrak{f} - \alpha)$. The equality $J(\alpha) = \deg \alpha - g + 1 + i(\alpha)$ is called the **Riemann-Roch theorem**.

For any irreducible algebraic curve Γ , there exists a birationally equivalent nonsingular curve $\tilde{\Gamma}$ that is unique up to isomorphism. The genus of $\tilde{\Gamma}$ is called the **effective genus** of Γ . A curve whose effective genus is zero is called a **rational** (or **unicursal**) curve. An **elliptic curve** is a curve whose effective genus is 1. An irreducible curve Γ with genus ≥ 2 is called a **hyperelliptic curve** if $\mathbf{K}(\Gamma)$ is a quadratic extension of a field $\mathbf{K}(t)$ for some t .

A positive divisor α on a nonsingular com-

plete irreducible curve Γ is called a **special divisor** if $i(\alpha) > 0$. In this case, $2(J(\alpha) - 1) \leq \deg \alpha$, where equality holds if and only if $\alpha = 0$ or $\alpha \sim \mathfrak{f}$, or Γ is a hyperelliptic curve (Clifford's theorem). Let Γ be a nonsingular complete irreducible curve and k be a subfield of \mathbf{K} such that Γ is defined over k . Denoting by \bar{k} the algebraic closure of k , we call a divisor $p = \sum n_i P_i$ on Γ a **prime rational divisor over k** if p satisfies the following three conditions: (i) p is invariant under any automorphism σ of \bar{k}/k ; (ii) for any j , there exists an automorphism σ_j of \bar{k}/k such that $P_j = P_i^{\sigma_j}$; (iii) $n_1 = \dots = n_l = [k(P_1):k]$. An element in the subgroup of $G(\Gamma)$ generated by prime rational k -divisors is called a **k -rational divisor**. Let $k(\Gamma)$ be the subset of $\mathbf{K}(\Gamma)$ consisting of functions f defined over k . Then $k(\Gamma)$ is a subfield of $\mathbf{K}(\Gamma)$, and the quotient field of $k(\Gamma) \otimes_k \mathbf{K} = \mathbf{K}(\Gamma)$. $k(\Gamma)$ is called the **function field of Γ over k** . Let p be a prime rational k -divisor, and let P be a point of p . Then $R_P \cap k(\Gamma)$ is a valuation ring of $k(\Gamma)$ uniquely determined by p and independent of the choice of the point P in p . We call this valuation ring the valuation ring determined by p .

D. Algebraic Function Fields

Let k be a field, and let K be a finite separable extension of a purely transcendental extension $k(x)$ of k such that k is maximally algebraic in K . Then K is called an **algebraic function field over k of dimension 1** (or of **transcendence degree 1**). The equivalence class of †exponential valuations of K that are trivial over k is called a **prime divisor** of K/k . An element of the free Abelian group generated by prime divisors is called a **divisor** of K/k . The group operation in the divisor group of K/k is usually denoted multiplicatively. Let R_p be the valuation ring of the prime divisor P , and let M_p be the maximal ideal of R_p . The **degree** $\deg P$ of the prime divisor P is defined by $[(R_p/M_p):k]$. If we replace the terms: curve Γ by function field K/k ; $\mathbf{K}(\Gamma)$ by K ; \mathbf{K} by k ; and points on Γ by prime divisors of K/k , we can develop the theory of the function field K/k , which is similar to the theory of nonsingular curves Γ (Sections B, C). Thus we define the **genus of the function field K/k** .

Suppose we are given an algebraic function field K/k of dimension 1. An algebraic curve Γ defined over k is called a **model** of K/k if $k(\Gamma)$ and K are k -isomorphic. For any function field of dimension 1, there always exist two elements x and y in K such that $K = k(x, y)$. Let $f(X, Y)$ be an irreducible polynomial such that $f(x, y) = 0$. Then the plane curve defined by the equation $f(X, Y) = 0$ is a model of K/k . Among

the models of K/k there exists a †normal model Γ_0 over k that is unique up to isomorphism (and the uniqueness of the normal model of the function field within the birational equivalence class of varieties holds only for curves). In particular, if k is the complex number field, the normal model Γ_0 is the †Riemann surface of the function field K/k . If Γ_0 has no singular point, the theory of the curve Γ_0 and the theory of the function field K/k are essentially identical. (This occurs, for example, when k is †perfect.) In that case the genus of Γ_0 is equal to that of K/k . In general, the genus of the function field is not less than the genus of the normal model Γ_0 , and it is greater than the latter if Γ_0 has a singular point. If the genus of K/k is zero, we can take a plane quadratic curve as a model of K/k . Moreover, K/k has a prime divisor of degree 1 if and only if K is a purely transcendental extension of k . A function field K/k of genus 1 is called an **elliptic function field**. If K has a prime divisor of degree 1, an elliptic function field K has a model of a plane cubic curve. Moreover, if the characteristic of the field k is different from 2, we can take as the model Γ_0 the curve defined by an equation of the form $Y^2 = 4X^3 - g_2X - g_3$. This is called **Weierstrass's canonical form**. The number $j = (g_2^3 - 27g_3^2)^{-1}g_2^3$ (#0) is a birational invariant of Γ_0 .

E. Jacobian Varieties

Let Γ be a nonsingular curve. A †group variety J is called the **Jacobian variety** of Γ if it has the following four properties (we fix an algebraically closed †field k of definition for Γ and J): (i) There exists an isomorphism Φ (of abstract groups) of $G_0(\Gamma)/G_1(\Gamma)$ into J . (ii) Φ is continuous in the following sense: Let \bar{a}, \bar{b} be elements of $G_0(\Gamma)/G_1(\Gamma)$ represented by a, b . If b is a specialization of a over a field K ($\supset k$), then $\Phi(b)$ is also a specialization of $\Phi(a)$ over K . (iii) If there exists a K -rational divisor in the class \bar{a} , then the point $\Phi(\bar{a})$ is also K -rational. (iv) For any $\xi \in J$, there exists a $k(\xi)$ -rational divisor α in G_0 such that $\Phi(\alpha \bmod G_1) = \xi$. A group variety J satisfying these conditions is necessarily a complete variety, hence a †Abelian variety, and is determined uniquely up to isomorphism. The construction of Jacobian varieties over a field of arbitrary characteristic is due to A. Weil [27] (for analytic construction \rightarrow 11 Algebraic Functions C).

Let P be a †generic point of Γ over k , and let P_0 be a fixed k -rational point. Then $\varphi(P) = \Phi(P - P_0)$ defines a rational mapping of Γ into J , and φ , which is an isomorphism of Γ and its image $\varphi(\Gamma)$, is determined uniquely by Φ up to translation on J . This mapping φ is called the

canonical function on Γ . The dimension of J is equal to the genus g of Γ . If P_1, \dots, P_g are independent generic points of Γ over k , then $k(P_1, \dots, P_g)$ is the function field of J over k , where $k(P_1, \dots, P_g)$ is the subfield invariant under the group of $g!$ automorphisms $(P_1, \dots, P_g) \rightarrow (P_{\alpha_1}, \dots, P_{\alpha_g})$. The Jacobian variety of Γ is also the †Picard variety of Γ , and it is equal to the †Albanese variety of Γ (- 16 Algebraic Varieties P). Hence for any function f on Γ with values in an Abelian variety A , there exists a unique homomorphism λ of J into A such that $f = \lambda \circ \varphi + \text{const}$. This λ is called the **linear extension** of f .

Let Θ be the set of points on J that can be written as $\varphi(P_1) + \dots + \varphi(P_{g-1})$. Then Θ is an irreducible subvariety of codimension 1. The divisor Θ is called the **canonical divisor** of J . The Jacobian variety that is polarized by the divisor Θ is called the **canonically polarized Jacobian variety** (\rightarrow 3 Abelian Varieties G). If two curves Γ and Γ' are birationally equivalent, the canonically polarized Jacobians of Γ and Γ' are isomorphic. Conversely, if the canonically polarized Jacobian varieties J of Γ and J' of Γ' are isomorphic, then Γ and Γ' are birationally equivalent (**Torelli's theorem**). Let r be any integer such that $1 \leq r \leq g$, and let W_r be the set of points that are written in the form

$$\varphi(P_1) + \dots + \varphi(P_r)$$

($W_1 = \varphi(\Gamma)$, $W_{g-1} = \Theta$, $W_g = J$). Then we have $\Theta^{(r)} = r! W_{g-r}$ (†numerically equivalent) and $(\Theta^{(g)}) = y!$, where $\Theta^{(r)}$ is the class of intersections of r copies of Θ . The existence of a divisor Θ is characteristic for Jacobian varieties. Actually, if A is an Abelian variety of dimension n that has an irreducible subvariety X^{n-1} of codimension 1 and a positive 1-cycle C such that $(X^{(n)}) = n!$ and $X^{(n-1)} = (n-1)! C$, then C is a nonsingular irreducible curve, A is the Jacobian variety of C , and X is the canonical divisor. The canonical divisor Θ is defined by a †theta function in the classical case. For a divisor $\alpha = \sum n_i P_i$, we define $\varphi(\alpha)$ to be $\sum n_i \varphi(P_i) \in J$. For fixed numbers $1 \leq r \leq g$, $0 < d$, we let W_r^d denote $\{\varphi(\alpha) \in J \mid l(\alpha) \geq d+1, \deg \alpha = r\}$. Then $W_r^d \subseteq W_r$ and is a †subscheme of J . We call the number $\rho = g - (d+1)(g-r+d)$ the **Brill-Noether number**. Then $\dim W_r^d \geq \rho$. Moreover, if Γ is a general curve, then $\dim W_r^d = \rho$. In particular, if $\rho < 0$, then $W_r^d = \emptyset$. This result has been verified recently by S. Kleiman, D. Laksov, P. Griffiths, and J. Harris [9, 14].

Let Γ be a nonsingular curve, and let ω be a differential form on Γ . If the divisor (ω) is ≥ 0 , the ω is called a regular 1-form or **differential form of the first kind**. Let Ω be the †sheaf of germs of regular differential forms. A differential form of the first kind is an element of

$H^0(\Gamma, \Omega)$, and vice versa. Let \mathfrak{f} be a canonical divisor. Then we have a natural isomorphism $H^0(\Gamma, \Omega) \cong L(\mathfrak{f})$, and the number of linearly independent differential forms of the first kind is equal to the genus g of Γ . The \dagger residue of a differential can be defined as in the classical case. A differential that has nonzero residues is called a **differential of the third kind**. The **residue theorem** $\sum \text{Res}_P \omega = 0$ holds for any differential ω . The form ω is called a **differential form of the second kind** if for any $P \in \Gamma$ there exists a rational function f_P such that $\omega - df_P$ is regular at P . The set of differential forms of the second kind forms a linear space G_2 over the universal domain and contains the subspace G , consisting of the differential forms of the first kind. The quotient space $G_2/dk(\Gamma)$ has dimension 29 or y according as the characteristic of the universal domain is 0 or not.

When the characteristic p of the universal domain is positive, we have what is called the Cartier operator. Let Γ be a curve defined over a perfect field k , let $L = k(\Gamma)$, and let t be an element of L that is transcendental over k and such that $L/k(t)$ is separable. Then any differential ω of L/k is written uniquely as $\omega = (f_0^p + f_1^p t + \dots + f_{p-1}^p t^{p-1}) dt$, where $f_i \in L$. Then the **Cartier operator** C given by $C\omega = f_{p-1} dt$ is well defined and independent of the choice of t and leaves G_1 invariant. Hence given a basis $\omega_1, \dots, \omega_g$ of G_1 , we obtain a matrix (a_{ij}) with coefficient in L by $C\omega_i = \sum a_{ij} \omega_j$ ($1 \leq i \leq g$). This $g \times g$ matrix A is called the **Hasse-Witt matrix** of Γ . The class of A modulo the transformations of the form $S^{-p}AS$ is a birational invariant of Γ and plays an important role in the theory of unramified cyclic p -extensions of the algebraic function field.

F. Generalized Jacobian Varieties

The notion of linear equivalence of divisors on a nonsingular curve can be extended to a more general situation. Such attempts have been made by M. Noether, F. Severi, and M. Rosenlicht, who succeeded in obtaining such a generalization [22].

Let Γ be an algebraic curve, and let P_1, \dots, P_t be points of Γ . Let \mathfrak{D}_{P_i} be the \dagger local ring of P_i . We set $\mathfrak{D} = \bigcap_{i=1}^t \mathfrak{D}_{P_i}$ and $\Gamma' = \Gamma - \{P_1, \dots, P_t\}$. An element of the free Abelian group $G(\Gamma)$ generated by points of Γ' is called a Γ -divisor. Let \mathfrak{a} be a Γ -divisor and set $L(\mathfrak{a}) = \{f \in \mathfrak{D} \mid (f) + \mathfrak{a} \geq 0\} \cup \{0\}$. Then $L(\mathfrak{a})$ is a finite-dimensional linear space (over the universal domain). The dimension of $L(\mathfrak{a})$ is denoted by $l(\mathfrak{a})$, and we set $\dim |a| = \bar{l}(\mathfrak{a}) - 1$. The upper bound π of $\deg(a) = \bar{\dim} |a|$ is a nonnegative integer and is called the **\mathfrak{D} -genus**

of Γ . We call $\bar{l}(\mathfrak{a}) = \pi - \deg \mathfrak{a} + \bar{\dim} |a|$ the **\mathfrak{D} -speciality index** of the divisor \mathfrak{a} . Let C be a nonsingular curve birationally equivalent to Γ , and let Q_1, \dots, Q_s be points of C that correspond to singular points of Γ . An **\mathfrak{D} -differential** ω is a differential form on C (of $\mathbf{K}(\Gamma) = \mathbf{K}(C)$) such that $\sum_{i=1}^s \text{Res}_{Q_i} f\omega = 0$ for any $f \in \mathfrak{D}$. Then $i(\mathfrak{a})$ is equal to the number of linearly independent \mathfrak{D} -differentials ω such that $(\omega) \geq \mathfrak{a}$ in Γ' . The equality $l(\mathfrak{a}) = \deg \mathfrak{a} - \pi + 1 + i(\mathfrak{a})$ is called the **generalized Riemann-Roch theorem**. An \mathfrak{D} -differential ω is called an **\mathfrak{D} -differential of the first kind** if ω is regular everywhere on Γ' . The number of linearly independent \mathfrak{D} -differentials of the first kind is equal to the \mathfrak{D} -genus π . Let g be the effective genus of Γ , i.e., the genus of C . Then we have the equality $\pi - g = \dim_k(\bar{\mathfrak{D}}/\mathfrak{D}) = \delta$, where $\bar{\mathfrak{D}}$ is the integral closure of \mathfrak{D} in $\mathbf{K}(\Gamma)$. The set of \mathfrak{D} -differentials forms an \mathfrak{D} -module that is in general not of rank 1. Hence in this case, we do not have the "canonical divisor." Let c be the conductor of $\mathfrak{D}/\mathfrak{D}$. Then c determines a divisor in a natural way. If we denote the degree of this divisor by d , we have the inequality $\delta + 1 \leq d \leq 2\delta$. We have $d = 2\delta$ if and only if the set of \mathfrak{D} -differentials forms an \mathfrak{D} -module of rank 1. This case occurs, for example, if Γ is a curve on a nonsingular surface or a complete intersection. Two Γ -divisors \mathfrak{a} and \mathfrak{b} are said to be **\mathfrak{D} -linearly equivalent** if there exists a unit f of \mathfrak{D} such that $\mathfrak{a} - \mathfrak{b} = (f)$. The set of Γ -divisors that are \mathfrak{D} -linearly equivalent to zero forms a subgroup $\bar{G}_t(\Gamma)$ of $G(\Gamma)$. There exists a group variety $J_{\mathfrak{D}}$, unique up to isomorphism, that satisfies the four conditions required for Jacobian varieties (Section E) with respect to the class group $\bar{G}_0(\Gamma)/\bar{G}_t(\Gamma)$. The variety J_0 is called the **generalized Jacobian variety**. The generalized Jacobian variety is not complete, in general. If J is the Jacobian variety of C , then $J_{\mathfrak{D}}$ is an extension of J by a connected \dagger linear algebraic group $I_{\mathfrak{D}}$. Any Abelian extension of the function field of Γ can be obtained by the \dagger isogenies of the generalized Jacobian variety of Γ [22]. This fact plays an important role in class field theory over algebraic function fields (\rightarrow 59 Class Field Theory G). The theory for nonsingular curves is considered as the special case in which $\mathfrak{D} = \mathbf{K}(\Gamma)$.

Suppose that Γ is situated in a projective space of dimension n . Let \mathfrak{p} be the prime ideal in $k[X_0, X_1, \dots, X_n]$ defining Γ and $\chi(\mathfrak{p}, m)$ be the number of linearly independent homogeneous polynomials of degree m modulo \mathfrak{p} . Then $\chi(\mathfrak{p}, m)$ is a polynomial in m for large m . This polynomial is called the **Hilbert polynomial** of \mathfrak{p} (or Γ). Let c be the constant term of the Hilbert polynomial. The number $p_a(\Gamma) = 1 - c$ is called the **arithmetic genus** of Γ and is equal to the \mathfrak{D} -genus of Γ . Let Γ be a nonsingular

irreducible curve in \mathbf{P}^3 of degree d . If Γ is contained in a plane, then $p_a(\Gamma) = (d-1) \cdot (d-2)/2$. Otherwise, $p_a(\Gamma) \leq d^2/4 - d + 1$ when d is even, and $p_a(\Gamma) \leq (d^2 - 1)/4 - d + 1$ when d is odd [11].

G. Sheaf Theory

Let Γ be an irreducible curve and \mathcal{O}_p be the local ring of p . Then $\mathcal{O}_\Gamma = \bigcup \mathcal{O}_p$ is an algebraic coherent sheaf, which is called the structure sheaf of Γ , and $\dim H^1(\Gamma, \mathcal{O}_\Gamma)$ is equal to the arithmetic genus π of Γ . Let α be a Γ -divisor, and let $\mathcal{O}_\Gamma(\alpha)$ be the sheaf of germs of rational functions f such that $(f) + \alpha \geq 0$ and $f \in \mathcal{O}_Q$ for every singular point Q of Γ (- 383 Sheaves D). Then $\dim H^1(\Gamma, \mathcal{O}_\Gamma(\alpha))$ is equal to the speciality index $\bar{i}(\alpha)$, and $\dim H^0(\Gamma, \mathcal{O}_\Gamma(\alpha))$ is equal to $I(\alpha)$. When Γ has no singular point, the Riemann-Roch theorem is deduced naturally from Serre's duality theorem: $H^1(\Gamma, \mathcal{O}_\Gamma(\alpha)) \cong H^0(\Gamma, \mathcal{O}_\Gamma(-\alpha))$.

H. Algebraic Correspondence

Let Γ be a nonsingular curve. A divisor of the product variety $\Gamma \times \Gamma$ is called an **algebraic correspondence** of Γ [26, 27]. Let D_0 be the subgroup consisting of divisors that are linearly equivalent to degenerate divisors $a \times \Gamma + \Gamma \times b$. Then the class group $\mathcal{C}(\Gamma) = G(\Gamma \times \Gamma)/D_0$ is called the **group of classes of algebraic correspondences**. We write $X \equiv 0$ if X is an element of D_0 . Let X be an algebraic correspondence, k a field of definition for Γ over which X is rational, and P a generic point of Γ over k . Then $X(P) = \text{pr}_2[X(P \times \Gamma)]$ is rational over $k(P)$. The composite $X_1 \circ X_2$ of two correspondences X_1 and X_2 is defined by $(X_1 \circ X_2)(P) = X_1(X_2(P))$ whenever they have meaning. The composite $X_1 \circ X_2$ determines an element of $\mathcal{C}(\Gamma)$ that depends only on the classes of X_1 and X_2 . This multiplication supplies the group $\mathcal{C}(\Gamma)$ with the structure of an associative ring. This ring is called the **correspondence ring** of Γ . The correspondence ring $\mathcal{C}(\Gamma)$ and the ring \mathcal{A} of endomorphisms of the Jacobian variety J are isomorphic, and the isomorphism is given by the following rule: Let ξ be an element of $\mathcal{C}(\Gamma)$, and let X be a divisor in ξ . Let P be a generic point of Γ with reference to k over which X is rational. Let P_0 be a k -rational point of Γ . Then the class of $X(P) - X(P_0)$ modulo $G_t(\Gamma)$ is independent of the choice of a divisor X in the given class. We set $\Psi(P) = \Phi(X(P) - X(P_0))$ and let λ be the linear extension of Ψ . The correspondence $\xi \rightarrow \lambda$ is an anti-isomorphism of $\mathcal{C}(\Gamma)$ and \mathcal{A} . Now we set $\mathcal{A}_0 = \mathcal{A} \otimes \mathbb{Q}$. Then \mathcal{A}_0 contains an automorphism t of order 2 called an **in-**

volution. Let l be a rational prime different from the characteristic p . Then \mathcal{A} has a faithful representation by $2g \times 2g$ matrices with coefficients in l -adic integers. The trace σ of this representation has the property that $\sigma(\beta \otimes \beta') > 0$ if $\beta \neq 0$ (Castelnuovo's lemma). \mathcal{A}_0 is an algebra of finite rank over \mathbb{Q} , and \mathcal{A} is a finitely generated Abelian group. Based on these results A. Weil proved the Riemann hypothesis for congruent ζ -functions on a nonsingular curve (- 450 Zeta Functions P).

I. Coverings

Let Γ and C be nonsingular curves such that there exists a regular mapping $\pi: \Gamma \rightarrow C$. Then there is an injection of the function field $\mathbf{K}(C)$ into $\mathbf{K}(\Gamma)$. If $\mathbf{K}(\Gamma)$ is separably algebraic over $\mathbf{K}(C)$, then Γ is called a **covering (curve)** of C . The integer $[\mathbf{K}(\Gamma): \mathbf{K}(C)] = n$ is called the **degree of covering**. Let P be a point of Γ and let $Q = \pi(P)$. Let t, s be local parameters at P on Γ and at Q on C , respectively. The nonnegative integer $v_P(ds/dt)$ is called the **differential index** at P and is denoted by m_P . The index m_P is zero except for a finite number of points. The divisor $\sum m_P P$ is called the **branch divisor**. The covering Γ is called an **unramified covering** if the branch divisor is zero. If we denote the branch divisor by α , we have the formula $2g(\Gamma) - 2 = n(2g(C) - 2) + \deg \alpha$, where $g(\Gamma)$ and $g(C)$ are genera of Γ and C , respectively. This is called the **Riemann-Hurwitz formula**. This formula yields at once that a rational curve has no nontrivial unramified covering and that Γ can be an unramified covering of itself if and only if Γ is an elliptic curve.

J. Theory of Moduli

Let $\mathcal{M}_g(k)$ be the set of isomorphism classes of complete nonsingular irreducible curves (here simply called "curves") of genus g defined over a field k . We can endow $\mathcal{M}_g(k)$ with a structure of an algebraic variety over k with the property that for any smooth family (over k) $\pi: \mathcal{C} \rightarrow S$ of curves of genus y the map $T: S \rightarrow \mathcal{M}_g(k)$ sending s to the isomorphism class of the fiber $\pi^{-1}(s)$ is a morphism. This algebraic variety is called the **(coarse) moduli space of curves of genus g** . Furthermore, the moduli space over $\text{Spec}(\mathbb{Z})$ exists (D. Mumford [16]). $\mathcal{M}_g(k)$ is normal, irreducible and quasiprojective (but not complete for $g > 0$) of dimension 0 ($g = 0$), 1 ($g = 1$), $3g - 3$ ($g \geq 2$) ($= 3g - 3 + \dim \text{Aut}(C)$) with only quotient singularity [5].

Since when $g = 1$ any elliptic curve C over an algebraically closed field k is isomorphic to a plane curve with the Weierstrass canonical

form $y^2 = 4x^3 - g_2x - g_3$ (if $\text{char}(k) \neq 2$; the case of $\text{char}(k) = 2$ needs a slight modification), the correspondence $C \rightarrow j(g_2, g_3)$ (\rightarrow Section D) defines an isomorphism $\mathcal{M}_1 \simeq \mathbf{A}_k^1$ (affine line). In the case of $g \geq 2$ and $k = \mathbf{C}$ we have another function-theoretic construction of \mathcal{M}_g due to Teichmüller (\rightarrow 11 Algebraic Functions F).

Let \mathcal{A}_g be the coarse moduli space (over \mathbf{Z}) of principally polarized Abelian varieties of dimension g (\rightarrow 3 Abelian Varieties 1). For a curve C we denote the Jacobian variety of C by $J(C)$ (\rightarrow Section E). The correspondence $C \rightarrow J(C)$ defines a morphism $i: \mathcal{M}_g \rightarrow \mathcal{A}_g$ which is injective (Theorem of Torelli). It is even an immersion (F. Oort, J. Steenbrink). If $g = 1, 2, 3$, then i is an open immersion whose image we can describe.

For $k = \mathbf{C}$ we can express the above map i by using periods of curves. Namely, let $\alpha_1, \dots, \alpha_g, \beta_1, \dots, \beta_g$ be a (canonical) basis of $H_1(C, \mathbf{Z})$ defined by normal sections of C (considered as a real surface). Let $\omega_1, \dots, \omega_g$ be a basis of differential forms of the first kind on C with $\int_{\beta_i} \omega_j = \delta_{ij}$. Then the matrix $\Omega = (\int_{\alpha_i} \omega_j)$ is symmetric and has a positive definite imaginary part, i.e., is an element of the Siegel upper half-space \mathfrak{S}_g of degree y . With the identification $\mathcal{A}_g \simeq \mathfrak{S}_g / \text{Sp}(g, \mathbf{Z})$ (\rightarrow 3 Abelian Varieties 1) the map $i: \mathcal{M}_g \rightarrow \mathcal{A}_g$ is nothing but the one sending the isomorphism class of C to $\text{Rmod } \text{Sp}(g, \mathbf{Z})$. For $g = 4$ the closure of $i(\mathcal{M}_4)$ is a principal divisor defined explicitly with theta constants (Schottky, J.-I. Igusa).

K. Stable Curves

A reduced connected complete curve C over k is called a **stable curve** of genus g (> 0) if (i) C has only ordinary double points as possible singularities; (ii) when Γ is a smooth rational irreducible component of C , then Γ intersects the other components in more than 2 points; (iii) $\dim, H^1(C, \mathcal{O}_C) = g$.

There exists a coarse moduli space \mathcal{S}_g of stable curves of genus g which contains \mathcal{M}_g as a Zariski open subset. The space \mathcal{S}_g defined over $\text{Spec}(\mathbf{Z})$ is complete and even projective; hence \mathcal{S}_g gives a compactification of \mathcal{M}_g . The completeness of \mathcal{S}_g follows from the **stable reduction theorem** as follows: let R be a discrete valuation ring with quotient field K and C be a smooth connected curve over K . Then there exists a finite separable algebraic extension L of K such that the curve $C \times_K L$ extends to a flat family of stable curves over $\text{Spec}(R_L)$, where R_L denotes the integral closure of R in L . In this case we say that the curve $C \times_K L$ has a **stable reduction** in R . With the above notation a curve C over K has a stable reduction in R if and only if its

Jacobian variety $J(C)$ has a stable reduction in R (\rightarrow 3 Abelian Varieties N).

Over \mathbf{C} , \mathcal{A}_g has the Satake compactification \mathcal{A}_g , which is a disjoint union of $\mathcal{A}_{g'}, 0 \leq g' \leq g$, as a set. The injection $i: \mathcal{M}_g \rightarrow \mathcal{A}_g$ (\rightarrow Section J) extends to a morphism $j: \mathcal{S}_g \rightarrow \mathcal{A}_g$ that sends the isomorphism class of a stable curve $C = C_1 \cup \dots \cup C_k$ (C_i irreducible) to that of $J(\tilde{C}_1) \times \dots \times J(\tilde{C}_k) \in \mathcal{A}_{g'}$, $g' = \sum_i \text{genus}(\tilde{C}_i)$, where \tilde{C}_i is the normalization of C_i . In particular the closure of the image of i in \mathcal{A}_g is the set of products of Jacobian varieties.

10 (111.5) Algebraic Equations

A. General Remarks

Let $F_1(X_1, \dots, X_r), \dots, F_r(X_1, \dots, X_r)$ be r tpolynomial in m variables X_1, \dots, X_m over a \dagger field k . Then the equations

$$F_1 = 0, \dots, F_r = 0$$

are called **algebraic equations in m unknowns**. When we consider these equations simultaneously, where $r \geq 2$, we call them a **system of r equations** or **simultaneous equations**. (For $r = 1$, a system of one equation means the single equation $F_1 = 0$.) Coefficients of F_1, \dots, F_r are called **coefficients** of the system, and the great-

est of the degrees of F_1, \dots, F_r is called the **degree** of the system.

To **solve** a system of equations (henceforth in this article we shall omit the word "algebraic") means to find the common \dagger zero points (in an \dagger algebraically closed field containing k) of elements F_1, \dots, F_r of the \dagger polynomial ring $k[X_1, \dots, X_r]$. If there exist no common zero points, the system is said to be **inconsistent**; if there exists a finite number of such points, it is said to be **regular**; and if there are an infinite number of such points, it is called **indeterminate**. The elimination method allows us to reduce the problem of solving a system of r equations to the case $r = 1$. In particular, any regular system of equations can be reduced to the case $m=r=1$.

B. Equations in One Unknown

For the above reason, it is important to consider an equation of the form $f(X) = 0$, where

$$f(X) = a_0 X^n + a_1 X^{n-1} + \dots + a_n, \quad a_0 \neq 0. \quad (1)$$

This gives the general form of an algebraic equation in one unknown.

According as $f(X)$ is reducible or not in the \dagger polynomial ring $k[X]$, the equation $f(X)=0$ is called **reducible** or **irreducible** (- 337 Polynomials). In some \dagger algebraic extension field K of k , $f(X)$ can be factored:

$$f(X) = a_0(X - \alpha_1)(X - \alpha_2) \dots (X - \alpha_n). \quad (2)$$

$\alpha_1, \dots, \alpha_n$ are called the **roots** of the equation $f(X) = 0$. Hence, any algebraic equation of degree n has exactly n roots (**Kronecker's theorem**). Now, $(-1)^i a_i / a_0$ is equal to the \dagger elementary symmetric function of degree i of $\alpha_1, \dots, \alpha_n$. Some of the roots $\alpha_1, \dots, \alpha_n$ may be identical. If α appears ρ times in $\alpha_1, \dots, \alpha_n$, we say that α is a ρ -tuple root, and ρ is called the **multiplicity** of the root α . When $\rho = 1$, α is called a **simple root**, and when $\rho \geq 2$, α is called a **multiple root**. Let β_1, \dots, β_v be all the distinct roots among $\alpha_1, \dots, \alpha_n$, and let ρ_i be the multiplicity of β_i ($i = 1, \dots, v$). Then

$$f(X) = a_0(X - \beta_1)^{\rho_1} \dots (X - \beta_v)^{\rho_v}, \quad (2')$$

$$\rho_1 + \dots + \rho_v = n.$$

If ρ_1, \dots, ρ_v are not divisible by the \dagger characteristic of k , the greatest common divisor g of f and

$$f' = na_0 X^{n-1} + (n-1)a_1 X^{n-2} + \dots + a_{n-1}$$

is $(X - \beta_1)^{\rho_1-1} \dots (X - \beta_v)^{\rho_v-1}$. Thus we can reduce the multiplicity of every root to 1 by dividing f by g . Any irreducible equation over a field of characteristic 0 has no multiple roots. Equation (1) has multiple roots if and only if

its [†]discriminant D is equal to 0 (- 149 Fields; 172 Galois Theory).

C. Equations of Special Type

In Sections C and D we assume that the characteristic of k is zero.

Binomial Equations. An equation of the type $X^m - a = 0$ is called a **binomial equation**. It is solved by **root extraction**. Let $\sqrt[m]{a}$ (mth root of a) be one of the roots (if a is a positive real number, $\sqrt[m]{a}$ usually denotes a positive real root). Then $\sqrt[m]{a}$ multiplied by $1, \zeta, \zeta^2, \dots, \zeta^{m-1}$ are the roots of $X^m - a = 0$, where ζ is a [†]primitive mth root of unity.

Reciprocal Equations. An equation $a_n X^n + a_{n-1} X^{n-1} + \dots + a_1 X + a_0 = 0$ is called a **reciprocal equation** if $a_0 = a_n, a_1 = a_{n-1}, a_2 = a_{n-2}, \dots$. A reciprocal equation of an odd degree $n = 2m + 1$ has a root $X = -1$, and dividing the left side by $X + 1$ we get a reciprocal equation of degree $2m$. A reciprocal equation of degree $n = 2m$ is reduced to an equation of degree m in $Y = X + X^{-1}$ and the quadratic equation $X^2 - XY + 1 = 0$.

D. Equations of Lower Degree

(- Appendix A, Table 1)

(1) A **linear equation** $a_0 X + a_1 = 0$ has a single root $-a_1/a_0$. (2) the roots of a **quadratic equation** $a_0 X^2 + a_1 X + a_2 = 0$ are given by $(-a_1 \pm \sqrt{a_1^2 - 4a_0 a_2})/2a_0$. (3) To solve a **cubic equation** $a_0 X^3 + a_1 X^2 + a_2 X + a_3 = 0$, we set $A_1 = 9a_0 a_1 a_2 - 2a_1^3 - 27a_0^2 a_3, A_2 = a_1^2 - 3a_0 a_2$, and solve the quadratic equation $T^2 - A_1 T + A_2 = 0$. Let t_1 and t_2 be the roots of this quadratic equation, and let ω be any cube root of 1. Then $(-a_1 + \omega \sqrt[3]{t_1} + \omega^2 \sqrt[3]{t_2})/3a_0$ is a root of the original cubic equation. (**Cardano's formula**). If we apply this method to a cubic equation $aX^3 + bX^2 + cX + d = 0$ with real coefficients, we need to use complex cube roots even if the roots of the equation are real. In fact, it has been proved that it is not possible to solve this equation within the real numbers in this case; i.e., if the cubic equation is irreducible over the extension $\mathbf{Q}(a, b, c, d)$ of the rational number field \mathbf{Q} , and if all of its roots are real, it is impossible to find the roots only by rational operations and with real radicals. This is called the **casus irreducibilis**. (4) A **quartic equation** $a_0 X^4 + a_1 X^3 + a_2 X^2 + a_3 X + a_4 = 0$ can be solved by means of reduction to a cubic equation (L. Ferrari) (- Appendix A, Table 1). Generally, the procedure of solving an algebraic equation, i.e.,

finding the roots of a given equation from its coefficients by means of a finite number of rational operations and extractions of radicals, is called a **solution by radicals** (or **algebraic solution**). The [†]general algebraic equation whose degree is ≥ 5 cannot be solved by radicals (N. H. Abel) (- 172 Galois Theory).

E. Analytic Theory

In this section, k denotes the field \mathbf{R} of real numbers or the field \mathbf{C} of complex numbers. These cases have been studied for a long time, for practical reasons.

Concerning the case $k = \mathbf{C}$, the field \mathbf{C} is [†]algebraically closed; i.e., every equation with coefficients from \mathbf{C} has a root in \mathbf{C} (**Gauss's theorem**, called the **fundamental theorem of algebra**). Accordingly, in the field \mathbf{C} , we always have equations (2) and (2').

Let $\alpha_1, \dots, \alpha_n$ be the roots of equation (1). Then each α_i is a continuous function of coefficients a, a_1, \dots, a_n . Concerning the location of roots of $f(X) = 0$ and $f'(X) = 0$ on the complex plane, we have the following theorems:

(1) Any convex polygon on the complex plane containing the roots of $f(X) = 0$ also contains the roots of $f'(X) = 0$ (Gauss).

(2) Let C be a rectifiable [†]Jordan curve not passing through a root of $f(X) = 0$. Then the number (C, f) of the roots of $f(X) = 0$ lying in the region enclosed by C is equal to $(1/2\pi i) \int_C (f'(z)/f(z)) dz$, where the multiplicity of the roots is taken into account.

(3) Let C be a Jordan curve on the complex plane. If $|f(z)| > |g(z)|$ at every point z on C , then the equations $f = 0$ and $f + g = 0$ have the same number of roots (counting multiplicity) within the region enclosed by C (**Rouché's theorem**).

(4) The absolute value of a root of equation (1) is less than

$$M = \max(|a_1/a_0|, \dots, |a_n/a_0|) + 1.$$

(5) Let D be the [†]discriminant of f , and assume that $|\alpha_i| \leq M$ ($i = 1, \dots, n$). Then $|\alpha_i - \alpha_j|^2 \geq D/(2M)^{n(n-1)-2} = E$. Since the value of $|D|$ is known from [†]and one value of M is given by theorem (4), we have one value of E . If we draw a circle on the complex plane with center at the origin and with radius M , and if we cover it with a net whose meshes have diameters less than $\sqrt{E}/2$, then the interior of each mesh contains at most one root of $f = 0$.

When $k = \mathbf{R}$, i.e., $f \in \mathbf{R}[X]$, let β_1, \dots, β_v denote the distinct roots of $f = 0$, and recall equation (2'). Suppose that $\beta_1, \dots, \beta_\lambda \in \mathbf{R}$ and the others $\notin \mathbf{R}$. Then $v - \lambda$ is an even integer 2κ , and we can renumber $\beta_{\lambda+1}, \dots, \beta_v$ so that $\beta_{\lambda+1} = \beta_{\lambda+\kappa+1}, \dots, \beta_{\lambda+\kappa} = \beta_v$ (β denotes the con-

jugate of β) and $\rho_{\lambda+1} = \rho_{\lambda+\kappa+1}, \dots, \rho_{\lambda+\kappa} = \rho_v$. In this case, $\beta_1, \dots, \beta_\lambda$ are the **real roots** of equation (2), and the other β 's are called the **imaginary roots**.

(6) If $f \in \mathbf{R}[X]$ and $a_0 > a_1 > \dots > a_n > 0$, then the absolute value of any root of equation (1) is less than 1 (**Kakeya-Eneström theorem**).

Concerning the real roots of an equation $f = 0$, where $f \in \mathbf{R}[X]$, we have the following theorems: Let $N(a, b)$ ($a, b \in \mathbf{R}$) denote the number of real roots in the interval (a, b) . Furthermore, let $V(c_1, c_2, \dots, c_p)$ denote the number of changes of sign in the sequence c_1, c_2, \dots, c_p of real numbers, which is defined as follows: Suppose that we have the sequence c_{v_1}, \dots, c_{v_q} after deleting the terms $c_i = 0$ from the sequence c_1, c_2, \dots, c_p . Then

$$V(c_1, c_2, \dots, c_p) = \frac{1}{2} \sum_{j=1}^{q-1} (1 - \operatorname{sgn} c_{v_j} c_{v_{j+1}}).$$

(7) $N(0, \infty) \equiv V(a_0, a_1, \dots, a_n) \pmod{2}$ and $N \leq V$ (**Descartes's theorem**).

(8) Let $V(c) = V(f(c), f'(c), \dots, f^{(n)}(c))$. Then $N(a, b) \equiv V(a) - V(b) \pmod{2}$ and $N \leq V(a) - V(b)$ (**Fourier's theorem**).

(9) We may assume that $f = 0$ has no multiple roots. Construct a finite series $f_0 = f, f_1 = f', \dots, f_l$ of polynomials over \mathbf{R} such that $f_{i-1} = f_i q_i - f_{i+1}$ for $i = 1, 2, \dots, l-1$ and $f_l \in \mathbf{R}$, by successive application of the \dagger division algorithm. Let $V(c) = V(f_0(c), f_1(c), \dots, f_l(c))$. Then $N(a, b) = V(a) - V(b)$ (**Sturm's theorem**). By means of this theorem we can determine the location of real roots as precisely as we wish.

(10) In order that every root α_i of an equation $f = 0$ with $a_n > 0$ lies on the left side of the imaginary axis, i.e., $\operatorname{Re} \alpha_i < 0$, it is necessary and sufficient that in the following matrix the \dagger principal minors composed of the first r rows and first r columns be positive for all $r = 1, 2, \dots, n$ (**Hurwitz's theorem**):

$$\begin{pmatrix} a_n & a_{n-1} & a_{n-2} & a_{n-3} & a_{n-4} & \dots \\ 0 & a_n & a_{n-1} & a_{n-2} & a_{n-3} & \dots \\ 0 & 0 & a_n & a_{n-1} & a_{n-2} & \dots \\ \dots & \dots & \dots & \dots & \dots & \dots \\ 0 & 0 & 0 & a_{n-2} & a_{n-3} & \dots \end{pmatrix}.$$

Also, for $f \in \mathbf{C}[X]$, various results have been obtained about under what conditions all the roots of $f = 0$ lie on one side of a given straight line or inside a given circle (e.g., the unit circle) (- 301 Numerical Solution of Algebraic Equations).

11 (X1.10) Algebraic Functions

A. Definition

An **algebraic function** is a multiple-valued \dagger analytic function $w = w(z)$ defined by an irreducible algebraic equation $P(z, w) = 0$ with complex coefficients.

B. History and Methods

The theory of algebraic functions evolved from the works of C. F. Gauss, N. H. Abel, and C. G. J. Jacobi on \dagger elliptic functions in the early 19th Century. Stimulated by their works, B. Riemann and K. Weierstrass established the foundations of the theory of complex functions and developed the important theory of algebraic functions.

The equation $P(z, w) = 0$ defines a curve in the 2-dimensional complex \dagger projective space with inhomogeneous coordinates z, w . Investigations from this point of view were initiated by Riemann, A. Clebsch, and P. Gordan. This approach was followed by A. Brill, M. Noether, and the Italian school (F. Severi, C. Segre, etc.) and has developed into contemporary algebraic geometry (\rightarrow 9 Algebraic Curves, 12 Algebraic Geometry).

The set of \dagger function elements $w(z)$ satisfying $P(z, w) = 0$ is a \dagger complex manifold \mathfrak{R} , a closed (= compact) \dagger Riemann surface, on which z and w are meromorphic functions. The field $K_{\mathfrak{R}}$ consisting of the meromorphic functions on \mathfrak{R} is an algebraic function field $\mathbf{C}(z, w)$. Conversely, for any closed Riemann surface \mathfrak{R} , the field $K_{\mathfrak{R}}$ is an algebraic function field in one variable over \mathbf{C} , and any pair of functions z and w with $K_{\mathfrak{R}} = \mathbf{C}(z, w)$ has the property that \mathfrak{R} is \dagger conformally equivalent to the Riemann surface determined in the above fashion by the irreducible algebraic equation $P(z, w) = 0$ satisfied by z and w . Two Riemann surfaces $\mathfrak{R}_1, \mathfrak{R}_2$ determined by the equations $P_1 = 0, P_2 = 0$ are conformally equivalent if and only if the fields $K_{\mathfrak{R}_1}$ and $K_{\mathfrak{R}_2}$ are \mathbf{C} -isomorphic. This condition is equivalent to the existence of a birational

transformation between the algebraic curves $P_1 = 0, P_2 = 0$. The "analytic method" (the method of studying algebraic functions as functions on Riemann surfaces) is the creation of Riemann. It was extended by F. Klein and D. Hilbert, and later by H. Weyl, who established in his monograph [6] a rigorous foundation of the analytic method for the theory of algebraic functions.

Given an arbitrary algebraic function field K in one variable over C , the set \mathfrak{R} of its \dagger prime divisors with a suitable topology and analytic structure is a closed Riemann surface whose function field $K_{\mathfrak{R}}$ coincides with K . The "algebraic method" (the method of studying algebraic functions as elements of an algebraic function field) was founded by J. W. Dedekind and H. Weber at the end of the 19th Century. In the 20th Century, the algebraic method has made remarkable progress, owing to the development of abstract algebra. It covers the case of an arbitrary ground field as well as that of more than one variable. The theory of algebraic functions has had considerable influence on the development of number theory because of a basic analogy between the two subjects.

The \dagger universal covering spaces (surface) $\tilde{\mathfrak{R}}$ of a closed Riemann surface \mathfrak{R} can be regarded, by conformal mapping, as the Riemann sphere, the plane, or the unit disk (or, equivalently, to the upper half-plane) if the \dagger genus g of \mathfrak{R} is 0, 1, or ≥ 2 , respectively. Then the \dagger covering transformation group G , consisting of \dagger linear fractional transformations without fixed points in $\tilde{\mathfrak{R}}$, is \dagger properly discontinuous and has a compact \dagger fundamental domain. Conversely, if D is one of the three domains just mentioned and if G is the group just described, then $\mathfrak{R} = D/G$ is a closed Riemann surface such that D and G are its universal covering space and covering transformation group. A meromorphic function on \mathfrak{R} is represented as an automorphic function on $\tilde{\mathfrak{R}}$ with respect to G . If $y = 0$, then $G = \{1\}$, $\tilde{\mathfrak{R}} = \mathfrak{R}$, and $K_{\mathfrak{R}}$ is the field of rational functions. If $g = 1$, then $K_{\mathfrak{R}}$ is the field of \dagger elliptic functions. The study of algebraic functions as automorphic functions was initiated by H. Poincaré and Klein. Recently, C. L. Siegel made a remarkable contribution to the investigation of the case of several variables. The theory of automorphic functions is also related to number theory. Works of E. Hecke, M. Eichler, and G. Shimura on this domain are noteworthy (- 32 Automorphic Functions, 73 Complex Multiplication).

Another important topic concerning algebraic functions (closed Riemann surfaces) is the problem of moduli. Riemann stated, without rigorous proof, that the set of conformal

equivalence classes of closed Riemann surfaces of genus $g (\geq 2)$ depends on $3g - 3$ complex parameters, called **moduli**. This has led to the modern theory of Teichmüller spaces, which is developing into an extensive new field (- 234 Kleinian Groups, 416 Teichmüller Spaces).

In the rest of this article, we deal mainly with the analytic method (for the case of two variables $\rightarrow [1]$).

C. Abelian Differentials

An **Abelian differential** on a closed Riemann surface \mathfrak{R} is, by definition, a complex \dagger differential form $\omega = a(z)dz$, where $a(z)$ is a meromorphic function of a local parameter z . Such a differential is said to be of the **first kind** if $a(z)$ is holomorphic, of the **second kind** if the residue vanishes everywhere, and of the **third kind** otherwise.

The indefinite integral $W(p) = \int_{p_0}^p \omega$ of an Abelian differential ω , where p_0 is assumed not to be a pole of ω , is called an **Abelian integral**. It is said to be of the **first, second, or third kind** if the same holds for ω . If y is a \dagger 1-cycle on \mathfrak{R} , the quantity $\int_y \omega$ is referred to as the **period** of ω along y . An **elliptic integral** is defined to be an Abelian integral on a closed Riemann surface of genus 1. For example, this is the case if the equation $P(z, w) = 0$ defining the surface is of degree 2 with respect to w and of degree 3 or 4 with respect to z . More generally, a closed Riemann surface is called **hyperelliptic** if $P(z, w)$ is of degree 2 with respect to w , or, equivalently, if \mathfrak{R} carries a meromorphic function with exactly two poles. An Abelian integral on such a surface is called a **hyperelliptic integral**.

On a closed surface \mathfrak{R} , let V_a be the linear space over C of the Abelian differentials of the first kind. Given a 1-cycle α of \mathfrak{R} , there exists a unique $\omega_\alpha \in V_a$ such that $\text{Re} \int_y \omega_\alpha$ is equal to the intersection number (α, y) for every 1-cycle y . This differential is also characterized by the property $((\omega, \omega_\alpha)_\mathfrak{R} \equiv) \int_\mathfrak{R} \omega \wedge * \bar{\omega}_\alpha = -2\sqrt{-1} \int_\alpha \omega$ for every $\omega \in V_a$. If $\{\alpha_1, \dots, \alpha_{2g}\}$ form a basis of the 1-dimensional homology group with integral coefficients, then $\text{Re} \omega_{\alpha_i} (i = 1, \dots, 2g)$ form a basis of the linear space V_h over R of the \dagger harmonic differentials on \mathfrak{R} as well as that of the space $\{\text{Re} \omega \mid \omega \in V_a\}$. Accordingly,

$$\dim_C V_a = g, \quad \dim V_h = 2g.$$

These identities show a close relationship between the topological structure of \mathfrak{R} and the space of the Abelian differentials on \mathfrak{R} (- 194 Harmonic Integrals).

One can choose a 1-dimensional homology basis $\{\alpha_i, \alpha_{g+i}\}_{i=1}^g$ so that $(\alpha_i, \alpha_j) = (\alpha_{g+i}, \alpha_{g+j}) = 0$, $(\alpha_i, \alpha_{g+i}) = 1$, and $(\alpha_i, \alpha_{g+j}) = 0 (i \neq j), (i, j = 1, 2, \dots, g)$. Such a basis is called a **canonical**

homology basis. If ω and σ are Abelian differentials of the first kind, then we have

$$(\omega, \bar{\sigma})_{\mathfrak{R}} = -\sqrt{-1} \left(\int_{\mathfrak{A}} \omega \int_{\mathfrak{A}_{g+j}} \bar{\sigma} - \int_{\mathfrak{A}_{g+j}} \omega \int_{\mathfrak{A}_j} \bar{\sigma} \right) = 0,$$

$$(\omega, \omega)_{\mathfrak{R}} = \sqrt{-1} \sum_{j=1}^g \left(\int_{\mathfrak{A}_j} \omega \int_{\mathfrak{A}_{g+j}} \bar{\omega} - \int_{\mathfrak{A}_{g+j}} \omega \int_{\mathfrak{A}_j} \bar{\omega} \right) \geq 0.$$

Together, these are called the (Riemann) **period relation**. The second formula implies that ω vanishes identically if the periods of ω along all α_j ($j = 1, \dots, g$) are zero.

Let $\alpha_1, \dots, \alpha_{2g}$ be a 1-dimensional homology basis, and let $\omega_1, \dots, \omega_g$ form a basis of V_a over \mathbb{C} . The $g \times 2g$ matrix Ω with $\int_{\alpha_j} \omega_i$ as its (i, j) -component is called a **period matrix**. Corresponding to the change of bases (a) and (w), it is subject to transformation into the form $A\Omega M$, where A is a $g \times g$ invertible complex matrix and M is a $2g \times 2g$ integral square matrix with determinant ± 1 . Conversely, two Riemann surfaces are conformally equivalent if they possess period matrices transformable to each other in this manner (**Torelli's theorem**). We can choose $\omega_1, \dots, \omega_g$ so that the corresponding period matrix with respect to a canonical homology basis becomes (I_g, T) with the $g \times g$ unit matrix I_g . Then from the period relation, T is symmetric and $\text{Im } T$ is positive definite.

On the complex linear space \mathbb{C}^g , consider the subgroup generated by the $2g$ column vectors of a period matrix Ω (the subgroup is also denoted by Ω). Since it is of rank $2g$ and properly discontinuous, a group manifold \mathbb{C}^g/Ω is obtained. It is determined by \mathfrak{R} uniquely up to analytic isomorphism and is called the **Jacobian variety** of \mathfrak{R} . The **generalized Jacobian variety** is introduced in a similar fashion by means of Abelian integrals of the second and third kinds (- 9 Algebraic Curves).

D. The Riemann-Roch Theorem

In the present context, a 0-chain with integral coefficients on a Riemann surface \mathfrak{R} is referred to as a **divisor**. A divisor $d = \sum n_i p_i$ ($n_i \in \mathbb{Z}$, $p_i \in \mathfrak{R}$) is an **integral divisor** (or **positive divisor**) if $n_i \geq 0$ in the reduced expression; d is a **prime divisor** if it consists of a single point p_1 and $n_1 = 1$. A divisor of a meromorphic function for an Abelian differential ω is defined by taking the p_i as the zeros (poles) off or ω and n_i ($= n_i$) as the multiplicity of the zero

(pole) at p_i . The divisors on \mathfrak{R} constitute an Abelian group \mathfrak{D} in which **principal divisors**, i.e., divisors of meromorphic functions, constitute a subgroup \mathfrak{P} . The factor group $\mathfrak{D}/\mathfrak{P}$ is called the **divisor class group**; an element of it is called a **divisor class**. The divisors of Abelian differential constitute a single divisor class, which is referred to as the **canonical divisor class** (or **differential divisor class**). The **degree** and the **dimension** of a divisor class D are defined as follows, independent of the choice of the representative $d = \sum n_i p_i \in D$: $\deg D = \sum n_i$, $\dim D = \dim_{\mathbb{C}} \{f | f \text{ is meromorphic, (divisor of } f) + d \text{ is a positive divisor}\}$. For example, the degree of the principal divisor class is zero.

In terms of these concepts, the **Riemann-Roch theorem** is stated as follows: For a divisor class D on a closed Riemann surface \mathfrak{R} of genus g and for an integer n , we have

$$\dim(D + nW) - \dim(-D - (1 - n)W) = \deg D + (2n - 1)(g - 1),$$

where W is the canonical divisor class (- 9 Algebraic Curves).

This theorem implies the following properties of \mathfrak{R} : (i) $\deg W = 2g - 2$. (ii) The holomorphic invariant forms φdz^2 (i.e., analytic tensors of order 2), referred to as **quadratic differentials**, constitute a linear space over \mathbb{C} of dimension 0 (if $g = 0$), 1 (if $g = 1$), or of dimension $3g - 3$ (if $g \geq 2$). The quadratic differentials have close connection with extremal quasiconformal mappings and play an important role in the theory of Teichmüller spaces (- 352 Quasiconformal Mappings, 416 Teichmüller Spaces). (iii) For a point $p \in \mathfrak{R}$, a positive integer m is called a **gap value** if \mathfrak{R} carries no meromorphic function having a pole only at p with multiplicity m . Then if $g = 0$, no point has gap values; and if $g \geq 1$, every point p has exactly g gap values; in this case, p also has a nongap value $m \leq g + 1$. A point p is called an **ordinary point** if the gap values at p are $1, 2, \dots, g$; otherwise p is called a **Weierstrass point**. If $g \geq 2$, then the total number N of Weierstrass points is not less than $2g + 2$ and not greater than $(g - 1)g(g + 1)$ (A. Hurwitz). Moreover, the case $N = 2g + 2$ occurs if and only if \mathfrak{R} is hyperelliptic, and then the gap values at Weierstrass points are $1, 3, \dots, 2g - 1$. This implies that every closed Riemann surface of genus 2 is hyperelliptic. (iv) Suppose the genus g of \mathfrak{R} is ≥ 2 . A conformal mapping f of \mathfrak{R} onto itself with the property that every 1-cycle γ is always homologous to $f(\gamma)$ is necessarily the identity transformation. Also, \mathfrak{R} is known to admit only a finite number of conformal mappings onto itself (H. Schwarz); the total number does not exceed $84(g - 1)$ (Hurwitz).

E. Abel's Theorem

Abel's theorem is stated as follows: A divisor d of degree zero is a principal divisor if and only if it is expressed as $d = \partial\gamma$ by means of a 1-chain γ that has the property that $\int_{\gamma} \omega = 0$ for every $\omega \in V_a$.

Given a divisor class D of degree zero, consider a 1-chain γ with $\partial\gamma \in D$. For every 1-cycle α there corresponds the quantity

$$\chi_{\alpha}(D) = \exp\left(2\pi\sqrt{-1} \operatorname{Re} \int_{\gamma} \omega_{\alpha}\right),$$

independent of the choice of γ . Thus D determines a \dagger character on the 1-dimensional homology group, called the **integral character**. Conversely, every character on the homology group is shown to be the integral character of some D . In terms of this notion, Abel's theorem can be stated as follows: D is the principal divisor class if and only if $\chi_{\alpha}(D) = 1$ for every α . This result shows that the 1-dimensional homology group with integral coefficients and the group of the divisor classes of degree zero (with compact topology) are, with respect to integral characters, mutually dual (in the sense of Pontryagin) topological Abelian groups (\rightarrow 422 Topological Abelian Groups). For the relationship between Abelian integrals and Jacobian varieties, in particular the \dagger Jacobi inverse problem, \dagger Abelian functions, and \dagger Riemann theta functions, \rightarrow 3 Abelian Varieties L. Also \rightarrow references to 234 Kleinian Groups, 352 Quasiconformal Mappings, 367 Riemann Surfaces, 416 Teichmüller Spaces.

12 (VIII.1) Algebraic Geometry

A. Introduction

Algebraic geometry is the branch of mathematics that deals with \dagger algebraic varieties, that is, point sets defined by several algebraic equations in a space of any dimension or those derived from these sets by means of certain constructions (\rightarrow 16 Algebraic Varieties). It may also be considered to be a theory of the \dagger field of algebraic functions in several variables in geometric language, and it is closely related to the theories of complex analytic manifolds, commutative algebra, and homological algebra. It also has an important connection with number theory through the theories of automorphic functions, Diophantine equations, and zeta functions.

To investigate local properties of algebraic varieties we consider varieties embedded in a \dagger affine space; to study global properties we usually consider varieties contained in \dagger projective spaces. A quantity (or property) that is invariant under \dagger projective transformations, isomorphisms, i.e., \dagger biregular and \dagger birational transformations, or birational transformations is called a \dagger projective invariant, a **relative invariant**, or an **absolute invariant** (birational invariant), respectively. The study of projective invariants is a part of projective geometry, whose methods are important in algebraic geometry. The notions of relative invariant and absolute invariant are used, for example, in the classification of algebraic varieties.

We usually assume that the coordinates of each point of the variety belong to a certain fixed field K . In the classical case, namely, when the field K is the field \mathbb{C} of complex numbers, the algebraic varieties are considered as complex spaces and are studied by applying the theories of partial differential equations, differential geometry, etc. Topological methods may also be applied. Algebraic geometry originated from such studies, but, for the study of properties such as rational mappings or algebraic systems, it became necessary to consider as well the case where the ground field K is not algebraically closed. Furthermore, to apply this to number theory, it is necessary to establish the theory over the field of any characteristic p . For this purpose it is necessary to establish a theory for varieties having ground domains as general as possible.

B. History

Analytic geometry began with the study of lines and quadratic curves (surfaces) and later came to include the study of cubic and quartic curves (surfaces), and so on. These subjects originally belonged exclusively to analytic (or projective) geometry. At that time, the study could not have been described by so specific a title as algebraic geometry.

The study of such theories as the construction of an algebraic plane curve by families of curves of lower degree or the algebraic m - n correspondence on a straight line probably began with research such as that by M. Chasles. The most outstanding event in the history of algebraic geometry was the introduction and development of the theory of algebraic functions (- 11 Algebraic Functions) by B. Riemann (1857). Before that time the degree of an algebraic curve (surface) was the only quantity known to be a projective invariant of the curve (surface).

With the theory of algebraic functions, Riemann gathered into one family all the curves that can be transformed onto each other by birational transformations. As the basis for his study, Riemann examined birational transformations in place of projective transformations. This idea led to the notion of the so-called Riemann surface. The genus of the surface was obtained as the characteristic number of the family of curves. The concept of genus was the first absolute invariant to appear in the history of algebraic geometry. Riemann based his theory on Abelian integrals using Dirichlet's principle, under the assumption that any algebraic curve reduces to one without singularities.

After Riemann many mathematicians tried

to reconstruct the theory more precisely without using transcendental methods. M. Noether attempted this reconstruction by using geometric methods. Using the Cremona transformation, he confirmed Riemann's assumption for curves: that any algebraic curve on a plane can be transformed by a birational transformation to a plane curve without singularities except for simple nodes. He also contributed in making more precise the basis conditions for the Riemann-Roch theorem, which is considered to be one of the most important theorems in the field. His results on space curves and surfaces are also noteworthy. J. Plücker defined the concept of genus in geometric terms and introduced the Plücker coordinates. A. Cayley and A. Brill worked along similar lines. Cayley's idea was developed later by B. L. van der Waerden and W. L. Chow, who introduced the associated form of an algebraic variety and its Chow coordinates.

Around 1890 the Italian school of algebraic geometry appeared. Following the tradition established by Noether, they employed algebraic-geometric methods and uncovered many new facts concerning algebraic surfaces. Among those who belonged to this school were G. Castelnuovo, F. Enriques, and F. Severi.

In France, H. Poincaré and E. Picard initiated their study of algebraic functions of two complex variables. After them S. Lefschetz investigated the theory of complex algebraic surfaces [11, 123]. The results attained by the Italian and French schools were very suggestive but lacked rigorous foundations.

On the other hand, rigorous number-theoretic theories of algebraic curves appeared in Germany. R. Dedekind and H. Weber developed the theory of algebraic function fields parallel to that of algebraic number fields. K. Hensel introduced the concept of p -adic numbers in analogy to power series expansions of analytic functions. E. Noether constructed an abstract theory of polynomial ideals from a formal theory by E. Lasker and F. S. Macaulay. Under her influence there appeared the arithmetic algebraic geometry (of curves) over an abstract field as developed by F. K. Schmidt and others.

In the higher-dimensional case, van der Waerden attempted to create a more rigorous foundation for algebraic geometry under the influence of Noether's abstract ideal theory (c. 1930) [14]. He introduced the concept of generic points and specialization, and specifically defined the multiplicity of intersections of two varieties in a projective space. He succeeded in getting a rigorous proof of Bezout's theorem: In n -dimensional projective

space, the number of intersections of an r -dimensional algebraic subvariety of degree l with an $(n - r)$ -dimensional subvariety of degree m is always lm if they intersect in only a finite number of points.

The problem of intersections was taken up by C. Chevalley and A. Weil in the 1940s. Chevalley developed the ideal theory of \dagger local rings (studied initially by W. Krull); he introduced topological concepts and applied them to the problem of intersections. The theory in this direction was later extended further by P. Samuel, M. Nagata, and J.-P. Serre.

Weil gave foundations of algebraic geometry over an abstract field and reconstructed the theory by introducing geometric language to designate objects of abstract algebra [15]. He thus gave quite a new aspect to the theory and extended H. Hasse's arithmetization of the theory of algebraic functions in one variable to the case of several variables. Reconstructing Severi's theory of algebraic correspondence over abstract fields, he succeeded in proving an analogy of the \dagger Riemann hypothesis on \dagger congruent zeta functions (- 450 Zeta Functions N). He also constructed, purely algebraically, the entire theory of \dagger Abelian varieties independent of characteristic.

Around 1930, O. Zariski gave another foundation to algebraic geometry by applying the generalized \dagger Valuation theory that had been introduced by Krull. Zariski clarified especially the properties of birational transformations by using valuation theory. Zariski's main theorem states that if a birational mapping is not \dagger regular at a \dagger normal point P (- 16 Algebraic Varieties 1), each component of the image of P by the mapping is of dimension ≥ 1 .

Zariski also solved the problem of \dagger resolution of singularities in the affirmative in the case of characteristic 0 for varieties of dimension ≤ 3 . The affirmative resolution of this problem (which Riemann assumed) says that any algebraic variety in a projective space can be transformed birationally to a projective algebraic variety without singularities. In 1964, H. Hironaka gave an affirmative answer for any dimension in the case of characteristic 0.

Along with the achievements in algebraic methods, great development took place in analytic methods. Unification of the concepts of Riemann surfaces and \dagger Riemannian manifolds led to the concept of \dagger complex analytic manifolds. Furthermore, G. de Rham's theorem on the duality of topologically defined homology and cohomology based on differential forms was proved; also, W. V. D. Hodge's theory of \dagger harmonic integrals was developed. In the case of the complex dimension 1, any

compact Riemann surface is derived from a certain projective algebraic curve. However, the situation is not so simple in the case of higher dimensions. Weil's concept of \dagger abstract complete algebraic varieties can be considered as an analog of compact complex manifolds. If a compact complex analytic variety is projective, then it must be an algebraic variety (\dagger Chow's theorem). K. Kodaira proved that a necessary and sufficient condition for a compact complex analytic manifold to be biholomorphically equivalent to a projective complex analytic manifold is that the manifold is a \dagger Hodge variety.

Using results on harmonic integrals, J. Igusa and Weil established the theory of \dagger Picard and \dagger Albanese varieties associated with algebraic manifolds of arbitrary dimensions as a generalization of the theory of \dagger Jacobian varieties associated with algebraic curves (- 9 Algebraic Curves E). Thus many ambiguities in the theory as developed by the Italian school were clarified. Later the theory was generalized to the case of characteristic p by T. Matsusaka, Chow, and S. Lang. The duality theorem in this case was later proved by M. Nishi and P. Cartier (- 3 Abelian Varieties D).

The concept of \dagger sheaves (- 383 Sheaves) had already been used in Kodaira's theory. Serre defined an abstract algebraic variety as a \dagger ringed space by using an analogy to the concept of complex analytic spaces; he considered it as a topological space with respect to the \dagger Zariski topology. By introducing \dagger coherent algebraic sheaves, Serre clarified the idea that classical invariants (such as \dagger arithmetic genus) may be considered cohomological quantities (\rightarrow 16 Algebraic Varieties E).

A. Grothendieck invented the concept of a \dagger scheme, which is far more general than that of an algebraic variety, by admitting the existence of \dagger nilpotent elements in structure sheaves and taking as a coordinate ring a general commutative ring with unity element. By the device of taking into account nilpotent elements, an analog of the method of successive approximation in analysis is now applicable. By masterful use of cohomological techniques, Grothendieck derived many results, including Zariski's important theorems.

In the classical case, F. Hirzebruch generalized the Riemann-Roch theorem to higher-dimensional manifolds. He made use of the language of sheaves and some topological results of A. Borel and R. Thom [S]. Later Grothendieck generalized the theorem for the abstract case as well. His idea in this work is recognized as the origin of \dagger K-theory.

Every nonsingular complete curve of genus 0 is isomorphic to the projective line, and any

nonsingular complete curve of genus 1 is isomorphic to a projective curve defined by the equation $X_2^2 X_0 = X_1(X_1 - X_0)(X_0 - \lambda X_1)$ for some $\lambda \neq 0, 1$. On the other hand, the set of all isomorphism classes of nonsingular complete curves of genus $g > 1$ is parametrized by a normal quasiprojective variety of dimension $3g - 3$. Such facts were first discussed by Riemann as the problem of moduli.

Concerning the moduli of manifolds of higher dimensions in the classical case, Kodaira and D. C. Spencer developed their theory of deformations of complex structures (\rightarrow 72 Complex Manifolds G). The meaning of number of moduli is clarified by deformation theory. Deformation theory has been extended in various ways, and deformation is considered as one of the fundamental concepts in algebraic geometry.

To investigate the global structure of the moduli varieties, D. Mumford introduced geometric invariant theory (- 16 Algebraic Varieties W).

Étale and crystalline cohomologies initiated by Grothendieck and others are useful for the study of algebraic varieties of positive characteristic. In particular, the conjecture made by Weil concerning congruent zeta functions has been solved affirmatively by P. Deligne with the help of étale cohomology [2].

Many important questions have been answered by means of the geometric theory. For example, (1) every vector bundle on \mathbf{A}_k^n is trivial (- 16 Algebraic Varieties Z); (2) there exist unirational but nonrational fields over \mathbf{C} (- 16 Algebraic Varieties J); (3) the fundamental groups of the complements of node-curves on $\mathbf{P}_\mathbf{C}^2$ are commutative (- 16 Algebraic Varieties I); (4) the cancellation theorem holds for \mathbf{A}_k^2 (\rightarrow 15 Algebraic Surfaces H); (5) whenever the tangent vector bundles are ample, the varieties are \mathbf{P}_k^n (\rightarrow 16 Algebraic Varieties R).

13 (IV.1 1) Algebraic Groups

A. Definitions and General Remarks [1, 2, 8]

Let k be a field and Ω a universal domain containing it. An **affine algebraic group** G defined over k is, by definition, a group G which has the structure of a (not necessarily irreducible) algebraic variety defined over k in an affine space Ω^N such that the group operation $(x, y) \mapsto x^{-1}y$ on G is an everywhere regular mapping defined over k . For such a group G , the set G_k of all k -rational points on G is an abstract group. The irreducible component G_0 of G (viewed as an algebraic set) containing the identity element e is unique and is a normal subgroup defined over k with finite index in G ; the decomposition of G into (absolute) irreducible components coincides with that into the cosets of G by G_0 . When $G = G_0$, the group G is called **connected**. It should be noted that for an algebraic group G defined over k , a coset gG_0 is not necessarily defined over k ; and if it is, a representative g cannot necessarily be taken to be k -rational.

However, if k is an infinite field and G is connected, and if moreover k is t perfect or G is t reductive, then G_k is t Zariski dense in G ([9], A. Borel and T. A. Springer [30]); hence G is uniquely determined by G_k . (In this case, G_k is sometimes referred to as a **k-group**.) When k is a t topological field, G_k is a ${}^+$ topological group with respect to the natural topology defined by that of k , which is generally stronger than the Zariski topology on G_k . For instance, when $k = \mathbf{R}$, $(G_0)_{\mathbf{R}}$ is a t Lie group with finitely many connected components.

A subgroup H of an affine algebraic group G , which is Zariski closed, is an affine algebraic group with respect to its natural induced structure and is called an **algebraic subgroup** of G . If H is defined over k , then H is k -closed; the converse is also true when k is t perfect. (An affine algebraic set A is called **k-closed** if A is a common zero of a set of polynomial equations with coefficients in k . The set A is k -closed if and only if all irreducible components of A are defined over the algebraic closure \bar{k} of k , and for every t Galois automorphism σ of k/\bar{k} , $A^\sigma = A$.) The notions of homomorphism and isomorphism for algebraic groups can be defined in a natural manner. For instance, for affine algebraic groups G and G' defined over k , a **rational homomorphism** $\varphi: G \rightarrow G'$ defined over k , or a **k-morphism** for short, is a homomorphism of G into G' that is at the same time an (everywhere regular) rational mapping defined over k . For a k -morphism φ of G into G' , the (set-theoretic) image $\varphi(G)$ is a closed subgroup of G' defined over k , the kernel $\varphi^{-1}(e')$ is a k -closed subgroup of G , and $\dim \varphi(G) = \dim G - \dim \varphi^{-1}(e')$. In particular, when $\dim G = \dim \varphi(G) = \dim G'$ (or equivalently, when $\varphi(G_0) = G'_0$ and $\varphi^{-1}(e')$ is finite), φ is called an **isogeny**. (Two groups G and G' are called **isogenous** if there exist a third group G'' and isogenies $G'' \rightarrow G$, $G'' \rightarrow G'$.) When a k -morphism φ is bijective and φ^{-1} is also an (everywhere regular) rational mapping defined over k , φ is called a **birational isomorphism** defined over k , or a **k-isomorphism** for short. It should be noted that a rational homomorphism which is an isomorphism of abstract groups is not necessarily an isomorphism of algebraic groups (e.g., a Frobenius homomorphism); a similar statement holds for an injective continuous homomorphism of topological groups.

Given a connected affine algebraic group G and a closed subgroup H , both defined over k , the quotient space G/H has the uniquely determined structure of an algebraic variety defined over k such that the canonical mapping $G \rightarrow G/H$ is separable. The t function field of G/H is then identified with the subfield of the function field of G formed by all H -invariant ele-

ments. In particular, if H is a closed normal subgroup, then G/H has a natural structure of an affine algebraic group (defined over the same ground field k) [8, 10, 11].

As an example, we have the group $GL(n)$ of all $n \times n$ nonsingular matrices (x_{ij}) . $GL(n)$ may be viewed as an algebraic set in Ω^{n^2+1} , defined by a single equation $\det(x_{ij}) \neq 0$, and as such is a connected algebraic group defined over the t prime field. In general, an algebraic group reahzed as a closed subgroup of $GL(n)$ is called a **linear algebraic group**. Since an affine algebraic group is always isomorphic to a linear algebraic group, these two terminologies are essentially synonymous [1, 2].

B. Generalization of the Definition

Replacing the term *affine algebraic set* (or *affine variety*) in the definition of an affine algebraic group by a more general term t *algebraic variety*, we obtain the notion of an **algebraic group** (**algebraic group variety**, or simply **group variety**). On this subject, the following facts are fundamental. A t complete connected algebraic group is an Abelian variety (\rightarrow 3 Abelian Varieties). More generally, given a connected algebraic group G defined over k , there always exists a (k -closed) largest linear connected closed normal subgroup L , and the factor group G/L is an Abelian variety. Furthermore, for a closed normal subgroup H of G , the factor group G/H is complete if and only if $H \supset L$ (**Chevalley's theorem** [8]). In particular, if a connected algebraic group G is complete and linear at the same time, then G reduces to the identity group. In view of these theorems, the study of algebraic groups can be reduced, in a sense, to the study of Abelian varieties and linear algebraic groups. For this reason, we henceforth restrict ourselves to linear algebraic groups, which are simply called algebraic groups. (The notion of t generalized Jacobian variety, introduced by M. Rosenlicht [12], is an example of an algebraic group in a general sense; \rightarrow 9 Algebraic Curves.) The notion of algebraic groups has been generalized further to that of t group schemes by A. Grothendieck [3, 4].

C. Lie Algebras

Since an algebraic group G defined over k has no singularities, the t tangent space \mathfrak{g} to G at the identity element e is defined and has the same dimension as G : $\dim \mathfrak{g} = \dim G$. The space \mathfrak{g} can be identified in a natural manner with the space of all left-invariant t derivations of the function field of G_0 and thus has the struc-

ture of a Lie algebra defined over k (\rightarrow 248 Lie Algebras). We call \mathfrak{g} (the Lie algebra \mathfrak{g}_k over k of all k -rational points in \mathfrak{g}) the **Lie algebra** of G (of the k -group G_k). If G is a linear algebraic group contained in $GL(n)$, then \mathfrak{g}_k is a Lie subalgebra of $\mathfrak{gl}(n, k)$ with the Lie product defined by $[x, y] = xy - yx$; a linear Lie algebra corresponding to a linear algebraic group is called an **algebraic Lie algebra**. When the characteristic of k is zero, conditions for a linear Lie algebra to be algebraic can be given in terms of the **replica** [5]. Also, in the case of characteristic zero, for $x \in \mathfrak{gl}(n, k)$, $x \in \mathfrak{g}_k$ if and only if $\exp(tx) \in G$, where t is a variable over k and $\exp(tx)$ is understood as a \dagger formal power series in t (contained in Ω). From this, we can prove, exactly as in the theory of Lie groups (\rightarrow 249 Lie Groups), a one-to-one correspondence between k -closed subgroups H of G and algebraic Lie subalgebras \mathfrak{h}_k of \mathfrak{g}_k , establishing a complete parallelism of the theories of algebraic groups and Lie algebras [5]. This parallelism breaks down when k has positive characteristic [1, 2]. On the other hand, over a field of characteristic $p > 0$, we have **formal groups**, an analog of local Lie groups introduced by J. Dieudonné [13], and also \dagger hyperalgebras, which play the role of Lie algebras in characteristic 0.

D. Tori [1, 2]

The group $G_m = GL(1)$, the multiplicative group of nonzero elements in Ω , is a 1-dimensional connected algebraic group defined over the prime field. In general, an algebraic group G that is isomorphic to the direct product $(G_m)^n$ is called an **(algebraic) torus**. When a torus G defined over k is isomorphic to (G_m) over an extension K of k , G is called **K-trivial** (or **K-split**), and the field K is called a **splitting field** for G . A torus G defined over k always has a splitting field K which is a finite separable extension of k .

In general, a rational homomorphism χ of an algebraic group G into G_m is called a **character** of G . If we define the sum of two characters χ_1 and χ_2 of G by $(\chi_1 + \chi_2)(g) = \chi_1(g) \cdot \chi_2(g)$ ($g \in G$), the totality of characters of G is an additive group, called the **character module** of G and denoted by $X(G)$. Let G be a torus defined over k and $X = X(G)$ its character module, and let K be a splitting field for G that is a finite \dagger Galois extension of k . If a K -isomorphism $G \cong (G_m)^n$ is given by the correspondence $G \ni g \rightarrow (\chi_1(g), \dots, \chi_n(g))$, then the χ_i are characters of G , and X is a \dagger free module of rank n generated by χ_1, \dots, χ_n . Furthermore, if Γ denotes the Galois group of K/k , then for $\sigma \in \Gamma$ and $\chi \in X$, the conjugate χ^σ is also a char-

acter of G ; under this action of Γ , X becomes a right f -module. We have complete duality between a torus G and its character module X in the following sense. There exists a one-to-one correspondence between the closed subgroups G_1 (defined over k) of G and a $(\Gamma$ -invariant) submodule X_1 of X for which X/X_1 has no p - \dagger torsion (where p is the characteristic of k). This correspondence is determined by the relation of the annihilators $X_1 = G_1^\perp$, $G_1 = X_1^\perp$, and under the correspondence the character modules of G_1 and of G/G_1 are canonically identified with X/X_1 and X_1 , respectively. Furthermore, let G' be another torus (defined over k and split over K) with the character module X' , and suppose that we have a $(k$ -) homomorphism $\varphi: G \rightarrow G'$. Then we can define a $(\Gamma$ -) homomorphism ${}^t\varphi: X' \rightarrow X$, called the **dual homomorphism** of φ , by the relation ${}^t\varphi(\chi') = \chi' \circ \varphi$ for $\chi' \in X'$; conversely, any $(\Gamma$ -) homomorphism of X' into X is obtained uniquely in this manner. In particular, φ is a $(k$ -) isomorphism if and only if its dual ${}^t\varphi$ is a $(\Gamma$ -) isomorphism. Since for any free $(\Gamma$ -) module X of finite rank there always exists a torus G (defined over k and split over K) such that $X(G) \cong X$ (as a special case of the existence theorem of k -forms), the \dagger categories of all tori (defined over k and split over K) and that of all free $(\Gamma$ -) modules of finite rank are mutually dual.

E. Semisimple Elements and Unipotent Elements

A matrix a is called \dagger semisimple if it is diagonalizable, i.e., if the \dagger minimal polynomial of a has only simple roots. A matrix a is called \dagger unipotent if $a - 1$ is nilpotent, i.e., if all characteristic roots of a are equal to 1. (When the characteristic of the ground field is zero, the unipotent elements u in $GL(n, k)$ and the nilpotent elements x in $\mathfrak{gl}(n, k)$ are in one-to-one correspondence by the relation $u = \exp x$.) Any nonsingular matrix a can be written uniquely as a product of a nonsingular semisimple matrix a' and a unipotent matrix a'' of the same size which are mutually commutative: $a = a' a'' = a'' a'$ (\dagger multiplicative Jordan decomposition); a' (a'') is called the **semisimple (unipotent) part** of a and is denoted by a_s (a_u); a_s can be expressed as a polynomial of the matrix a with scalar coefficients. For an element a of a (linear) algebraic group G , the semisimplicity (unipotency) of a does not depend on the matrix representation of G . Moreover, these properties are preserved by homomorphisms of algebraic groups. Also, if $a \in G$, then $a, a_u \in G$.

For an algebraic group G , we denote the

totality of semisimple (unipotent) elements contained in G by $G_s (G_u)$ and call it the **semi-simple (unipotent) part** of G . (Note that G_s and G_u are not necessarily subgroups.) A torus G is then characterized by the property that $G = G_0 = G_s$. On the other hand, an algebraic group G such that $G = G_u$ is called **unipotent**. For instance, the additive group of the universal domain,

$$G_a \cong \left\{ \begin{pmatrix} 1 & x \\ 0 & 1 \end{pmatrix} \middle| x \in \Omega \right\},$$

is a 1-dimensional connected unipotent algebraic group.

F. Solvable Groups and Nilpotent Groups [1, 2, 7, 9]

For two closed normal subgroups H_1, H_2 (defined over k) of an algebraic group G , the \dagger commutator group $[H_1, H_2]$ (in the sense of abstract group theory) is also a closed normal subgroup (defined over k) of G . In view of this fact, an algebraic group G is called **solvable (nilpotent)**, when it is \dagger solvable (\dagger nilpotent) as an abstract group. For example, the totality $T(n)$ of $n \times n$ nonsingular *upper unipotent* matrices, i.e., matrices of the form

$\begin{pmatrix} * & \dots & * \\ & \ddots & \\ 0 & & * \end{pmatrix}$, is a connected solvable algebraic group. A unipotent algebraic group is always nilpotent.

For any connected solvable algebraic group $G \subset GL(n)$, there always exists an element a in $GL(n)$ such that $a^{-1}Ga \subset T(n)$ (**Lie-Kolchin theorem** [1, 2]). A connected solvable algebraic group G has a \dagger composition series $G = G_0 \supset G_1 \supset \dots \supset G_r = \{e\}$ such that each G_i is a connected closed normal subgroup of G and G_{i-1}/G_i is isomorphic to either G_m or G_s . If G is defined over k , the subgroup G_u is a connected k -closed normal subgroup of G , and for any maximal torus T in G , we have a decomposition into a \dagger semidirect product $G = T \cdot G_u$ (in the sense of algebraic groups, i.e., the natural map $T \times G_u \rightarrow G$ is birational). It is known that for any algebraic group G defined over k there exists a maximal torus defined over k ([4], A. Borel and T. A. Springer [30]). G is nilpotent if and only if G has a unique maximal torus T ; when that is so, $T = G_s$ and T is contained in the \dagger center of G . For a connected solvable algebraic group G defined over k , we can take $a \in GL(n, k)$ such that $a^{-1}Ga \subset T(n)$ (see the Lie-Kolchin theorem) if and only if all characters $\chi \in X(G)$ are defined over k ; when this condition is satisfied, G is called **k -solvable**. G_u is then defined over k , and G/G_u is a k -trivial torus.

When the characteristic of k is zero, any commutative unipotent algebraic group (defined over k) is (k -) isomorphic to the direct product $(G_a)^n$. When k is an algebraically closed field of characteristic $p > 0$, any connected commutative unipotent algebraic group defined over k is k -isogenous to a direct product of a certain number of the groups W_m of \dagger Witt vectors (of length m) (Chevalley-Chow theorem [12]). A 1-dimensional connected unipotent algebraic group defined over a perfect field k is k -isomorphic to G_a [1, 2].

G. Borel's Theory

Let G be an algebraic group and V an algebraic variety (both defined over k). We say that V is a **transformation space** of G (defined over k), or simply G acts on V , if there is given an everywhere regular rational mapping $G \times V \ni (g, v) \rightarrow gv \in V$ (defined over k) such that $g_1(g_2v) = (g_1g_2)v$, $ev = v$ ($g_1, g_2 \in G, v \in V$). When the action of G on V is \dagger transitive, V is called a \dagger homogeneous space of G . For a closed subgroup H of a connected algebraic group G (both defined over k), the quotient space G/H has the natural structure of a homogeneous space of G (defined over k). A. Borel [1, 2] proved the following theorems:

(1) If G is a connected solvable algebraic group and V a complete transformation space of G , then G has at least one fixed point in V . More precisely, in order that a connected algebraic group G defined over k be k -solvable, it is necessary and sufficient that for any complete transformation space V of G defined over k for which $V_k \neq \emptyset$, G have at least one k -rational fixed point in V [9].

(2) Let G be a connected algebraic group. A maximal connected solvable closed subgroup of G is called a **Borel subgroup** of G . Then (i) all pairs (T, B) formed by a maximal torus T in G and a Borel subgroup B containing it are conjugate to each other with respect to inner automorphisms of G . (ii) For a closed subgroup H of G , the quotient space G/H is complete if and only if H contains a Borel subgroup of G ; and, when that is so, G/H is actually a \dagger projective algebraic variety. (For instance, if $G = GL(n)$, $B = T(n)$, then G/B is a so-called \dagger flag manifold.) (iii) The conjugates of $B(T)$ cover the whole group G (G_s). A closed subgroup of G is called **parabolic** if it contains a Borel subgroup of G . A parabolic subgroup H coincides with its own \dagger normalizer $N(H)$; in particular, H is always connected. Parabolic subgroups are significant in the theory of automorphic functions. (For the parabolic subgroups associated with BN-pairs \rightarrow Sections Q, R.)

When G is a connected algebraic group defined over a perfect field k , proposition (i) can be sharpened: The pairs (A, H) formed by a maximal k -trivial torus A in G and a maximal connected k -solvable subgroup H containing it are conjugate to each other with respect to the inner automorphisms defined by elements in G_k . The normalizer $N(H)$ of such a k -solvable subgroup H is a minimal k -closed parabolic subgroup of G . When the maximal connected k -solvable subgroups of G are reduced to the identity group, G is called **k -compact** or **k -anisotropic**. (Otherwise, G is called **k -isotropic**.) For instance, the † orthogonal group $G = SO(n, f)$ of a † quadratic form f of n variables is k -compact if and only if the form f is **anisotropic**, i.e., the homogeneous equation $f = 0$ has no solution other than zero in k . Similar facts hold for other classical groups. When k is a † local field, G is k -compact if and only if G_k is compact as a topological group. In general, a k -compact group is † reductive.

H. The Weyl Group

Let G be a connected algebraic group and Q an arbitrary torus in G . The † centralizer $Z(Q)$ of Q is then connected and coincides with the connected component of the normalizer $N(Q)$. Hence the factor group $W = N(Q)/Z(Q)$ is finite and can be identified with a subgroup of the automorphism group of Q (or of its character module $X(Q)$) in a natural manner. The group W is called the **Weyl group** of G relative to Q . In particular, when $Q = T$ (a maximal torus), the order of W is equal to the number of Borel subgroups containing T . In this case, the centralizer $C = Z(T)$ is called a **Cartan subgroup** of G ; it is characterized by the property that C is a (maximal) connected nilpotent closed subgroup of G which coincides with the connected component of its own normalizer $N(C)$. The notions of Borel subgroups, Cartan subgroups, and maximal tori are preserved under rational homomorphisms of algebraic groups.

1. Semisimple Groups and Reductive Groups

In an algebraic group G defined over k , there exists a largest connected solvable closed normal subgroup R , called the **radical** of G . The unipotent part R_u of R is called the **unipotent radical** of G . When $R = \{e\}$, G is called **semisimple**. When R is a torus, namely, $R_u = \{e\}$, G is called **reductive**. Semisimplicity and reductiveness are preserved under forming a direct product and taking the image (or inverse image) of an isogeny. For a reductive group G , the $+$ commutator subgroup $D(G)$ is

semisimple, and $G = D(G) \cdot R$, $D(G) \cap R = \text{finite}$; in other words, G is isogenous to the direct product of a connected semisimple algebraic group and a torus. In general, if R is the radical of a connected algebraic group G and R_u is the unipotent radical of R , then the factor groups G/R , G/R_u are semisimple and reductive, respectively. Furthermore, if the characteristic of the field k is zero, there exists a reductive closed subgroup H of G such that G decomposes into a semidirect product $G = H \cdot R_u$ (**Chevalley decomposition** [5]). (In this case, R and R_u are k -closed, and H can be taken to be k -rational; such an H is unique up to inner automorphisms defined by elements in G_k .) Also in the case of characteristic zero, reductive algebraic groups are characterized by the property that all rational representations are completely reducible. But when k has the characteristic $p > 0$, this property characterizes tori (M. Nagata).

J. Root Systems [1, 2, 14]

Let G be a connected semisimple algebraic group, T a maximal torus, and $X = X(T)$ its character module. A character $\alpha \in X$ is called a **root** of G relative to T if there exists an isomorphism x_α of G_a onto its image in G such that

$$t^{-1}x_\alpha(\xi)t = x_\alpha(\alpha(t)\xi) \quad \text{for all } \xi \in G_a, t \in T.$$

For a root α , such an isomorphism x_α is uniquely determined up to a scalar multiplication in G_a ; hence we put $P_\alpha = x_\alpha(G_a)$.

If we denote by r the totality of roots (relative to T), r satisfies the following axioms, where $E = X \otimes Q$ and E^* is the † dual space of E with respect to the inner product (\cdot, \cdot) : (i) For each $\alpha \in r$, there corresponds $\alpha^* \in E^*$ such that $\langle \alpha^*, \alpha \rangle = 2$ and $\langle \alpha^*, \beta \rangle \in \mathbb{Z}$ for all $\beta \in r$. (ii) If we define a reflection w_α of E by

$$w_\alpha x = x - \langle \alpha^*, x \rangle \alpha \quad \text{for } x \in E,$$

then $w_\alpha \beta \in r$ for all $\beta \in r$. (In particular, $w_\alpha \alpha = -\alpha \in r$.) (iii) If $\alpha, \beta \in r$ are linearly dependent, then $\beta = \pm \alpha$. (iv) If $\dim E = r$, r contains r linearly independent elements.

In general, a finite subset r in a finite-dimensional vector space E over Q satisfying the axioms (i)–(iv) is called a **root system** in E . (This root system is sometimes said to be reduced, to distinguish it from the root system defined in Section Q, which does not satisfy axiom (iii).) For a root system r , the elements α^* of E^* corresponding to $\alpha \in r$ are uniquely determined by these conditions, and the set $r^* = \{\alpha^*\}$ is a root system in E^* ($\alpha^* \in r^*$ is called a **coroot**). Also, the group W of linear transformations of E (E^*) generated by w_α

(w_{α}) with $\alpha \in \mathfrak{r}$ is finite and is called the **Weyl group** of the root system \mathfrak{r} . If we identify E^* with E by means of any W -invariant (positive definite) metric on E , then $a^* = (2/\langle \alpha, \alpha \rangle)\alpha$. When \mathfrak{r} is a root system of a semisimple algebraic group,

$$\langle \alpha^*, \chi \rangle \in \mathbb{Z} \quad \text{for all } \alpha \in \mathfrak{r}, \chi \in X, \quad (1)$$

so that X is W -invariant, and the Weyl group of the root system \mathfrak{r} can be identified with the group $N(T)/Z(T)$ of Section H. (In general, a maximal torus in a connected reductive algebraic group coincides with its own centralizer, so that the Weyl group W can be identified with $N(T)/Z(T)$.)

When a "linear ordering (compatible with the addition) is given in E , we denote by \mathfrak{r}_+ the set of all positive roots in \mathfrak{r} . An element $\alpha \in \mathfrak{r}_+$ is called a **simple root** if it cannot be written as $\alpha = \alpha' + \alpha''$ with $\alpha', \alpha'' \in \mathfrak{r}_+$. If $\Delta = \{\alpha_1, \dots, \alpha_r\}$ is the totality of (distinct) simple roots in \mathfrak{r}_+ , the elements $\alpha_1, \dots, \alpha_r$ are linearly independent, and any root $\alpha \in \mathfrak{r}$ can be written uniquely in the form $\alpha = \pm \sum_{i=1}^r m_i \alpha_i$, with $m_i \in \mathbb{Z}$, $m_i \geq 0$. In general, a subset A of \mathfrak{r} having this property is called a **fundamental system**; a fundamental system is always obtained in the manner explained from a linear ordering on E . For a fundamental system A , the cone A , in E^* , defined as the set of x in E^* satisfying the inequalities $\langle \alpha_i, x \rangle > 0$ ($1 \leq i \leq r$), is called a **Weyl chamber**. If we denote by L_α the hyperplane defined by the linear equation $\langle \alpha, x \rangle = 0$ for a root α , then $E^* = \bigcup_{\alpha \in \mathfrak{r}} L_\alpha = \bigcup_{\Delta} \Lambda_\Delta$, and W acts simply transitively on the set of all Weyl chambers $\{\Lambda_\Delta\}$. The Weyl group W is generated by \mathfrak{r} reflections w_{α_i} ($1 \leq i \leq r$).

In a semisimple algebraic group G , Borel subgroups B containing a (fixed) maximal torus T are in one-to-one correspondence with the fundamental systems A (or \mathfrak{r}_+) relative to T by the relation $B_u = \prod_{\alpha \in \mathfrak{r}_+} P_\alpha$, where $P_\alpha = x_\alpha(G_u)$. (More precisely, every element in B_u can be written uniquely as a product of the elements in P_α , where the ordering of the P_α is taken arbitrarily.)

K. Bruhat Decomposition

If we take a representative s_w of $w \in W$ in $N(T)$, there is a decomposition $G = \bigcup_{w \in W} B s_w B$ (disjoint union). Furthermore, if for $w \in W$ we put $N_w = \prod_{\alpha \in \mathfrak{r}_+ \cap w\mathfrak{r}_+} P_\alpha$, and in particular $N = N_e = B_u$, and denote by w_0 the unique element in W such that $w_0 \Delta = -\Delta$, then the element in $B s_w B$ can be written uniquely as a product of elements in $N_{w w_0}, s_w T, N$. Hence we have

$$G = \bigcup_{w \in W} N_{w w_0} \cdot s_w T \cdot N,$$

which is called a **Bruhat decomposition** of G . In

particular, if we put $N' = s_{w_0}^{-1} N s_{w_0}$ (which is the unipotent part of the Borel subgroup corresponding to $-\Delta$), then $N' T N$ is a Zariski open set in G , and the natural map $N' \times T \times N \rightarrow G$ is birational. This implies that the function field of G is rational (i.e., purely transcendental over Ω).

L. Structure of Semisimple Groups

A subset \mathfrak{r}_1 of a root system \mathfrak{r} is called a **closed subsystem** if $\mathfrak{r}_1 \cap \mathfrak{r} = \mathfrak{r}_1$, where \mathfrak{r}_1 denotes the submodule of X generated by \mathfrak{r}_1 . A closed subsystem satisfies conditions (i), (ii), and (iii) of a root system. For a closed subsystem \mathfrak{r}_1 of a root system \mathfrak{r} of a semisimple algebraic group G , the subgroup $G(\mathfrak{r}_1)$ of G generated by the P_α ($\alpha \in \mathfrak{r}_1$) is a semisimple closed subgroup with a maximal torus $T_1 = (G(\mathfrak{r}_1) \cap T)_0$, of which the root system relative to T_1 coincides with the restriction of \mathfrak{r}_1 on T_1 and the coroot system can be identified with $\mathfrak{r}_1^* = \{\alpha^* | \alpha \in \mathfrak{r}_1\}$. The subgroup $G(\mathfrak{r}_1)$ is normal if and only if $\mathfrak{r} - \mathfrak{r}_1$ is also a closed subsystem; when this is so, $G = G(\mathfrak{r}_1) \cdot G(\mathfrak{r} - \mathfrak{r}_1)$, $G(\mathfrak{r}_1) \cap G(\mathfrak{r} - \mathfrak{r}_1) = \text{finite}$. All connected closed normal subgroups of G are obtained in this manner. In order that G be **simple** (sometimes called **absolutely simple** or **almost simple**) as an algebraic group (i.e., without proper connected normal subgroups), it is necessary and sufficient that \mathfrak{r} be **irreducible** (i.e., \mathfrak{r} cannot be decomposed into a disjoint union of two proper closed subsystems). In general, a root system \mathfrak{r} can be decomposed uniquely into the disjoint union $\mathfrak{r} = \mathfrak{r}_1 \cup \dots \cup \mathfrak{r}_s$ of irreducible closed subsystems \mathfrak{r}_i such that $\mathfrak{r}_1 \cup \dots \cup \mathfrak{r}_i$ ($1 \leq i \leq s$) are also closed subsystems; correspondingly, G is isogenous to the direct product $G_1 \times \dots \times G_s$ of (absolutely) simple algebraic groups $G_i = G(\mathfrak{r}_i)$. (G is actually a direct product if it is simply connected or an adjoint group.) The subgroups G_i are determined uniquely and only by G .

M. k-Forms [15]

Let K be an extension of k and G_1 an algebraic group defined over K . An algebraic group G defined over k is called a **k-form** of G_1 if there is a K -isomorphism f of G onto G_1 . Suppose further that K/k is finite separable, and for every Galois automorphism σ of k/k , put $\varphi_\sigma = f^\sigma \circ f^{-1}$. Then φ_σ is an isomorphism of G_1 onto G_1^σ , and the φ_σ satisfy the relation $\varphi_\sigma^\tau \circ \varphi_\tau = \varphi_{\sigma\tau}$. Conversely, given a collection of isomorphisms $\{\varphi_\sigma\}$ satisfying these conditions, there always exists a k -form G (with a K -isomorphism f onto G_1 such that $\varphi_\sigma = f^\sigma \circ f^{-1}$), which is unique up to k -isomorphism (Weil). In particular, if K/k is a

finite Galois extension with Galois group Γ , then $\{\varphi_\sigma\}$ is a (continuous) $^+1$ -cocycle of Γ in $\text{Aut}_K(G_1)$ (the group of all K -automorphisms of G_1), and by the above correspondence the k -isomorphism classes of k -forms G are in one-to-one correspondence with the (continuous) 1 -cohomology classes of the cocycle $\{\varphi_\sigma\}$ (in the cohomology set $H^1(\Gamma, \text{Aut}_K(G_1))$) (- 172 Galois Theory J)

To a given finite separable extension K/k of degree d and an algebraic group G_1 defined over K of dimension n , we can associate a certain algebraic group $\mathfrak{R}_{K/k}(G_1)$ defined over k of dimension dn , which is obtained from G_1 by restricting the ground field [19]. A more precise definition is as follows. Let $\{\sigma_1, \sigma_2, \dots, \sigma_d\}$ ($\sigma_1 = 1$) be a set of automorphisms of \bar{k}/k such that $\sigma_i K$ ($1 \leq i \leq d$) are all distinct. Then one can find a k -form \tilde{G} of $\tilde{G}_1 = \prod_{i=1}^d G_1^{\sigma_i}$ with an isomorphism $\tilde{f}: \tilde{G} \rightarrow \tilde{G}_1$ such that $\tilde{\varphi}_\sigma = \tilde{f}^\sigma \circ \tilde{f}^{-1}$ is given by $\tilde{\varphi}_\sigma((x_i)) = (x_i \sigma)$, where i^σ is defined by the relation $(\sigma_i \sigma) K = \sigma_{i^\sigma} K$. If we denote by p_1 the canonical projection of \tilde{G}_1 onto its first component G_1 and put $p = p_1 \circ \tilde{f}$, then the pair (\tilde{G}, p) is uniquely characterized (up to k -isomorphism) by the following universality property: If \tilde{G}' is any algebraic group defined over k and φ is a K -morphism of \tilde{G}' into G_1 , then there exists a (uniquely determined) k -morphism $\tilde{\varphi}$ of \tilde{G}' into \tilde{G} such that $\varphi = p \circ \tilde{\varphi}$. The group \tilde{G} (together with p) is denoted by $\mathfrak{R}_{K/k}(G_1)$. For the group of rational points, $\tilde{G}_k = G_k$. When the algebraic group G_1 has some additional structure (such as that of $^+ \text{vector space}$, $^+ \text{algebra}$, etc.), then $\mathfrak{R}_{K/k}(G_1)$ automatically has the same kind of additional structure.

N. Chevalley's Fundamental Theorems

Let G, G' be connected semisimple algebraic groups, and let $T(T')$ be a maximal torus in $G(G')$, $X(X')$ its character module, $r(r')$ a root system of $G(G')$ relative to $T(T')$, etc. If we have an $^+ \text{isogeny}$ φ of G onto G' such that $\langle p(T) = T' \rangle$, then there is a bijection $\alpha \rightarrow \alpha'$ of r onto r' such that $\psi(\alpha') = q_\alpha \alpha$, where ψ is the dual homomorphism of φ , T and q_α is a positive integer, which equals 1 if the characteristic is zero and is a power of p if the characteristic is $p > 0$. Conversely, any injective homomorphism $\psi: X' \rightarrow X$ satisfying this condition (with respect to a certain bijection $r \rightarrow r'$ and q_α) comes from an isogeny $\varphi: G \rightarrow G'$ in the manner already stated. In particular, φ is an isomorphism if and only if ψ is an isomorphism such that $\psi(r') = r$ (i.e., $q_\alpha = 1$ for all $\alpha \in r$) [7]. The isomorphism class of G is thus completely determined by the pair (X, r) , so that we sometimes write $G = G(X, r)$. A connected semi-

simple algebraic group G defined over k is called of **Chevalley type** over k (or **k -split**) if there exists a k -trivial maximal torus T in G . If, in the above theorem, G and G' are of Chevalley type over k and T and T' are k -trivial, then the theorem remains true if we replace isogeny by k -isogeny. In particular, the k -isomorphism class of a connected semisimple algebraic group of Chevalley type over k is completely determined by (X, r) . Chevalley also showed that, for any pair (X, r) satisfying condition (1) above, there exists a connected semisimple algebraic group $G(X, r)$ of Chevalley type defined over the prime field. Therefore, since the classification of semisimple algebraic groups of Chevalley type is reduced essentially to that of root systems (X, r) , it turns out that, over any ground field k , there exist as many connected simple algebraic groups of Chevalley type as connected simple complex Lie groups (\rightarrow 249 Lie Groups; Appendix A, Table 5.1).

For a given semisimple algebraic group $G = G(X, r)$ defined over k , put $X_0 = r_z (=$ the submodule of X generated by r), $X^0 = \{x \in F | \langle \alpha^*, x \rangle \in \mathbb{Z} \text{ for all } \alpha \in r\}$. Then we have natural isogenies $G(X^0, r) \rightarrow G(X, r) \rightarrow G(X_0, r)$ (with $q_\alpha = 1$), all of which can be taken to be defined over k . The group $G(X^0, r)(G(X_0, r))$ is called the **simply connected group** (the **adjoint group**) isogenous to G . When the characteristic of k is zero, these isogenies (which are already known in the classical theory of complex Lie groups) are essentially the only possible isogenies among the semisimple algebraic groups. But when the characteristic is $p > 0$, there are, in addition to these, the Frobenius homomorphism (with $q_\alpha = p$) and the following "singular" isogenies (for which $q_\alpha = 1$ or p depending on α): $B_n \rightarrow C_n, F_4 \rightarrow F_4$ ($p = 2$), $G_2 \rightarrow G_2$ ($p = 3$). In particular, when k is a finite field, taking the set of fixed points of the singular k -isogenies, we obtain the simple finite groups of M. Suzuki and R. Ree (- 151 Finite Groups).

0. Classification Theory

A connected semisimple algebraic group G defined over k is called **k -(almost) simple** if there is no proper connected closed normal subgroup of G defined over k . (When G is k -simple and k -split, the factor group $D(G_k)/\text{center}$ is an abstract simple group except for a few special cases [17]. For more general results \rightarrow Section Q.) For a k -simple algebraic group G , let G_k be any one of its absolutely simple components, and let k be the smallest field of definition for G_k containing k . Then k_1/k is a finite separable extension, and G is k -isogenous to $\mathfrak{R}_{k_1/k}(G_k)$. Hence the problem of

classifying all k -simple groups (up to isogeny) is equivalent to that of finding all k -forms of simple groups of Chevalley type. This latter problem can be reduced, in principle, to the classification of compact k -forms and that of certain diagrams (i.e., † Dynkin diagrams along with an action of the Galois group) [16], J. Tits [30] (- Appendix A, Table 5.1). For instance, when k is a finite field (or, more generally, a field of dimension ≤ 1 [15]), there is no compact k -simple group; hence, using a simple classification theory of the diagrams, we can show that the only absolutely simple algebraic groups G defined over k are either of Chevalley type or of the types introduced by R. Steinberg (denoted by 2A_n , 2D_n , 3D_4 , 6D_4 , 2E_6). Connected semisimple algebraic groups composed of the groups of these types are characterized by the property that they have a Borel subgroup defined over k . Such groups are said to be of **Steinberg type over k** (or **k -quasi-split**). Absolutely simple algebraic groups over a p -adic field have been classified by M. Kneser and J. Tits [30, 31]. When the characteristic of k is not equal to 2, the classification of simple groups of classical type (except for the type D_4) is known to be equivalent to that of semisimple † associative algebras with † involution [18]. A similar relation also holds between some of the exceptional simple groups and † Cayley algebras or † Jordan algebras (H. Hijikata, T. A. Springer, J. Tits).

The following is a list of absolutely simple algebraic groups of classical type.

- I. k -forms of $SL(n)$ ($n \geq 2$).
 - 1.1. $G_{1k} = SL(m, \mathfrak{R}) = \{g \in M_m(\mathfrak{R}) \mid N(g) = 1\}$, where \mathfrak{R} is a † central division algebra over k with $(\mathfrak{R}:k) = r^2$, $n = mr$, and N denotes the † reduced norm in $M_m(\mathfrak{R})$.
 - 1.2. $G_{1k} = SU(m, \mathfrak{R}, f) = \{g \in SL(m, \mathfrak{R}) \mid f(gx, gy) = f(x, y) \text{ for } x, y \in \mathfrak{R}^m\}$, where \mathfrak{R} is a central division algebra over a quadratic extension k' of k with an involution ι of the second kind (which means that $\{\xi \in k' \mid \xi' = \xi\} = k$), $(K:k') = r^2$, $n = mr$, and f is a (nondegenerate) † Hermitian form of m variables over \mathfrak{R} with respect to the involution ι .
- II. k -forms of $SO(n)$ ($n \geq 3$, $n \neq 4$), $Sp(n)$ (n even, $n \geq 2$).

$G_{1k} = SU(n, \mathfrak{R}, f)$, where \mathfrak{R} is a central division algebra over k with an involution ι of the first kind (i.e., such that $\{\xi \in k \mid \xi' = \xi\} = k$), $(\mathfrak{R}:k) = r^2$, $n = mr$, and f is a nondegenerate c -Hermitian form of m variables over \mathfrak{R} with respect to the involution ι . In this case, $\dim\{\xi \in K \mid \xi' = \xi\} = r(r + \varepsilon_0)/2$ with $\varepsilon_0 = \pm 1$, and G_1 is a k -form of SO or Sp according as $\varepsilon\varepsilon_0 = 1$ or -1 . ($SO(8)$ may have other k -forms coming from the so-

called triality.) The case where the characteristic of k is 2 can also be discussed by a method given by J. Tits (*Inventiones Math.* 5, 1968).

When k is a local field or an algebraic number field, the only central division algebra with an involution of the first kind is a † quaternion algebra (and, if ι is the " † canonical involution," then $\varepsilon_0 = -1$).

P. Algebraic Groups over an Algebraic Number Field

Let G be a connected algebraic group defined over an algebraic number field k of finite degree. Let $\{v\}$ be the totality of † prime divisors (i.e., equivalence classes of valuations) of k . Taking the † restricted direct product of a family of locally compact topological groups $\{G_{k_v}\}$, we obtain a locally compact topological group G_A , called the **adele group** of G [19] (- 6 Adeles and Ideles). In particular, when $G = G_m$, the adele group $I = (G_m)_A$ is exactly the † idele group introduced by Chevalley in class field theory. If we identify $x \in G_k$ with an adele whose components are all equal to x , G_k becomes a discrete subgroup of G_A .

Concerning the finiteness property of G_A/G_k , the following results have been obtained [21, 22]: A character $\chi \in X_k(G)$ (= the module of all k -rational characters of G) gives rise to a (continuous) homomorphism $\chi_A: G_A \rightarrow I = (G_m)_A$. Put $G_A^0 = \{g \in G_A \mid |\chi_A(g)| = 1 \text{ for all } \chi \in X_k(G)\}$, where $||$ is the standard norm in I . Then G_A^0 is † unimodular, and the quotient space G_A^0/G_k is of finite volume with respect to the (unique) invariant measure on it. G_A^0/G_k (G_A/G_k) is compact if and only if the semisimple part G/R (the reductive part G/R_u) of G is k -compact. From the arithmetic point of view, it is important to determine explicitly the volume of G_A^0/G_k with respect to the invariant measure normalized in a certain manner; such a volume is called the **Tamagawa number** of G and is usually denoted by $\tau(G)$ [19, 23]. For instance, Siegel's formulas on the volume of the fundamental domain of the unit group of a quadratic form f over k are essentially equivalent to a theorem on the Tamagawa number stating that $\tau(SO(f)) = 2$.

Let \mathfrak{o} be the † ring of integers in k and L an \mathfrak{o} -lattice in the vector space on which G is acting. We can define in a natural manner an action of G_A on the set of all \mathfrak{o} -lattices; then the orbit $G_A L(G_k L)$ of L with respect to $G_A(G_k)$ is called the **genus (class)** of L . The † stability subgroup $G_{A,L}$ of L in G_A is open, and the double coset space $G_{A,L} \backslash G_A/G_k$ is finite (finiteness of the class number). Moreover, let $\{v_1, \dots, v_r\}$ be the totality of † infinite prime

divisors of k , and put $G_\infty = \prod_{i=1}^r G_{k_i}$. Then G_∞ is a Lie group, and the canonical projection G_L on G_∞ of $G_{A,L} \subset G_A$ is a discrete subgroup of finite type. (In general, (discrete) subgroups of G_∞ which are t commensurable with G_L are called **arithmetic subgroups**.) As in the adèle case, $\chi \in X_k(G)$ gives rise to a (continuous) homomorphism $\chi_\infty: G_\infty \rightarrow (\mathbf{R}^\times)'$, and if $G_\infty^0 = \{g \in G_\infty \mid \chi_\infty(g) = 1\}$, then the quotient space G_∞^0/G_L is of finite volume. Moreover, G_∞^0/G_L (G_∞/G_L) is compact if and only if G_A^0/G_k (G_A/G_k) is compact.

In addition to these, the t approximation theorem and the t Hasse principle are also extended to (classical, or general) algebraic groups (M. Eichler, M. Kneser, G. Shimura, Hijikata, Springer; \rightarrow [30]).

Q. Structure of Reductive Groups [24]

Let G be a connected t reductive group defined over a field k . Then G has a t maximal torus defined over k and G is t split over a finite t separable extension K of k . The structure of the group G_K can be discussed as in Sections I, J, K, and L. Here, we discuss the structure of G_k , i.e., a t k -form of G .

Let S be a **maximal k -split torus** of G , i.e., a k -subtorus of G that is k -split and maximal with respect to these properties. Any two such tori are conjugate over k , i.e., by an element of G_k . Their dimension is called the k -rank of G . To say that G is of k -rank zero is equivalent to saying that G is t k -anisotropic. The centralizer $Z = Z_\infty(S)$ of S in G is a reductive k -group, and its derived group is k -anisotropic. Let $N = N_\infty(S)$ be the normalizer of S in G . The t Weyl group ${}_k W = N/Z$ relative to S is called the **k -Weyl group** of G . A **k -root** of G with respect to S is a nontrivial character of S that appears when one diagonalizes the representation of S in the t Lie algebra \mathfrak{g} of G , S operating via adjoint representation. Denote by ${}_k r$ the set of all k -roots of G with respect to S .

There is a decomposition of the Lie algebra \mathfrak{g} of G : $\mathfrak{g} = \mathfrak{g}_0 + \sum_{\alpha \in {}_k r} \mathfrak{g}_\alpha$ where $\mathfrak{g}_\alpha = \{X \in \mathfrak{g} \mid \text{Ad}(s)X = \alpha(s)X \text{ for all } s \in S\}$. Then \mathfrak{g}_0 is the Lie algebra of Z , and there is a unique unipotent k -subgroup P_α of G normalized by S such that its Lie algebra is \mathfrak{g}_α . The set ${}_k r$ is a t root system in a suitable Euclidean space whose Weyl group is isomorphic to ${}_k W$; if G is k -split, ${}_k r$ is the ordinary root system, and the P_α are as in Section J. In general, ${}_k r$ need not be reduced (i.e., axiom (iii) in Section J need not be satisfied), nor should $\dim \mathfrak{g}_\alpha = \dim P_\alpha$ always be 1.

A closed subgroup of G defined over k which is minimal among the parabolic subgroups of G is called a **minimal paraholic k -subgroup** of G . (If G is k -split, a minimal para-

bolic k -subgroup is a t Borel subgroup of G .) Any two minimal paraholic k -subgroups are conjugate to each other over k . If P is one such subgroup, then there exists a maximal k -split torus S such that P is the semidirect product of the reductive k -subgroup $Z = Z_\infty(S)$ and the t unipotent radical $U = R_\infty(P)$ of P . The expression $P = ZU$ is called a **Levi-decomposition** of P , and Z is called a **Levi-subgroup** of P . Any two Levi-subgroups of P are conjugate by an element in U_k . There is an ordering of ${}_k r$ such that P is generated by Z and P_α with $\alpha > 0$. The minimal parabolic k -subgroups containing a given maximal k -split torus S correspond to the t Weyl chambers of ${}_k r$. They are permuted simply transitively by the Weyl group ${}_k W$.

Fix an ordering of ${}_k r$, and let ${}_k \Delta$ be the t fundamental system of ${}_k r$ with respect to the given order. For any subset θ of ${}_k \Delta$, denote by P_θ the subgroup generated by $Z = Z_\infty(S)$ and P_α , where α is a linear combination of the roots of ${}_k r$ in which all roots not in θ occur with a coefficient ≥ 0 . Then P_θ contains P and, in particular, $P_\emptyset = P$. P_θ is called a **standard paraholic k -subgroup** of G containing P . Any paraholic k -subgroup of G is conjugate over k to a unique P_θ . If S_θ is the identity component of $\bigcap_{\alpha \in \theta} (\ker \alpha)$, then S_θ is a k -split torus of G and $P_\theta = Z(S_\theta)R_u(P_\theta)$. This shows that any paraholic k -subgroup of G has a Levi-decomposition and its Levi-subgroups are conjugate to each other over k . Let P be a minimal paraholic k -subgroup of G containing a maximal k -split torus S . Put $U = R_\infty(P)$, $Z = Z_\infty(S)$, and $N = N_\infty(S)$. Then, $N = N_k Z$, so G_k is the disjoint union over ${}_k W$ of double cosets $U_k n_w P_k$ ($w \in {}_k W$), where n_w is a representative in N_k of $w \in {}_k W$. More precisely, if $w \in {}_k W$, there exist two k -subgroups U'_w and U''_w such that $U = U'_w \times U''_w$ (product of k -varieties), the map $U'_w \times P \rightarrow U n_w P$ sending (x, y) onto $x n_w y$ is an isomorphism, and

$$(G/P)_k = G_k/P_k = \bigcup_{w \in {}_k W} \pi((U'_w)_k),$$

where π is the projection $G \rightarrow G/P$. This is called a **relative Bruhat decomposition**. If G is k -split, this gives an ordinary Bruhat decomposition (\rightarrow Section K). If θ is a subset of ${}_k \Delta$, let W_θ be the subgroup of ${}_k W$ generated by reflections defined by the α 's in θ . If θ, θ' are subsets of ${}_k \Delta$, then there is a bijection of double cosets

$$(P_\theta)_k \backslash G_k / (P_{\theta'})_k = W_\theta \backslash {}_k W / W_{\theta'}.$$

(Note that all these properties follow from the fact that (P_k, N_k) is a BN-pair in G_k ; \rightarrow Section R.)

If G is k -isotropic, let G^+ be the subgroup of G_k generated by all U_k , where U runs over the unipotent radicals of the minimal paraholic k -

subgroups of G . Kneser and Tits conjectured that when G is semisimple and simply connected and k arbitrary, $G_k = G^+$. Platonov showed that this conjecture fails for some k -forms of SL_n ($n \geq 2$), but it is true in many cases, e.g., when G is k -split or k -quasi-split (J. Tits, *Sém. Bourbaki* 29e, no. 505, 1976677). In this case, if G is simple as an algebraic group and the cardinality of k is ≥ 4 , then $G_k/Z(G_k)$ is simple as an abstract group. The connected semisimple algebraic k -groups over a finite field k are k -split or k -quasi-split (\rightarrow Section 0). J. Tits has given a reduction process for classifying the groups over an arbitrary field k . He defined the index of the k -group (to a certain extent a generalization of Witt's theorem characterizing a quadratic form by means of its index and anisotropic kernel) and gave all possible indices of the k -groups and also a complete list in the case of local field (J. Tits [30, 31]).

R. Buildings and BN-pairs [25]

The origin of the notations of buildings and BN-pairs lies in an attempt to give a systematic procedure for the geometric interpretation of the semisimple Lie groups and, in particular, the exceptional groups. The theory has various applications to the groups of Lie types. To describe this precisely, we must introduce a number of definitions.

A **complex** A is a set with an order relation \subset , read "is a **face** of" or "is contained in" such that for a given element A , the ordered subset $S(A)$ of all faces of A is isomorphic to the set of all subsets of a set. The subset $S(A)$ of A is called a **simplex** in A . A complex has a smallest element, which we denote by 0. For an element A , the number $\text{rk } A$ of minimal nonzero faces of A is called the **rank** of A . Define $\text{rk } A = \sup\{\text{rk } A' \mid A' \in \Delta\}$. A **morphism** $\alpha: \Delta \rightarrow \Delta'$ (where A and A' are complexes) is a mapping of the underlying sets such that for every $A \in \Delta$, $S(A) \cong S(\alpha(A))$. A subcomplex of A is a complex whose underlying set is a subset of A such that the inclusion is a morphism. If $A \in \Delta$, the **star** $\text{St}(A)$ of A is the set of all elements of A containing A . With the order relation induced from A , $\text{St}(A)$ is a complex. If $B \in \text{St}(A)$, the rank of B in $\text{St}(A)$ is called the **codimension** of A in B and is denoted by $\text{codim}_B A$.

A complex A is called a **chamber complex** if every element is contained in a maximal element, which is called a **chamber**, and if given two chambers C, C' , there exists a sequence of chambers $C = C_0, C_1, \dots, C_m = C'$ such that $\text{codim}_{C_{i-1}}(C_{i-1} \cap C_i) = \text{codim}_{C_i}(C_{i-1} \cap C_i) \leq 1$ for all $i = 1, 2, \dots, m$. A chamber complex is called **thick** (resp. **thin**) if every element of

codimension 1 is contained in at least three (resp. exactly two) chambers. An endomorphism φ of a thin chamber complex A is called a **folding** if $\varphi^2 = \text{id}$ and if any chamber on $\varphi(\Delta)$ is the image of exactly two chambers in A by φ . For any folding φ , $\varphi(\Delta)$ is called a **root**. A thin chamber complex is called a **Coxeter complex** if for any pair of **adjacent** chambers C, C' , i.e., chambers such that $\text{codim}_C(C \cap C') = 1$, there is a root containing C and not C' . Let Σ be a Coxeter complex. For any root $\varphi(\Sigma)$ of Σ , there is only one root $\varphi'(\Sigma)$, called the **opposite** of $\varphi(\Sigma)$, such that $\varphi(\Sigma) \cap \varphi'(\Sigma)$ does not contain any chamber and $\varphi(\Sigma) \cup \varphi'(\Sigma) = \Sigma$; there is also an involutive automorphism called the **reflection** associated with φ that transforms $\varphi(\Sigma)$ onto $\varphi'(\Sigma)$. The group $W(C)$ generated by all reflections of Σ is called the **Weyl group** of Σ , which turns out to be a **Coxeter group**, i.e., there exist sets I and $\{m_{ij}\}$, $(i, j) \in I \times I$, where m_{ij} are integers or ∞ and $m_{ii} = 1$, such that the group is presented by the generators $\{r_i\}_{i \in I}$ and the fundamental relations $(r_i r_j)^{m_{ij}} = 1$, $i, j \in I$, $m_{ij} \neq \infty$. A Coxeter complex is called **irreducible** if it is not the join of two nonempty Coxeter subcomplexes.

A **building** is a thick chamber complex A with a system \mathfrak{A} of Coxeter subcomplexes, called the **apartments** of A such that (i) every two simplexes of A belong to an apartment. (ii) If $\Sigma, \Sigma' \in \mathfrak{A}$, there exists an isomorphism of Σ onto Σ' that fixes $\Sigma \cap \Sigma'$ (elementwise). Since the apartments of a building are isomorphic to each other, we can define the Weyl group, rank, and irreducibility of the building to be those of its apartment. A building with finitely many chambers is said to be of **spherical type**. If a building can be realized as a simplicial decomposition of a Euclidean space, then one says it is of **Euclidean type**.

Examples of buildings are provided by **BN-pairs**. A **BN-pair** or **Tits system** in a group G is a system (B, N) consisting of two subgroups of G such that

- (BNO) B and N generate G ;
- (BN1) $B \cap N = H \triangleleft N$; and
- (BN2) The group $W = N/H$ has a generating set R such that for any $r \in R$ and any $w \in W$,
- (BN2') $rBw \subset BwB \cap BrwB$,
- (BN2'') $rBr \neq B$.

The group W is called the **Weyl group** of the BN-pair. For any subset S of R , let W_S denote the subgroup of W generated by S . Set $P_S = B W_S B$. Then P_S is a subgroup of G and the mapping $S \mapsto P_S$ is a bijection of the lattice of all subsets of R onto the lattice of all subgroups of G containing B . A subgroup of G is called **parabolic** if it is conjugate to some P_S . Let A be the set of all left cosets of all subgroups P_S , $S \subset R$, ordered by the opposite of the inclusion relation. Let G operate on A on

the left. Let Σ be the subset $\{nP_S \mid n \in N, S \subset R\}$ of A , and \mathfrak{A} be the set of G -translates of Σ . Then (A, \mathfrak{A}) is a building whose Weyl group is W .

Let G be a reductive algebraic group defined over a field k and P be a minimal parabolic k -subgroup of G containing a maximal k -split torus S and set $N = N_k(S)$. Then (P_k, N_k) is a BN-pair in G_k . Therefore there is a building of spherical type associated with the group G . Conversely, the buildings of rank ≥ 3 and irreducible spherical type (roughly speaking) all turn out to be associated with simple algebraic or classical groups (J. Tits [25]). This result gives a complete and unified description of structures that were discovered previously in certain cases. For example, the building of type A , gives a projective space (E. Abe, T. Tsuzuku), that of type C_n gives a polar space (Veldkamp), and that of a k -form of type E_6 gives a Cayley space (J. Tits). As an application, one can show that a finite building of rank ≥ 3 and irreducible spherical type is isomorphic to the building of an absolutely simple algebraic group over a finite field.

When k is local (i.e., endowed with a complete discrete valuation whose residue field is Perfect), the reductive group defined over k has another BN-pair such that the associated building is Euclidean. This theory was initiated by N. Iwahori and H. Matsumoto [26], who considered split semisimple groups. Later, quasi-split and classical groups were studied by H. Hijikata, and the theory for the general case was given by F. Bruhat and J. Tits [27, 28]. To distinguish from the usual BN-pair structure, the subgroups conjugate to B in this case are called **Iwahori subgroups**, and parabolic subgroups are called **paraholic subgroups**. The Euclidean buildings are the "ultrametric analogs" of the Riemannian symmetric spaces. In other words, in the study of p -adic simple groups, they play a role similar to that of the symmetric spaces in the theory of simple groups.

14 (V.13) Algebraic Number Fields

A. Introduction

A complex number that satisfies an algebraic equation with rational integral coefficients is said to be an **algebraic number**. If the coefficient of the term of highest degree of the equation is 1, this algebraic number is said to be an **algebraic integer**. The set A of all algebraic numbers is a field which is the \dagger algebraic closure of the rational number field \mathbb{Q} in the complex number field \mathbb{C} . The set I of all algebraic integers is an \dagger integral domain which contains the integral domain \mathbb{Z} of all the rational integers. The \dagger field of quotients of I is A .

B. Principal Order

An extension field k of \mathbb{Q} of finite degree (which we shall always suppose to be contained in \mathbb{C}) is said to be an **algebraic number field** of finite degree, and k is a subfield of A . The intersection $\mathfrak{o} = k \cap I$ is an integral domain whose field of quotients is k ; \mathfrak{o} is called the **principal order** of k . (More generally, a subring R of \mathfrak{o} containing 1 is said to be an **order** of k if the field of quotients of R is k . The set \mathfrak{f} of all elements y of \mathfrak{o} such that $y\mathfrak{o} \subset R$ is an **ideal** of \mathfrak{o} ; in addition \mathfrak{f} is called the **conductor** of R .) Let n be the degree of k over \mathbb{Q} . Then the additive group of the principal order \mathfrak{o} of k is a \dagger free Abelian group of \dagger rank n . A \dagger basis $(\omega_1, \dots, \omega_n)$

of \mathfrak{o} as a free Abelian group (or \mathbb{Z} -module) is said to be a **minimal basis** of \mathfrak{o} (or of k). Let $\omega_j^{(i)}$ ($i = 1, \dots, n$) be \dagger conjugate elements of ω_j over \mathbb{Q} , and let $A = |\omega_j^{(i)}|$ be the determinant whose (i, j) entry is $\omega_j^{(i)}$. Then $D_k = A^2$ is a rational integer that is independent of the choice of a minimal basis of \mathfrak{o} . D_k is called the **discriminant** of k . If $k \neq \mathbb{Q}$, then $|D_k| > 1$ (**Minkowski's theorem**, 1891). For any given rational integer m there are only a finite number of algebraic number fields whose discriminants are equal to m (C. Hermite and H. Minkowski, 1896). The proof of these theorems depends on the methods of geometry of numbers (- 182 Geometry of Numbers).

C. Ideals of the Principal Order

An \dagger ideal \mathfrak{a} of the principal order \mathfrak{o} is said to be an **integral ideal** of k . In particular, a prime ideal ($\neq 0$) of \mathfrak{o} is called simply a prime ideal of k . The domain \mathfrak{o} is not necessarily a \dagger principal ideal ring but is always a \dagger Dedekind domain. That is, every ideal \mathfrak{a} of \mathfrak{o} is uniquely expressed (up to the order of the factors) as a finite product of powers of prime ideals of \mathfrak{o} . This theorem is called the **fundamental theorem of the principal order**.

The quotient ring $\mathfrak{o}/\mathfrak{a}$ of \mathfrak{o} by an ideal \mathfrak{a} ($\neq 0$) of \mathfrak{o} is a finite ring. The number of elements of $\mathfrak{o}/\mathfrak{a}$ is called the **absolute norm** of \mathfrak{a} and is denoted by $N(\mathfrak{a})$. We have $N(\mathfrak{a}\mathfrak{b}) = N(\mathfrak{a})N(\mathfrak{b})$. Every prime ideal \mathfrak{p} ($\neq 0$) of \mathfrak{o} is a \dagger maximal ideal of \mathfrak{o} , and $\mathfrak{o}/\mathfrak{p}$ is a finite field. Let the \dagger characteristic of $\mathfrak{o}/\mathfrak{p}$ be p , where p is a prime number. Then $\mathfrak{o}/\mathfrak{p}$ is a finite extension of the \dagger prime field $\mathbb{Z}/p\mathbb{Z}$. Let the degree of $\mathfrak{o}/\mathfrak{p}$ over $\mathbb{Z}/p\mathbb{Z}$ be f . Then $N(\mathfrak{p}) = p^f$, and f is said to be the **degree** of the prime ideal \mathfrak{p} .

Let s be a complex variable. The (complex-valued) function

$$\zeta_k(s) = \sum_{\mathfrak{a}} 1/N(\mathfrak{a})^s = \prod_{\mathfrak{p}} 1/(1 - (N(\mathfrak{p}))^{-s})$$

of $s \in \mathbb{C}$ is called the **Dedekind zeta function** of k (R. Dedekind, 1871). Here the summation extends over all ideals \mathfrak{a} of \mathfrak{o} , and the product extends over all prime ideals \mathfrak{p} of \mathfrak{o} . This series converges absolutely for $\text{Re } s > 1$, and the function $\zeta_k(s)$ has a single-valued \dagger analytic continuation to a \dagger meromorphic function on the whole complex plane (- 450 Zeta Functions).

D. Units

An algebraic integer ε of k is said to be a **unit** of k if ε^{-1} is also an algebraic integer. Hence ε is a unit of k if and only if the \dagger Principal ideal

(E) is 0. The set E_k of all units of k forms an Abelian group under multiplication, which is called the **unit group** of k . The set of all elements of E_k of finite order coincides with the set of all the roots of unity contained in k and forms a cyclic group of a finite order w . Let n be the degree of k over Q . Then for each element $\alpha \in k$ there are n conjugate elements $\alpha^{(i)}$ over Q . Let $\alpha^{(i)}$ ($i = 1, \dots, r_1$) be real for any $\alpha \in k$, and let $\alpha^{(r_1+j)}$ and $\alpha^{(r_1+r_2+j)}$ ($j = 1, \dots, r_2$) be pairs of complex conjugates for any $\alpha \in k$. Then we have $n = r_1 + 2r_2$. The unit group E_k of k is the direct product of a cyclic group of order w and the free Abelian multiplicative group of rank $r = r_1 + r_2 = 1$. This theorem is called **Dirichlet's unit theorem** (1846). A basis $(\varepsilon_1, \dots, \varepsilon_r)$ of this free group is called a system of **fundamental units** of k .

Let $l^{(i)}\alpha = \log|\alpha^{(i)}|$ ($i = 1, \dots, r_1$), $l^{(j)}\alpha = 2\log|\alpha^{(j)}|$ ($j = r_1 + 1, \dots, r_1 + r_2$) for $\alpha \in k$. For r elements η_1, \dots, η_r of E_k ,

$$R[\eta_1, \dots, \eta_r] = \begin{vmatrix} l^{(1)}\eta_1 & l^{(1)}\eta_2 & \dots & l^{(1)}\eta_r \\ l^{(2)}\eta_1 & l^{(2)}\eta_2 & & l^{(2)}\eta_r \\ \vdots & \vdots & \ddots & \vdots \\ l^{(r)}\eta_1 & l^{(r)}\eta_2 & & l^{(r)}\eta_r \end{vmatrix}$$

is called the **regulator** of (η_1, \dots, η_r) (Dedekind). In order for η_1, \dots, η_r to be multiplicatively independent, it is necessary and sufficient that $R[\eta_1, \dots, \eta_r] \neq 0$. The absolute value of $R[\eta_1, \dots, \eta_r]$ takes the minimum positive value R for fundamental units $(\varepsilon_1, \dots, \varepsilon_r)$. $R = R[\varepsilon_1, \dots, \varepsilon_r]$ is independent of the choice of fundamental units $(\varepsilon_1, \dots, \varepsilon_r)$ of k . R is called the **regulator** of k . In general, $R[\eta_1, \dots, \eta_r]/R$ is equal to the index $[E_k : H]$ of the group H generated by the roots of unity in k and η_1, \dots, η_r . H. W. Leopoldt conjectured that units in k , which are multiplicatively independent over Z , remain multiplicatively independent over Z_p (the ring of p -adic integers) when they are considered as elements of the tensor product $k \otimes Q_p$ over Q . This conjecture was affirmatively proved in some special cases by J. Ax (Illinois J. Math., 9 (1965)) and others.

If k/Q is a Galois extension, there exists a unit ε of k such that the conjugates of ε over Q contain r multiplicatively independent units (Minkowski's theorem).

E. Ideal Classes

An \mathfrak{o} -module contained in k (i.e., $\mathfrak{a}\mathfrak{o} \subset \mathfrak{a}$) such that $\alpha\mathfrak{a} \subset \mathfrak{o}$ holds for some element $\alpha (\neq 0)$ of k is said to be a **fractional ideal** of k . For two fractional ideals $\mathfrak{a}, \mathfrak{b}$ of k the "product" $\mathfrak{a}\mathfrak{b}$ defined by $\{\sum \alpha_i \beta_i \text{ (finite sum)} \mid \alpha_i \in \mathfrak{a}, \beta_i \in \mathfrak{b}\}$ is also a fractional ideal. Thus the set of the

fractional ideals of k forms a multiplicative commutative semigroup. For a fractional ideal \mathfrak{a} the set $\mathfrak{a}^{-1} = \{\alpha \in k \mid \alpha\mathfrak{a} \subset \mathfrak{o}\}$ is also a fractional ideal of k , and we have $\mathfrak{a}\mathfrak{a}^{-1} = \mathfrak{o}$. Thus the set of all nonzero fractional ideals of k forms an Abelian group \mathfrak{I}_k under multiplication with \mathfrak{o} as identity. Each fractional ideal $\mathfrak{a} (\neq \mathfrak{o})$ is uniquely expressed as a finite product of powers of prime ideals, if we admit negative powers. Namely, \mathfrak{I}_k is a free Abelian multiplicative group with the set of all prime ideals as basis. Given fractional ideals \mathfrak{a} and \mathfrak{b} , we say that \mathfrak{a} is **divisible** by \mathfrak{b} if $\mathfrak{a} \subset \mathfrak{b}$; in this case, we call \mathfrak{b} a **divisor** of \mathfrak{a} and \mathfrak{a} a **multiple** of \mathfrak{b} . Also, $\mathfrak{a} \subset \mathfrak{b}$ if and only if there exists an integral ideal \mathfrak{c} such that $\mathfrak{a} = \mathfrak{b}\mathfrak{c}$. Given fractional ideals $\mathfrak{a} = \prod \mathfrak{p}_i^{e_i}$ and $\mathfrak{b} = \prod \mathfrak{q}_j^{f_j}$ ($e_i \neq 0, f_j \neq 0$), we say that \mathfrak{a} and \mathfrak{b} are **relatively prime** if $\{\mathfrak{p}_i\}$ and $\{\mathfrak{q}_j\}$ are disjoint. Usually a fractional ideal of k is simply called an ideal of k .

For an element $\alpha (\neq 0)$ of k , $(\alpha) = \alpha\mathfrak{o}$ is a (fractional) ideal of k , and (α) is said to be a **principal ideal** of k . The set P_k of all principal ideals (α) ($\alpha \in k, \alpha \neq 0$) is a subgroup of \mathfrak{I}_k . Since $(\alpha) = \mathfrak{o}$ is equivalent to $\alpha \in E_k$, we have $P_k \cong k^*/E_k$, where k^* is the multiplicative group of all nonzero elements of k .

Each coset of \mathfrak{I}_k modulo P_k is called an **ideal class** of k , and the group $\mathfrak{C}_k = \mathfrak{I}_k/P_k$ is called the **ideal class group** of k . Each ideal class contains an integral ideal \mathfrak{a} with $N(\mathfrak{a}) \leq \sqrt{|D_k|}$ (more precisely, with $N(\mathfrak{a}) \leq (4/\pi)^{r_2} (n!/n^n) \sqrt{|D_k|}$). From this it follows that \mathfrak{C}_k is a finite Abelian group. The order h of \mathfrak{C}_k is called the **class number** of k . For the calculation of the class number the \dagger residue at the pole $s = 1$ of the Dedekind zeta function is used. Namely,

$$\lim_{s \rightarrow 1+0} (s-1)\zeta_k(s) = gh,$$

$$g = 2^{r_1+r_2} \pi^{r_2} R_k / w_k \sqrt{|D_k|},$$

where R_k is the regulator of k and w_k is the number of roots of unity in k (Dedekind, 1877). This formula is used, in particular, for the computation of the class numbers of \dagger quadratic fields and \dagger cyclotomic fields (- 347 Quadratic Fields). The class numbers of cubic and quartic (real) \dagger cyclic fields over Q were computed by H. Hasse in the case where the \dagger conductor of k/Q is less than 100 (*Abh. Deutsch. Akad. Wiss. Berlin*, 2 (1948)). Hasse has also given a detailed computation of the class number of cyclotomic fields [15]. In general, let the degree $n = [k: Q]$ be fixed and let $|D_k| \rightarrow \infty$. Then

$$\lim (\log(h_k R_k) / \log \sqrt{|D_k|}) = 1.$$

(This formula was proved for $n = 2$ by C. L. Siegel, 1935, and for general n by R. Brauer, *Amer. J. Math.*, 69 (1947).)

F. Valuations

All the \dagger Archimedean and \dagger non-Archimedean valuations of an algebraic number field k can be obtained as follows (- 439 Valuations):

Archimedean Valuations. Let $\eta = [k: \mathbf{Q}]$, and let η conjugates of $\alpha \in k$ be $\alpha^{(1)}, \dots, \alpha^{(\eta)}$ such that $\alpha^{(i)}$ ($i = 1, \dots, r_1$) is real, and $\alpha^{(r_1+j)}$ and $\alpha^{(r_1+r_2+j)}$ ($j = 1, \dots, r_2$) are pairs of complex conjugates. We write $|\alpha|_i = |\alpha^{(i)}|$ ($j = 1, r_1 + r_2$); these are Archimedean valuations of k that are not mutually equivalent. The equivalence classes of these valuations are denoted by $p_{\infty}^{(1)}, \dots, p_{\infty}^{(r_1+r_2)}$, respectively, and are called the \dagger infinite prime divisors of k . The first r_1 infinite prime divisors are called \dagger real and the remaining r_2 are called \dagger imaginary (or complex). The valuations of k defined by

$$|\alpha|_{p_j} = |\alpha|_j, \quad j = 1, \dots, r_1, \\ = |\alpha|_j^2, \quad j = r_1 + 1, \dots, r_1 + r_2,$$

are called \dagger normal valuations of k . Here $|_{p_j}$ ($j = r_1 + 1, \dots, r_1 + r_2$) are valuations in the wider sense. If $r_1 = \eta$ we call k a **totally real field**, and if $r_1 = 0$ we call k a **totally imaginary field**.

Non-Archimedean Valuations. Let p be a prime ideal of k and α an element of k . Let $(\alpha) = p^a b$, where p and b are relatively prime. Put $v_p(\alpha) = a$. Then for any constant ρ ($0 < \rho < 1$),

$$|\alpha|_p = \rho^{v_p(\alpha)}$$

is a non-Archimedean valuation of k . This valuation of k is called the \dagger p -adic valuation of k ; p -adic valuations for different prime ideals are mutually inequivalent. The valuation $|\alpha|_p$ with $\rho = (N(p))^{-1}$ is called a \dagger normal valuation of k . The equivalence class of valuations containing $|_p$ is denoted by the same letter p and is called a \dagger finite prime divisor of k .

A formal finite product of powers of finite or infinite prime divisors $m^* = \prod p_i^{e_i}$ is called a **divisor** of k . If all $e_i \geq 0$, then m^* is called an **integral divisor** of k . Given divisors $m^* = \prod p_i^{e_i}$ and $n^* = \prod p_i^{f_i}$, we write $m^* \cdot n^*$ if $e_i \leq f_i$ ($i = 1, 2, \dots$).

Any valuation of k is equivalent to one of the valuations defined previously (A. Ostrowski, 1918; E. Artin, 1932). For any element α ($\neq 0$) of k the \dagger product formula $\prod_p |\alpha|_p = 1$ holds, where p runs over all finite and infinite prime divisors of k and $|_p$ are the normal valuations of k . Conversely, let k be a field, and let $V = \{ |_p \}$ be a set of inequivalent valuations of k such that (i) for any $a \in k$ ($a \neq 0$) $|\alpha|_p \neq 1$ holds only for a finite number of p in V ; (ii) the product formula $\prod_p |\alpha|_p = 1$ ($\alpha \in k$,

$\alpha \neq 0$) holds; and (iii) there is at least one Archimedean valuation in V . Then k is an algebraic number field and V is the set of all the prime divisors of k (Artin and G. Whaples, *Bull. Amer. Math. Soc.*, 51 (1945)).

G. Ideal Classes in the Narrow Sense

For $a, \beta \in k$, the expression $a \equiv \beta \pmod{p_{\infty}^{(i)}}$ means $\alpha^{(i)} \beta^{(i)} > 0$ for a real infinite prime divisor $p_{\infty}^{(i)}$ and $\alpha^{(i)} \beta^{(i)} \neq 0$ for an imaginary infinite prime divisor $p_{\infty}^{(i)}$. We call an element $\alpha \in k$ **totally positive** if all real conjugates $\alpha^{(i)}$ ($i = 1, \dots, r_1$) are positive. In the notation just given, this means $a \equiv 1 \pmod{p_{\infty}^{(i)}}$ ($i = 1, \dots, r_1$). The set of all principal ideals (a) generated by totally positive elements $a \in k$ is a multiplicative subgroup P_k^+ of P_k . Each coset of \mathfrak{J}_k modulo P_k^+ is called an **ideal class of k in the narrow sense**. Let E_k^+ be the group of all totally positive units of k . Then we have $(\mathfrak{J}_k : P_k^+) = h 2^{r_1} / (E_k : E_k^+)$.

H. Multiplicative Congruence

Let m be an integral ideal of k , and let $k^*(m)$ be the multiplicative group of all elements a in k such that (a) is relatively prime to m . Any element $\alpha \in k^*(m)$ can be expressed in the form $\alpha = \beta/\gamma$ such that $\beta, \gamma \in o$ and $(\beta), (\gamma)$ are relatively prime to m .

Consider an integral divisor $m^* = m \prod p_{\infty}^{(i)}$ which is a formal product of m and infinite prime divisors $p_{\infty}^{(i)}$ of k . We call m the finite part of m^* . Given an element $\alpha \in k^*(m)$ and elements $\beta, \gamma \in k^*(m) \cap o$ such that $a = \beta/\gamma$, we set $a \equiv 1 \pmod{m^* n^*}$ if $\beta \equiv \gamma \pmod{m n}$, and $a \equiv 1 \pmod{p_{\infty}^{(i)}}$. The set of all a in $k^*(m)$ such that $a \equiv 1 \pmod{m^*}$ forms a multiplicative group. We write $a \equiv \beta \pmod{m^*}$ for $a, \beta \in k$ if $\alpha/\beta \in k^*(m)$ and $\alpha/\beta \equiv 1 \pmod{m^*}$. This congruence is called the **multiplicative congruence**. In the following discussion we shall write $\text{mod } m^*$ for $\text{mod } m^*$.

We denote by $\mathfrak{J}_k(m)$ the group of all ideals of k that are relatively prime to an integral ideal m , and by $S(m^*)$ the group of all principal ideals (a) such that $a \in k^*(m)$, $a \equiv 1 \pmod{m^*}$; $S(m^*)$ is known as the **ray** modulo m^* . Any subgroup H of $\mathfrak{J}_k(m)$ which contains $S(m^*)$ is called an **ideal group** modulo m^* , and the factor group $\mathfrak{J}_k(m)/H$ is called a **group of congruence classes** of ideals modulo m^* .

If $n^* \mid m^*$ for integral divisors m^* and n^* of k , then $\mathfrak{J}_k(m) \subset \mathfrak{J}_k(n)$ and $S(m^*) \subset S(n^*)$. If H is an ideal group modulo n^* , then $Q(H) = H \cap \mathfrak{J}_k(m)$ is an ideal group modulo m^* , and we have $\mathfrak{J}_k(n)/H \cong s.(m)/@.(H)$. For any given ideal group H_0 modulo m^* there is a smallest

integral divisor \mathfrak{f}^* such that $\mathfrak{f}^* \mid \mathfrak{m}^*$, and there exists an ideal group H modulo \mathfrak{f}^* with $\Phi(H) = H_0$ (i.e., if there is an ideal group H' modulo \mathfrak{n}^* with $\Phi(H') = H_0$, then $\mathfrak{f}^* \mid \mathfrak{n}^*$). We call \mathfrak{f}^* the **conductor** of the ideal group H . The notion of multiplicative congruence is used in \dagger class field theory and in the theory of \dagger norm-residue symbols.

I. Ideal Theory for Relative Extensions

If an algebraic number field K has a subfield k , we say that K/k is a **relative algebraic number field**. Let \mathfrak{D} be the principal order of K . For a (fractional) ideal \mathfrak{a} of k , $\mathfrak{D}\mathfrak{a}$ is an ideal of K . We write $\mathfrak{D}\mathfrak{a} = E(\mathfrak{a})$ and call $E(\mathfrak{a})$ the **extension** of \mathfrak{a} to K . For ideals $\mathfrak{a}, \mathfrak{b}$ of k , we have $E(\mathfrak{a}\mathfrak{b}) = E(\mathfrak{a})E(\mathfrak{b})$ and $E(\mathfrak{a}) \cap k = \mathfrak{a}$.

Let $\Psi_i: K \rightarrow \mathbb{C}$ be k -isomorphisms ($i = 1, \dots, n$), where $n = [K:k]$. We write $K^{(i)} = \Psi_i(K)$ and $A^{(i)} = Y_i(A)$ for $A \in K$. For an ideal \mathfrak{A} of K , $\mathfrak{A}^{(i)} = \{A^{(i)} \mid A \in \mathfrak{A}\}$ is an ideal of $K^{(i)}$, and $\mathfrak{A}^{(i)}$ is called the **conjugate ideal** of \mathfrak{A} in $K^{(i)}$. Let L be the composite field of $K^{(1)}, \dots, K^{(n)}$. Then the ideal generated by $\mathfrak{A}^{(1)} \dots \mathfrak{A}^{(n)}$ in L is the extension of an ideal \mathfrak{a} of k . We write $\mathfrak{a} = N_{K/k}(\mathfrak{A})$ and call \mathfrak{a} the **relative norm** of \mathfrak{A} over k . We have $N_{K/k}(\mathfrak{A}\mathfrak{B}) = N_{K/k}(\mathfrak{A})N_{K/k}(\mathfrak{B})$ and $N_{K/k}(E(\mathfrak{a})) = \mathfrak{a}$ (for an ideal \mathfrak{a} of k). In particular, for $k = \mathbb{Q}$, $N_{K/\mathbb{Q}}(\mathfrak{A}) = (N(\mathfrak{A}))$.

Let \mathfrak{p} be a prime ideal of k . Then $E(\mathfrak{p}) = \mathfrak{P}_1^{e_1} \mathfrak{P}_2^{e_2} \dots \mathfrak{P}_g^{e_g}$ in \mathfrak{D} , where $\mathfrak{P}_1, \dots, \mathfrak{P}_g$ are prime ideals of K . Let f_i be the degree of the finite field $\mathfrak{D}/\mathfrak{P}_i$ over $\mathfrak{o}/\mathfrak{p}$. Then $N_{K/k}(\mathfrak{P}_i) = \mathfrak{p}^{f_i}$; f_i is called the **relative degree** of \mathfrak{P}_i over k , and e_i is called the (relative) **ramification index** of \mathfrak{P}_i over k . We have the relation $n = \sum_{i=1}^g e_i f_i$ between these numbers. If $e_i = e_g = 1$, the prime ideal \mathfrak{p} is said to be **unramified** for K/k . Otherwise, \mathfrak{p} is said to be **ramified** for K/k . If every prime ideal of k is unramified for K/k , we call K/k an **unramified extension**. (For an infinite prime divisor \mathfrak{p}_∞ of k we write $\mathfrak{p}_\infty = \prod_{i=1}^g \mathfrak{P}_\infty^{(i)e_i}$ if the Archimedean valuation $|\cdot|_{\mathfrak{p}_\infty}$ of k can be extended to g Archimedean valuations $|\cdot|_{\mathfrak{P}_\infty^{(i)}} (i = 1, \dots, g)$ of K , where $e_i = 2$ if $\mathfrak{P}_\infty^{(i)}$ is imaginary and \mathfrak{p}_∞ is real, $e_i = 1$ otherwise.)

J. Relative Differents and Relative Discriminants

Let K/k be a relative algebraic number field and $\mathfrak{o}, \mathfrak{o}_K$ be the principal orders of k, K , respectively. Put $\mathfrak{M} = \{A \in K \mid \text{Tr}_{K/k}(A\mathfrak{D}) \subset \mathfrak{o}\}$, where $\text{Tr}_{K/k}$ is the \dagger trace (- 149 Fields J). Then \mathfrak{M} is a (fractional) ideal of K and $\mathfrak{M}^{-1} = \mathfrak{D}_{K/k}$ is an integral ideal of K ; $\mathfrak{D}_{K/k}$ is called the **rela-**

tive different of K over k . When $k = \mathbb{Q}$, $\mathfrak{D}_{K/\mathbb{Q}}$ is simply called the **different** of K . For $L \supset K \supset k$, we have the **chain theorem**: $\mathfrak{D}_{L/k} = \mathfrak{D}_{L/K} \mathfrak{D}_{K/k}$.

Let the conjugates of $A \in K$ over k be $A^{(1)}, \dots, A^{(n)}$, and assume that $A^{(1)} = A$. Put $\delta_{K/k}(A) = \prod_{i=2}^n (A - A^{(i)})$ for $A \in K$. If $A \in \mathfrak{D}$, then $\delta_{K/k}(A) \in \mathfrak{D}_{K/k}$. $\mathfrak{D}_{K/k}$ is generated by $\{\delta_{K/k}(A) \mid A \in \mathfrak{D}\}$. The integral ideal $\mathfrak{E}^{(i)}$ generated by $\{A - A^{(i)} \mid A \in \mathfrak{D}\}$ in the field $L = K^{(1)}K^{(2)} \dots K^{(n)}$ was called an *element* by D. Hilbert. We also have $\mathfrak{D}_{K/k} = \mathfrak{E}^{(2)}\mathfrak{E}^{(3)} \dots \mathfrak{E}^{(n)}$. The integral ideal $\mathfrak{d}_{K/k} = N_{K/k}(\mathfrak{D}_{K/k})$ of k is called the **relative discriminant** of K/k . If $k = \mathbb{Q}$, $\mathfrak{d}_{K/\mathbb{Q}} = (D_K)$.

For the relative different $\mathfrak{D}_{K/k}$ to be divisible by a prime ideal \mathfrak{P} of K , it is necessary and sufficient that $E(\mathfrak{p}) = \mathfrak{P}^e \mathfrak{P}_2^{e_2} \dots \mathfrak{P}_g^{e_g}$ with $e > 1$, where $\mathfrak{p} = \mathfrak{P} \cap k$ (**Dedekind's discriminant theorem**, 1882). Hence a prime ideal \mathfrak{p} of k is ramified for K/k if and only if \mathfrak{p} divides the relative discriminant $\mathfrak{d}_{K/k}$; there are thus only a finite number of prime ideals of k which ramify for K/k . In particular, K/k is unramified if and only if $\mathfrak{d}_{K/k} = 0$.

K. Arithmetic of Galois Extensions

Let K/k be a relative algebraic number field such that K is a \dagger Galois extension of k of degree n , and let G be the \dagger Galois group of K/k . Let $\mathfrak{o}, \mathfrak{D}$ be the principal order of k, K , respectively. The conjugate ideals of an ideal \mathfrak{A} of K are given by $\mathfrak{A}^\sigma = \{A^\sigma \mid A \in \mathfrak{A}\} (\sigma \in G)$. If $N_{K/k}(\mathfrak{A}) = \mathfrak{a}$, then $E(\mathfrak{a}) = \prod_{\sigma \in G} \mathfrak{A}^\sigma$. For a prime ideal \mathfrak{p} of k , $E(\mathfrak{p}) = (\mathfrak{P}_1 \mathfrak{P}_2 \dots \mathfrak{P}_g)^e$, where $N_{K/k}(\mathfrak{P}_i) = \mathfrak{p}^{f_i} (i = 1, \dots, g)$, $n = efg$, and $\mathfrak{P}_1, \dots, \mathfrak{P}_g$ are mutually conjugate prime ideals of K over k .

Hilbert (1894) developed the decomposition theory of a prime ideal \mathfrak{p} of k for a Galois extension K/k in terms of the Galois group G as follows: Let \mathfrak{P} be a prime ideal of \mathfrak{D} . Then

$$Z = \{\sigma \in G \mid \mathfrak{P}^\sigma = \mathfrak{P}\}$$

is a subgroup of the Galois group G of K/k . Z is called the **decomposition group** of \mathfrak{P} over k . Let $G = \bigcup_i Z\tau_i$ be the left coset decomposition of G . Then $\mathfrak{P}_i = \mathfrak{P}^{\tau_i} (i = 1, \dots, g)$ are all the conjugate ideals of \mathfrak{P} over k .

The subgroup

$$T = \{\sigma \in Z \mid A^\sigma \equiv A \pmod{\mathfrak{P}}, A \in \mathfrak{D}\}$$

of the decomposition group Z is normal, and T is called the **inertia group** of \mathfrak{P} over k . The quotient group Z/T is a cyclic group of order f (the relative degree of \mathfrak{P}). There exists an element σ of Z such that

$$A^\sigma \equiv A^{N(\mathfrak{p})} \pmod{\mathfrak{P}}, \quad A \in \mathfrak{D},$$

and σ is uniquely determined mod T ; σT gen-

erates the cyclic group Z/T . This σ is called the **Frobenius substitution** (or **Frobenius automorphism**) of \mathfrak{P} over k . For $m = 1, 2, \dots$,

$$V^{(m)} = \{\sigma \in Z \mid A^\sigma \equiv A \pmod{\mathfrak{P}^{m+1}}, A \in \mathfrak{D}\}$$

are normal subgroups of Z ; the group $V^{(m)}$ is called the m th **ramification group** of \mathfrak{P} over k . Let

$$\begin{aligned} V^{(0)} &= \dots = V^{(v_1)} \supsetneq V^{(v_1+1)} = \dots \\ &= V^{(v_2)} \supsetneq \dots \supsetneq V^{(v_{r-1}+1)} = \dots \\ &= V^{(v_r+1)} \supsetneq V^{(v_r+1)} = 1 \end{aligned}$$

Let $V_\rho = V^{(v_\rho+1)}$ ($\rho = 0, 1, \dots, r$), where $v_0 = -1$. In particular, $V_0 = V^{(0)} = T$. The integers v_1, v_2, \dots are called the **ramification numbers** of \mathfrak{P} . The group T/V_1 is isomorphic to a subgroup of the multiplicative group of the finite field $\mathfrak{D}/\mathfrak{P}$. Hence T/V_1 is a cyclic group whose order e_0 is a divisor of $N(\mathfrak{P}) - 1$. The group V_m/V_{m+1} ($m \geq 1$) is isomorphic to a subgroup of the additive group of the finite field $\mathfrak{D}/\mathfrak{P}$. Hence V_m/V_{m+1} is an Abelian group of type (p, p, \dots, p) whose order divides $N(\mathfrak{P})$. From $e = |T| = (T: V_1)/|V_1|$ it follows that $e = e_0 p^h$, $(e_0, p) = 1$. Here G_1 denotes the order of a finite group G . Hence the decomposition group of \mathfrak{P} is a \dagger solvable group. The relation between the ramification numbers for K/k and those for an intermediate Galois extension F/k was completely determined by J. Herbrand (*J. Math. Pures Appl.*, 10 (1931)) [III].

Let \mathfrak{P}^d be the \mathfrak{P} -component of the relative different $\mathfrak{D}_{K/k}$ of a Galois extension K/k . Then

$$d = \sum_{\rho=0}^{r-1} (v_{\rho+1} - v_\rho)(|V_\rho| - 1) = \sum_{i=0}^{v_r} (|V^{(i)}| - 1).$$

In particular, $d = 0$ if $T = 1$, and $d = e - 1$ if $V^{(1)} = 1$.

Let k_Z, k_T , and $k_{V^{(m)}}$ be the intermediate fields which correspond to the subgroups Z, T , and $V^{(m)}$, respectively, in the sense of \dagger Galois theory; the fields k_Z, k_T , and $k_{V^{(m)}}$ are called the **decomposition field**, the **inertia field**, and the m th **ramification field** of \mathfrak{P} , respectively. Let \mathfrak{P} be a prime ideal of K containing \mathfrak{p} , and let \mathfrak{p}_Z and \mathfrak{p}_T be prime ideals in k_Z and k_T such that $\mathfrak{p}_Z = \mathfrak{P} \cap k_Z$ and $\mathfrak{p}_T = \mathfrak{P} \cap k_T$. Then we have $E(\mathfrak{p}) = \mathfrak{p}_Z \mathfrak{p}_Z^{(2)} \mathfrak{p}_Z^{(g)}$ for k_Z/k ; $E(\mathfrak{p}_Z) = \mathfrak{p}_T$ and $N_{k_T/k_Z}(\mathfrak{p}_T) = \mathfrak{p}_Z^f$ for k_T/k_Z ; and $E(\mathfrak{p}_T) = \mathfrak{P}^e$ for K/k_T .

If a prime ideal \mathfrak{p} of k is unramified for a Galois extension K/k then we have $E(\mathfrak{p}) = \mathfrak{P}_1 \mathfrak{P}_2 \mathfrak{P}_g$, $\mathfrak{P}_i = \mathfrak{P}^{f_i}$ ($i = 1, \dots, g$), $N_{N/k}(\mathfrak{P}_i) = \mathfrak{p}^{f_i}$, and $n = fg$. The Frobenius automorphism $\sigma_i: A^{\sigma_i} \equiv A^{N^{(v)}} \pmod{\mathfrak{P}_i}$ ($A \in \mathfrak{D}$) for the prime ideal \mathfrak{P}_i is uniquely determined, and its order is f_i . Since $\mathfrak{P}_i = \mathfrak{P}^{f_i}$, we have $\sigma_i = \tau_i^{-1} \sigma_1 \tau_i$. Hence $\sigma_1, \dots, \sigma_g$ belong to the same \dagger conjugate class of G . In particular, if G is an Abelian group, then $\sigma_1 = \dots = \sigma_g$ and

$$A^{\sigma_1} \equiv A^{N^{(v)}} \pmod{\mathfrak{p}}, \quad A \in \mathfrak{D}.$$

We then write

$$\sigma_1 = \left(\frac{k}{\mathfrak{p}} \right) \in G$$

and call this symbol the **Artin symbol** for \mathfrak{p} for the Abelian extension K/k . For an ideal $\mathfrak{a} = \prod \mathfrak{p}^{e_i}$ of k that is relatively prime to the relative discriminant of K/k , we define

$$\left(\frac{K/k}{\mathfrak{a}} \right) = \prod \left(\frac{K/k}{\mathfrak{p}} \right)^{e_i} \quad (\in G)$$

Evidently, we have

$$\left(\frac{K/k}{\mathfrak{ab}} \right) = \left(\frac{K/k}{\mathfrak{a}} \right) \left(\frac{K/k}{\mathfrak{b}} \right).$$

The arithmetic of quadratic fields (\rightarrow 347 Quadratic Fields) and the arithmetic of cyclotomic fields (\rightarrow Section L) have been developed since the 19th Century.

L. Arithmetic of Cyclotomic Fields

A complex number ζ whose m th power is 1 but whose m' th power is not 1 for $m' < m$ is called an m th **primitive root of unity**. There are $\varphi(m)$ primitive roots of unity: $\exp(2\pi i r/m)$ ($(r, m) = 1$), where φ is \dagger Euler's function. These $\varphi(m)$ primitive roots of unity are the zeros of an irreducible polynomial over \mathbb{Q} of degree $\varphi(m)$:

$$F_m(X) = \prod_{d|m} (X^{m/d} - 1)^{\mu(d)},$$

where μ is the \dagger Möbius function. The coefficient of the highest term of $F_m(X)$ is 1, and the other coefficients are all rational integers.

$F_m(X)$ is called a **cyclotomic polynomial**. An example is

$$\begin{aligned} F_{12}(X) &= (X^{12} - 1)(X^2 - 1)/(X^6 - 1)(X^4 - 1) \\ &= X^4 - X^2 + 1. \end{aligned}$$

The algebraic number field $K_m = \mathbb{Q}(\zeta_m)$ ($\zeta_m = \exp(2\pi i/m)$) obtained by adjoining an m th primitive root of unity to \mathbb{Q} is a Galois extension over \mathbb{Q} of degree $\varphi(m)$ whose Galois group G is isomorphic to the multiplicative Abelian group of \dagger reduced residue classes of \mathbb{Z} modulo m : $G = \{\sigma_r \mid \zeta_m^{\sigma_r} = \zeta_m^r, (r, m) = 1\}$. K_m is called the m th **cyclotomic field**. Cyclotomic fields are \dagger Abelian extensions of \mathbb{Q} . Conversely, every Abelian extension of \mathbb{Q} is a subfield of a cyclotomic field (**Kronecker's theorem**, 18.53, 1877).

We can choose $(1, \zeta_m, \zeta_m^2, \dots, \zeta_m^{\varphi(m)-1})$ as a minimal basis of K_m . Let $m = l_1^{h_1} l_2^{h_2} \dots l_t^{h_t}$ be the decompositions of m in powers of prime numbers l_1, \dots, l_t . Put $K^{(i)} = K_{l_i^{h_i}}$. Then K_m is the composite field $K_m = K^{(1)} K^{(2)} \dots K^{(t)}$. The different of K_m is given by $\mathfrak{D}_{K_m/\mathbb{Q}} =$

$\mathfrak{D}_{K^{(1)}/Q} \mathfrak{D}_{K^{(2)}/Q} \dots \mathfrak{D}_{K^{(l)}/Q}$, and the discriminant of K_m is given by $D_{K_m} = D_{K^{(1)}}^{n_1} D_{K^{(l)}}^{n_l}$ ($n_i = \varphi(m)/\varphi(l^{h_i})$). If $m = l^h$, the discriminant of K_m is $D_{K_m} = \varepsilon l^a$ ($a = l^{h-1}(hl - h - 1)$), where $\varepsilon = -1$ if $l^h = 4$ or $l \equiv 3 \pmod{4}$, and $\varepsilon = 1$ otherwise. Hence the discriminant of K_m is $D_{K_m} = (\sqrt{-1} m / \prod_{p|m} p^{1/(p-1)})^{\varphi(m)}$. Suppose that $m \not\equiv 2 \pmod{4}$. Then a prime number p ramifies for K_m/Q if and only if p divides m . In particular, if $m = l^h$ ($h > 2$), then only 1 ramifies for K_m/Q and $(l) = [l^{\varphi(m)}]$, $N(l) = l$ (l is explicitly given by $l = (1-i, \dots)$). For $l \neq 2$ the ramification numbers for l are $v_i = l^i$ ($i = 1, 2, \dots$), and the ramification fields are K_l, K_{l^2}, \dots . For $l = 2$ the ramification numbers are 1, 3, 7, and the ramification fields are Q, K_4, K_8 .

In K_m/Q a prime number p ($p \nmid m$) is decomposed as $(p) = \mathfrak{p}_1 \mathfrak{p}_g$, $N(\mathfrak{p}_i) = p^f$ ($i = 1, \dots, g$) and $fg = \varphi(m)$. Here the degree f of \mathfrak{p}_i is determined as the minimal positive integer f such that $p^f \equiv 1 \pmod{m}$. Hence the decomposition law of a prime number p in K_m/Q is determined by its residue class modulo m . This is a prototype form of class field theory (- 59 Class Field Theory).

The class number of the cyclotomic field K_m can be calculated by Dedekind's formula (- Section E; see also Hilbert [4]). Here we shall give the result for $m = l$ (a prime number). Let ζ be a primitive root modulo l . For $\zeta = \exp(2\pi i/l)$, we put

$$\varepsilon = \varepsilon(\zeta) = \left(\frac{1 - \zeta^r}{1 - \zeta} \frac{1 - \zeta^{-r}}{1 - \zeta^{-1}} \right)^{1/2}.$$

Then ε is a unit in K_l . Define an element σ of the Galois group of K_l/Q by $\zeta^\sigma = \zeta^r$, and put $\varepsilon_i = \varepsilon^{\sigma^i}$ ($i = 0, 1, \dots$). Then $\varepsilon_0, \varepsilon_1, \dots, \varepsilon_{\rho-1}$ ($\rho = (l-3)/2$) are multiplicatively independent units. That is, the regulator $R[\varepsilon_0, \varepsilon_1, \dots, \varepsilon_{\rho-1}] = E \neq 0$. The units $\varepsilon_0, \varepsilon_1, \dots, \varepsilon_{\rho-1}$ are called **circular units**. The class number h of K_l is the product of two factors, $h = h_1 h_2$. Here h_2 is the class number of the real subfield $K'_l = Q(\zeta + \zeta^{-1})$. E. E. Kummer called k_1 the **first factor** and h_2 the **second factor** of the class number h . Let $\chi_1, \chi_2, \dots, \chi_{l-1}$ be the multiplicative characters of the reduced residue classes of \mathbf{Z} modulo l , and let χ_i ($i = 1, \dots, \rho+1$) be the characters among them such that $\chi_i(-1) = -1$. Then

$$h_1 = \frac{(-1)^{\rho+1}}{(2l)^\rho} \prod_{i=1}^{\rho+1} \left(\sum_{a=1}^{l-1} a \chi_i(a) \right), \quad h_2 = \frac{|E|}{R_0}$$

(Kummer, 1850). Here R_0 is the regulator of K'_l . Since circular units belong to K'_l , the class number h_2 of K'_l is equal to the index of the subgroup generated by $\pm 1, \varepsilon_0, \dots, \varepsilon_{\rho-1}$ in the group of units of K'_l . The class number h of K_l is equal to 1 for $l \leq 19$ and it has been conjectured that there exist no more fields K_l

with $h = 1$. H. L. Montgomery and K. Uchida solved this conjecture by proving that the first factor $h_1 > 1$ for $l > 19$ (*Tôhoku Math. J.*, **23** (1971)). J. M. Masley and Montgomery proved that there are precisely 29 distinct K_m with class number 1 (*J. Reine Angew. Math.*, **286/287** (1976)).

According to Kummer, l divides h if and only if l divides h_2 . Since h_1 can be computed explicitly, we can readily determine whether $l \mid h$ or not (- 145 Fermat's Problem; Appendix B, Table 4.111). A prime l is called **regular** if $l \nmid h$, otherwise it is called **irregular**. Thus an odd prime $l \geq 5$ is irregular if and only if there exists an even integer j with $2 \leq j \leq l-3$ such that l divides the numerator of the j th Bernoulli number B_j . This criterion of Kummer can be strengthened as follows. Let S denote the l -Sylow subgroup of the ideal class group \mathfrak{C}_{K_l} of the prime cyclotomic field $K_l = Q(\zeta_l)$. Because the Galois group G of $Q(\zeta_l)/Q$ operates on S , the Abelian group S becomes naturally a $\mathbf{Z}_l[G]$ -module. Choosing the canonical character $\theta: G \rightarrow \mathbf{Z}_l^*$ defined by $\zeta_l^\sigma = \zeta_l^{\theta(\sigma)}$ for any $\sigma \in G$, we have a direct decomposition $S = \prod_{i=0}^{l-2} S^{(i)}$, where $S^{(i)} = \{s \in S \mid s^\sigma = s^{\theta^i(\sigma)}, \sigma \in G\}$. Then it is necessary and sufficient for $l \mid h$ (the numerator of B_j) that $S^{(l-j)} \neq 0$ (K. A. Ribet, *Inventiones Math.*, **34** (1976)). Moreover, because G is naturally isomorphic to the multiplicative group of the reduced residue classes of $\mathbf{Z}/l\mathbf{Z}$, each θ^i becomes a \dagger Dirichlet character. Let

$$B_{1, \theta^{-i}} = \frac{1}{l} \sum_{a \in \mathbf{F}_l^*} \theta^{-i}(a) a;$$

then this number, regarded as an element in Q_l , is equal to a factor of the product (up to ± 1 and 2) appearing in the class number formula for h . Let m_i be the l -exponent of $B_{1, \theta^{-i}}$ for each odd i ($2 < i \leq l-3$). Then it is conjectured that the order of $S^{(i)}$ is precisely equal to l^{m_i} for each odd i with $2 < i \leq l-3$. In particular, if $S' = \prod_{j: \text{even}} S^{(j)}$ is trivial, then this is known to be true. In general, it is also conjectured that $l \nmid h_2$ holds for any prime l (**Vandiver's conjecture**). If the group $S^{(i)}$ is cyclic, then $S^{(i)}$ is of order l^{m_i} (A. Wiles, *Inventiones Math.*, **58** (1980)).

When a Galois extension K over a finite algebraic number field k has the Galois group isomorphic to the additive group of the l -adic integer ring \mathbf{Z}_l , the extension K/k is called a **\mathbf{Z}_l -extension** or **r -extension**. Then for each integer $n \geq 0$ there exists a unique subfield k_n of K with degree l^n over k . Let $\mathbf{k} = K_l = Q(\zeta_l)$ ($l > 2$), and let K be the union of all l^{n+1} th cyclotomic fields $K_{l^{n+1}}$ ($n \geq 0$). Then K/k is a typical example of a \mathbf{Z}_l -extension with subfields $k_n = K_{l^{n+1}}$. Let K/k be a \mathbf{Z}_l -extension with sub-

fields k_n , and let l^{e_n} denote the l -component of the class number of k_n . Then there exist integers $\lambda \geq 0$, $\mu \geq 0$, v independently of n such that $e_n = \lambda n + \mu l^n + v$ for all sufficiently large numbers n (K. Iwasawa, Bull. Amer. Math. Soc., 65 (1959)). These numbers λ , μ , v are called the **Iwasawa invariants** for the Z_l -extension K/k . There exists a unique Z_l -extension K° over the rationals \mathbf{Q} . An extension $K^\circ k$ over k obtained by taking the composite of K° and k is called the **basic Z_l -extension** of k or the **cyclotomic Z_l -extension** of k . We denote its Iwasawa invariants by $\lambda_l(k)$, $\mu_l(k)$, $v_l(k)$. It is known that there are Z_l -extensions with arbitrarily large μ . But it is conjectured that $\mu_l(k) = 0$ holds for the basic Z_l -extension of any k . In particular, in the case $k = K_l = \mathbf{Q}(\zeta_l)$ it has been computed that $\mu_l(k) = 0$ for $l < 125,000$ (for $l < 4001$ by K. Iwasawa and C. C. Sims, J. Math. Soc. Japan, 18 (1966); for $l < 30,000$ by W. Johnson, Math. Comp., 29 (1975); for $l < 125,000$ by S. Wagstaff, Math. Comp., 32 (1978)). By applying the theory of uniform distributions to l -adic situations, B. Ferrero and L. C. Washington (Ann. Math., 109 (1978)) proved that $\mu_l(k) = 0$ when k/\mathbf{Q} is Abelian. In particular, when $k = K$, and $k_n = K_l^{n+1}$, $e_n > 0$ if and only if the class number of K_l is divisible by l (P. Furtwangler, 1911).

Since any quadratic field is a subfield of a cyclotomic field (by a † Gaussian sum formula we have $\mathbf{Q}(\sqrt{m}) \subset \mathbf{Q}(\zeta_{|d|})$, where d is the discriminant of $\mathbf{Q}(\sqrt{m})$), the computation of the class number of quadratic fields and the proof of the law of reciprocity for the † Legendre symbol follow from the arithmetic of cyclotomic fields.

M. Arithmetic of Kummer Extensions

Assume that an algebraic number field k contains an n th primitive root of unity. Then a † Kummer extension $K = k(\sqrt[n]{\mu})$ ($\mu \in k$) is a † cyclic extension of k . Assume that $[K:k] = n$. In order that a prime ideal \mathfrak{p} of k ramify for K/k , it is necessary that \mathfrak{p} be a divisor appearing in (n) or (μ) . If $\mathfrak{p} \nmid (n)$ and $v_{\mathfrak{p}}(\mu) \not\equiv 0 \pmod{n}$, then \mathfrak{p} ramifies for K/k . A prime ideal \mathfrak{p} which is relatively prime to (μ) has the decomposition $E(\mathfrak{p}) = \mathfrak{P}_1 \mathfrak{P}_n$ with distinct primes \mathfrak{P}_i in K if and only if the equation $\mu \equiv \xi^n \pmod{\mathfrak{p}^n}$ is satisfied by some $\xi \in \mathfrak{o}$ for any positive integer m . In particular, if $\mathfrak{p} \nmid (n)$ and $v_{\mathfrak{p}}(\mu) = 0$, we have $E(\mathfrak{p}) = \mathfrak{P}_1 \mathfrak{P}_n$ if and only if $\mu \equiv \xi^n \pmod{\mathfrak{p}}$ is solvable in \mathfrak{o} .

If for an element μ of \mathfrak{o}

$$\mu \equiv \xi^n \pmod{\mathfrak{p}}$$

is solvable by some $\xi \in \mathfrak{o}$, μ is said to be a

residue of the n th power modulo \mathfrak{p} . Assume that $\mathfrak{p} \nmid (n)$ and $v_{\mathfrak{p}}(\mu) = 0$. Let f be the minimal positive integer such that μ^f is a residue of the n th power modulo \mathfrak{p} . Then \mathfrak{p} is decomposed in K as $E(\mathfrak{p}) = \mathfrak{P}_1 \mathfrak{P}_g$, and $N_{K/k}(\mathfrak{P}_i) = \mathfrak{p}^f$ ($i = 1, \dots, g$).

N. Power-Residue Symbol

Let $\zeta_n = \exp(2\pi i/n) \in k$, and let \mathfrak{p} be relatively prime to (n) and (α) ($\alpha \in k$). Then for some r we have

$$\alpha^{(N(\mathfrak{p})-1)/n} \equiv \zeta_n^r \pmod{\mathfrak{p}},$$

and we write

$$\zeta_n^r = \left(\frac{\alpha}{\mathfrak{p}} \right)_n$$

This symbol is called the n th **power-residue symbol** (Kummer). Generalizing this definition, we can define the n th power-residue symbol $(\alpha/\mathfrak{b})_n$ for an ideal \mathfrak{b} of k which is relatively prime to the relative discriminant of $k(\sqrt[n]{\alpha})/k$ by using the † Artin symbol $((K/k)/\mathfrak{b})$:

$$(\sqrt[n]{\alpha})^\sigma = \left(\frac{\alpha}{\mathfrak{b}} \right)_n \sqrt[n]{\alpha}, \quad \sigma = \left(\frac{K/k}{\mathfrak{b}} \right).$$

This symbol satisfies

$$\left(\frac{\alpha}{\mathfrak{b}_1 \mathfrak{b}_2} \right)_n = \left(\frac{\alpha}{\mathfrak{b}_1} \right)_n \left(\frac{\alpha}{\mathfrak{b}_2} \right)_n,$$

$$\left(\frac{\alpha_1 \alpha_2}{\mathfrak{b}} \right)_n = \left(\frac{\alpha_1}{\mathfrak{b}} \right)_n \left(\frac{\alpha_2}{\mathfrak{b}} \right)_n$$

if all the symbols are well defined. In particular, α is a residue of the n th power modulo \mathfrak{p} if and only if $(\alpha/\mathfrak{p})_n = 1$. This symbol coincides with the † quadratic residue symbol for $n = 2$, $k = \mathbf{Q}$, and $\mathfrak{p} \neq 2$.

0. Law of Reciprocity for the Power-Residue Symbol

Several formulas concerning the power-residue symbol are known which are similar to that for the quadratic residue symbol (F. G. M. Eisenstein, Kummer, Furtwangler, Takagi, Artin, Hasse). These can be proved by means of Artin's † general law of reciprocity in class field theory (\rightarrow 59 Class Field Theory).

There are many formulas concerning the reciprocity of the power-residue symbol. One of them is as follows: Let $n = l$ be a prime number. Let $\alpha, \beta \in k$ and assume that (i) α is totally positive; (ii) $v_{\mathfrak{p}}(\alpha) \equiv 0 \pmod{l}$ if $v_{\mathfrak{p}}(\beta) \not\equiv 0 \pmod{l}$, and $v_{\mathfrak{p}}(\beta) \equiv 0 \pmod{l}$ if $v_{\mathfrak{p}}(\alpha) \not\equiv 0 \pmod{l}$, for any prime ideal \mathfrak{p} ; and (iii) $\alpha \equiv 1 \pmod{l}$ and $\beta \equiv 1 \pmod{(1 - \zeta_l)}$. Then

$$\left(\frac{\alpha}{\beta}\right)_l \left(\frac{\beta}{\alpha}\right)_l^{-1} = \zeta_l^a,$$

$$a = \text{Tr}_{k/\mathbb{Q}} \left(\frac{\alpha-1}{l} \frac{\beta-1}{1-\zeta_l} \right)$$

(general law of reciprocity, Hasse, 1924). This result is a generalization of the formula of Eisenstein (1850). If $\alpha(\in k)$ is totally positive and $\alpha \equiv 1 \pmod{l}$, then

$$\left(\frac{\zeta_l}{\alpha}\right)_l = \zeta_l^b, \quad b = \text{Tr}_{k/\mathbb{Q}} \left(\frac{\alpha-1}{l} \right).$$

If $\alpha \equiv 1 \pmod{l(1-\zeta_l)}$, then

$$\left(\frac{l}{\alpha}\right)_l = \zeta_l^c, \quad c = \text{Tr}_{k/\mathbb{Q}} \left(\frac{\alpha-1}{l(1-\zeta_l)} \right);$$

$$\left(\frac{1-\zeta_l}{\alpha}\right)_l = \zeta_l^d, \quad d = -\text{Tr}_{k/\mathbb{Q}} \left(\frac{\alpha-1}{l(1-\zeta_l)} \right)$$

(complementary law of reciprocity, Hasse, 1924).

P. Norm Residue

Let \mathfrak{m} be an integral divisor of k such that $\mathfrak{m} = \prod_i \mathfrak{p}_i^{e_i} \prod_j \mathfrak{p}_j^{(j)} (e_i > 0)$ with finite prime divisors $\{\mathfrak{p}_i\}$ and infinite prime divisors $\{\mathfrak{p}_j^{(j)}\}$, and let β be an element of k that is relatively prime to \mathfrak{m} . For a relative algebraic number field K/k and an element B of K , we set $\beta \equiv N_{K/k}(B) \pmod{\mathfrak{m}}$ if the following two conditions are satisfied: (i) $\beta \equiv N_{K/k}(B) \pmod{\mathfrak{p}_i^{e_i}}$ for every finite \mathfrak{p}_i and (ii) $\beta^{(j)} > 0$ for every infinite prime $\mathfrak{p}_j^{(j)}$ such that $\beta^{(j)}$ is real and its extension to K is imaginary. $\beta \in k$ is then said to be a **norm residue** modulo \mathfrak{m} for K/k if there exists a number B of K such that $\beta \equiv N_{K/k}(B) \pmod{\mathfrak{m}}$.

Let \mathfrak{p} be a finite prime divisor of k . If β is a norm residue modulo \mathfrak{p}^c for a sufficiently large c , then β is a norm residue modulo \mathfrak{p}^e for any $e > c$. Let c be the smallest such integer ($c \geq 0$). Then the ideal $\mathfrak{f}_{\mathfrak{p}} = \mathfrak{p}^c$ is said to be the **\mathfrak{p} -conductor** of norm residue for K/k . If \mathfrak{p} is unramified for K/k , then $c = 0$; i.e., every $\beta \in k$ which is relatively prime to \mathfrak{p} is a norm residue modulo \mathfrak{p}^e for any $e > 0$. For a ramified \mathfrak{p} put $\mathfrak{f}_{\mathfrak{p}} = \mathfrak{p}^c$. For a Galois extension K/k , c is not greater than

$$\sum_{\rho=0}^{r-1} \frac{|V_{\rho}|}{|V_0|} (v_{\rho+1} - v_{\rho}) = \sum_{i=0}^{v_r} \frac{|V^{(i)}|}{|V_0|}.$$

In particular, for an Abelian extension K/k this value is an integer and is equal to c (Hasse, *J. Fac. Sci. Univ. Tokyo*, 1934). For example, the l -conductor of the cyclotomic field $K_{\mathfrak{p}^h}/\mathbb{Q}$ is l^h . We define the \mathfrak{p}_{∞} -conductor for K/k for an infinite prime divisor \mathfrak{p}_{∞} of k by $\mathfrak{f}_{\mathfrak{p}_{\infty}} = \mathfrak{p}_{\infty}$ if \mathfrak{p}_{∞} is real and its extension to K is imaginary, and $\mathfrak{f}_{\mathfrak{p}_{\infty}} = 1$ otherwise (- 257 Local Fields F).

Q. Norm Residue Symbol

For an Abelian extension K/k , the positive divisor

$$\mathfrak{f} = \prod_{\mathfrak{p}} \mathfrak{f}_{\mathfrak{p}}$$

(where \mathfrak{p} runs over all finite and infinite prime divisors of k) is called the **conductor** of K/k (\rightarrow 59 Class Field Theory). For $a \in k$ ($a \neq 0$) take α_0 such that $\alpha/\alpha_0 \equiv 1 \pmod{\mathfrak{f}_{\mathfrak{p}}}$ and $\alpha_0 \equiv 1 \pmod{\mathfrak{f}\mathfrak{f}_{\mathfrak{p}}^{-1}}$, and put $(\alpha_0) = \mathfrak{p}^a \mathfrak{b}$ with \mathfrak{b} relatively prime to \mathfrak{p} . Then \mathfrak{b} is relatively prime to the relative discriminant $\mathfrak{d}_{K/k}$. We define a new symbol by

$$\left(\frac{\alpha, K/k}{\mathfrak{p}}\right) = \left(\frac{K/k}{\mathfrak{b}}\right) \quad (\in G),$$

where $((K/k)/\mathfrak{b})$ is the Artin symbol. This value is independent of the choice of the auxiliary element α_0 . The new symbol is called the **norm-residue symbol** (Hasse, *J. Reine Angew. Math.*, 162 (1930)). In particular, for an infinite real prime divisor $\mathfrak{p}_{\infty}^{(j)}$ of k whose extension $\mathfrak{P}_{\infty}^{(j)}$ for K is imaginary, we have

$$\left(\frac{\alpha, K/k}{\mathfrak{p}_{\infty}^{(j)}}\right) = 1 \text{ or } \sigma$$

according to whether the conjugate $\alpha^{(j)}$ is positive or negative, where σ is the automorphism of K/k induced from the complex conjugation of the completion C of K with respect to $\mathfrak{P}_{\infty}^{(j)}$.

The norm-residue symbol has the following properties:

$$(1) \left(\frac{\alpha\alpha', K/k}{\mathfrak{p}}\right) = \left(\frac{\alpha, K/k}{\mathfrak{p}}\right) \left(\frac{\alpha', K/k}{\mathfrak{p}}\right);$$

(2) if \mathfrak{p} is unramified for K/k , then

$$\left(\frac{\alpha, K/k}{\mathfrak{p}}\right) = \left(\frac{K/k}{\mathfrak{p}}\right)^{-v_{\mathfrak{p}}(\alpha)};$$

(3) in order that α be a norm residue modulo $\mathfrak{f}_{\mathfrak{p}}$ for K/k , it is necessary and sufficient that

$$\left(\frac{\alpha, K/k}{\mathfrak{p}}\right) = 1;$$

(4) the **product formula** for the norm-residue symbol (Hasse) is

$$\prod_{\mathfrak{p}} \left(\frac{\alpha, K/k}{\mathfrak{p}}\right) = 1,$$

where \mathfrak{p} runs over all finite and infinite prime divisors of k ; and (5) if the domain of the variable α is the whole k ($\neq 0$), or the set of all α such that (α) is relatively prime to \mathfrak{p} , or the set of all α such that $\alpha \equiv 1 \pmod{\mathfrak{p}^n}$ ($v_{\mathfrak{p}} + 1 \leq m \leq v_{\mathfrak{p}+1}$), then the range of $((\alpha, K/k)/\mathfrak{p})$ is the decomposition group Z of \mathfrak{p} , the inertia group T of \mathfrak{p} , or the ramification group V_{ρ}

of p , respectively (Hasse, S. Iyanaga, 1933) (- 257 Local Fields F).

R. Hilbert Norm-Residue Symbol

The symbol first introduced by Hilbert for quadratic fields can be defined in a general algebraic number field k containing an n th primitive root ζ_n of unity. Let $\alpha, \beta \in k$ ($\alpha \neq 0$, $\beta \neq 0$), and let p be a prime divisor. Then the following n th root of unity $((\alpha, \beta)/p)_n$ is defined by using the norm-residue symbol:

$$\left(\frac{\alpha, \beta}{p}\right)_n \sqrt[n]{\beta} = (\sqrt[n]{\beta})^\sigma,$$

$$\sigma = \left(\frac{\alpha, k(\sqrt[n]{\beta})/k}{p}\right).$$

This symbol $((\alpha, \beta)/p)_n$ is called the **Hilbert norm-residue symbol**. It is also called the **Hilbert-Hasse norm-residue symbol**. For $\alpha, \alpha', \beta \in k$, we have

$$(1) \left(\frac{\alpha\alpha', \beta}{p}\right)_n = \left(\frac{\alpha, \beta}{p}\right)_n \left(\frac{\alpha', \beta}{p}\right)_n;$$

(2) the law of symmetry:

$$\left(\frac{\alpha, \beta}{p}\right)_n = \left(\frac{\beta, \alpha}{p}\right)_n^{-1};$$

and (3) the **product formula** for the Hilbert norm-residue symbol:

$$\prod_p \left(\frac{\alpha, \beta}{p}\right)_n = 1$$

(Hilbert, Furtwängler, Takagi, Artin, Hasse). For detailed properties concerning the norm-residue symbol, power-residue symbol, and Hilbert norm-residue symbol and for references for them see Hasse [6].

In general, the problem of obtaining various laws of reciprocity for the power-residue symbol is reduced to the one of computing the Hilbert norm-residue symbol explicitly. Detailed formulas for these symbols are called **explicit reciprocity laws**; they are treated as a topic in the number theory of local fields (- 257 Local Fields H).

S. Density Theorem

Let M be a set of prime ideals of k . If

$$\lim_{s \rightarrow 1+0} \sum_{p \in M} \frac{1}{N(p)} \bigg/ \log \frac{1}{s-1}$$

exists, its value is said to be the **density** of M . The density of the set of all prime ideals of k is 1. Let H be an ideal group modulo an integral divisor m . Then the density of the set of all prime ideals contained in each coset of $\mathfrak{J}(m)$

modulo H is $1/|\mathfrak{J}(m):H|$. In particular, let H be the ray $S(m)$. Then this result implies that each coset of $\mathfrak{J}(m)$ modulo $S(m)$ contains infinitely many prime ideals (a generalization to algebraic number fields of the **†prime number theorem** for arithmetic progression).

Let K/k be a Galois extension, C be a conjugate class of the Galois group G of K/k , and $M(C)$ be the set of all prime ideals p of k such that the **†Frobenius** automorphism of each prime factor \mathfrak{P}_i of p in K belongs to C . Then the density of $M(C)$ is $|C|/|G|$ (**Chebotarev's density theorem**, *Math. Ann.*, 95 (1926)).

Each element σ of the Galois group G of K/k can be expressed by the permutation z of the conjugate fields $K^{(1)}, \dots, K^{(n)}$ of K over k . Let z be expressed as the product of r **†cycles** of length f_1, \dots, f_r . Hence $n = f_1 + \dots + f_r$. Let $C(f_1, \dots, f_r)$ be the set of all such σ in G , and let $M(f_1, \dots, f_r)$ be the set of all prime ideals p of k such that p is decomposed in K/k as the product of r prime ideals of K with relative degree f_1, \dots, f_r . Then the density of $M(f_1, \dots, f_r)$ is $|C(f_1, \dots, f_r)|/|G|$ (Artin, *Math. Ann.*, 89 (1923)).

T. Relation to the Arithmetic of Local Fields

It is quite useful to investigate the relation between the arithmetic of algebraic number fields and that of local fields. For example, let a prime ideal p of an algebraic number field k be decomposed as $E(p) = \mathfrak{P}_1^{e_1} \cdot \mathfrak{P}_2^{e_2} \cdot \dots \cdot \mathfrak{P}_g^{e_g}$, $N_{K/k}(\mathfrak{P}_i) = p^{f_i}$ ($i = 1, \dots, g$) in an extension K of k . Let $K_{\mathfrak{p}}$ and k_p be the completion of K and k with respect to \mathfrak{P} -adic and p -adic valuations, respectively. Then we have $[K_{\mathfrak{p}} : k_p] = e_i f_i$ and $K \otimes_k k_p \cong K_{\mathfrak{p}_1} + \dots + K_{\mathfrak{p}_g}$ (direct sum). The relative different $\mathfrak{D}_{K/k}$ is expressed as (the p -component of $\mathfrak{D}_{K/k}$) $= \prod_{i=1}^g \mathfrak{D}_{K_{\mathfrak{p}_i}/k_p}$. For a Galois extension K/k the p -conductor $\mathfrak{f}_p = p^c$ for the norm-residue and the conductor p^c of local extension $K_{\mathfrak{p}}/k_p$ have the same exponent c . For a local field $K_{\mathfrak{p}}/k_p$, each norm-residue modulo \mathfrak{f}_p is a norm of an element of K . Hence precise results concerning the norm-residue in local fields can be applied immediately to a global field K/k (- 257 Local Fields).

We can also apply the method of the idele group of an algebraic number field k , and therefrom we can prove results concerning the ideal class group, unit group, and zeta function of k (\rightarrow 6 Adeles and Ideles).

U. History of the Arithmetic of Algebraic Number Fields

C. F. Gauss (1832) was the first to generalize the notion of integers to algebraic number

fields in considering the elements of $\mathbf{Z}[\sqrt{-1}]$, now called **Gaussian integers** ($\mathbf{Z}[\sqrt{-1}]$ is the principal order of $\mathbf{Q}(\sqrt{-1})$). After investigations by G. L. Dirichlet and Kummer, the notion of ideals was introduced by Dedekind (1871) [2]. L. Kronecker gave another foundation for the arithmetic of algebraic number fields (1882) [3]. Dirichlet proved the unit theorem and, introducing the analytic method to number theory, gave the class number formula of quadratic fields (\rightarrow 347 Quadratic Fields). H. Minkowski first applied the theory of lattice points to number theory (\rightarrow 182 Geometry of Numbers), and K. Hensel introduced the p -adic method (\rightarrow 257 Local Fields). Hilbert (1897) [4] and Hasse (1926, 1927, 1930) [6] summarized the main results on the arithmetic of algebraic number fields known at that time. In particular, Hilbert's report centered around the arithmetic of Galois extensions, and Hasse's around the class field theory obtained by T. Takagi, E. Artin, and H. Hasse (\rightarrow 59 Class Field Theory). Since c. 1950, when the notions of ideles and adeles were introduced, cohomology-theoretic methods have been successfully applied to number theory (\rightarrow 6 Adeles and Ideles). Recently various local methods, for example, the Iwasawa theory of \mathbf{Z}_p -extensions, t formal groups, and $^t p$ -adic L -functions (T. Kubota and H. W. Leopoldt, *J. Reine Angew. Math.*, 214/215 (1964)) have been frequently applied to research in algebraic number fields.

15 (VIII.3) Algebraic Surfaces

A. Definition

An algebraic variety of dimension 2 is called an **algebraic surface**. In this article, by a surface we mean a complete irreducible algebraic surface defined over an algebraically closed field \mathbf{K} .

B. History

The history of algebraic surfaces originated with the study of algebraic functions of two variables. In the case of algebraic functions of one variable, the introduction of t Riemann surfaces attached to such functions played an essential role in the development of the theory. The study of algebraic functions of two variables led naturally to the consideration of the surfaces defined by a suitable polynomial equation. H. Poincaré and E. Picard are among those who studied the homological structure of the surface defined by the equation $P(x, y, z) = 0$. The theory of t Abelian integrals (Picard integrals) is one of the consequences of

such topological investigations. S. Lefschetz obtained further results in this direction.

M. Noether and geometers of the Italian school, such as F. Enriques, G. Castelnuovo, and F. Severi, studied algebrogeometric properties of algebraic surfaces. In particular, the Italian school geometers recognized the importance of irregularity and thoroughly investigated its geometric meaning. In the early 20th Century they succeeded in constructing the great edifice of the theory of algebraic surfaces. Though some of their results lack rigorous proof, efforts to build a foundation for those results have led to the recent developments in algebraic geometry. A significant contribution to the modernization of the theory was made by O. Zariski and K. Kodaira.

The resolution of singularities of an algebraic surface is one of the most fundamental problems in the field. When the universal domain is the complex number field, function-theoretic methods were used by Italian-school geometers and R. J. Walker (Ann. Math., 36 (1935)). Zariski introduced the valuation-theoretic method to deal with the problem when the characteristic of the universal domain is zero. S. Abhyankar (1966) succeeded in resolving the case of positive characteristics.

C. Divisors and Linear Systems

In what follows, let S denote a nonsingular surface. S can be embedded into some projective space. Let Σ be a linear system of divisors on S and f_0, \dots, f_n be a basis of the defining module for Σ over \mathbf{K} . Associated with Σ we have a rational mapping $\Phi_\Sigma: S \rightarrow \mathbf{P}^n$ defined by $\Phi_\Sigma(P) = (f_0(P), \dots, f_n(P))$ for general points P on S . Pullbacks of hyperplanes by Φ_Σ are called **variable components** of Σ . Any member of Σ is a sum of a variable component and a fixed component of Σ . Let S' denote the closure of the image of S by Φ_Σ . If $\dim S' = 2$, a general variable component is irreducible. If $\dim S' = 1$, then a general variable component is composed of an algebraic system of dimension 1, which is called an **algebraic pencil**. These result from Bertini's theorems. For any divisors D and D' on S , the **intersection number** (or the Kronecker index) $I(D \cdot D')$ is defined; this number is a symmetric bilinear form such that $I(D \cdot D) = I(D_1 \cdot D'_1)$ for any divisors D_1 and D'_1 linearly equivalent to D and D' , respectively. If C is a nonsingular curve on S , $I(C \cdot D)$ coincides with the degree of the restriction $C \cdot D$ of D to C . $I(D \cdot D) = (D^2)$ is said to be the **self-intersection number** of D . If D is an ample divisor on S , then $(D^2) > 0$ and $I(D \cdot C) > 0$ for any irreducible curve C on S . These properties

characterize an ample divisor (Y. Nakai; \rightarrow 16 Algebraic Varieties E).

Let Σ be an irreducible linear system of dimension $r (\geq 1)$, and let C be a generic component of Σ . Let C' be a member of Σ different from C . Then the set of C -divisors $C \cdot C'$ forms a linear system of dimension $r - 1$ on C . This is called the **trace** of Σ on C and is denoted by $\text{Tr}_C \Sigma$. The trace is, in general, not complete. The integer $\dim |\text{Tr}_C \Sigma| - \dim \text{Tr}_C \Sigma = \delta(\Sigma)$ is called the **deficiency** of Σ . The deficiency of the complete linear system $|D|$ is denoted by $S(D)$.

Let x be a point of S , and let \mathcal{O}_x be the local ring of x . Then $\mathcal{O}_S = \bigcup_{x \in S} \mathcal{O}_x$ is an algebraic coherent sheaf, called the **structure sheaf** of S . Let D be a divisor on S . The sheaf of germs of rational functions f such that $(f) + D > 0$ is denoted by $\mathcal{G}'(D)$. Then $H^0(S, \mathcal{O}_S(D))$ is a defining module for the complete linear system $|D|$. $D > 0$ if and only if $\mathcal{O}_S(-D)$ is a sheaf of \mathcal{O}_S -ideals. The quotient sheaf $\mathcal{O}_S/\mathcal{O}_S(-D)$ will be denoted by \mathcal{O}_D . If D is a prime divisor, then \mathcal{O}_D is the structure sheaf of the algebraic curve D (\rightarrow 9 Algebraic Curves). Let \mathcal{F} be a sheaf on S . We set

$$\chi(S, \mathcal{F}) = \sum_{q=0}^2 (-1)^q \dim H^q(S, \mathcal{F}).$$

$\chi(S, \mathcal{O}_S)$ will be denoted simply by $\chi(S)$. We call $p_a(S) = \chi(S) - 1$ the **arithmetic genus** of the algebraic surface S . Sometimes $\chi(S)$ is referred to as the arithmetic genus of S . We set $\chi_S(D) = \chi(S) - \chi(S, \mathcal{O}_S(-D))$. The integer $p_r(D) = 1 - \chi_S(D)$ is, by definition, the **arithmetic genus of the divisor** D . If D is a prime divisor, then $p_r(D)$ coincides with the arithmetic genus of the algebraic curve, i.e., $p_r(D) = \dim H^1(D, \mathcal{O}_D)$.

D. Riemann-Roch Theorem

Let S be a nonsingular surface and let K denote a canonical divisor on S , i.e., $K = (\omega)$ for some nonzero rational 2-form ω on S . If C is a nonsingular irreducible curve on S , $(K + C) \cdot C$ becomes a canonical divisor on C ; hence, $\deg((K + C) \cdot C) = 2p_a(C) - 2$ by a corollary to the Riemann-Roch theorem on C (\rightarrow 9 Algebraic Curves C). Since $I((K + C) \cdot C) = \deg((K + C) \cdot C)$, it follows that $p_a(C) = I((K + C) \cdot C)/2 + 1$. Moreover, the formula

$$p_a(D) = I((K + D) \cdot D)/2 + 1$$

holds for an arbitrary curve D on S ; this is called the **adjunction formula**. For any divisor, we define $p_r(D)$ to be $I(D \cdot (D + K))/2 + 1$. Then

$$\begin{aligned} \chi(S, \mathcal{O}(D)) &= \chi(S) - \chi_S(-D) = \chi(S) + p_a(-D) - 1 \\ &= I(D \cdot (D - K))/2 + \chi(S). \end{aligned}$$

This formula is called the **Riemann-Roch theorem** on S (\rightarrow 366 Riemann-Roch Theorems C). Applying Serre's duality theorem to D (\rightarrow 16 Algebraic Varieties E) we have

$$\dim H^i(S, \mathcal{O}(D)) = \dim H^{2-i}(S, \mathcal{O}(K-D))$$

for $i=0, 1, 2$.

In particular, $\dim H^2(S, \mathcal{O}(D)) = l(K-D)$, which is called the **index of speciality** of D ; $\dim H^1(S, \mathcal{O}(D)) = \dim H^1(S, \mathcal{O}(K-D))$ is called the **superabundance** of D , denoted by $h^1(D)$. The inequality

$$l(D) + l(K-D) \geq \chi(S, \mathcal{O}(D)) = I(D \cdot (D-K))/2 + \chi(S)$$

is called the **Riemann-Roch inequality**, where equality holds if and only if $h^1(D) = 0$. If D is a curve with s connected components, then

$$l(D+K) = h^1(-D) + p_a(D) - s + \chi(S).$$

In addition, if $h^1(0) = 0$, then $h^1(-D) = 0$ and thus $l(D+K) = p_a(D) - s + \chi(S)$. This is called the **Riemann-Roch theorem for the adjoint system**. Note that $|D+K|$ is called the **adjoint system** of D . The Noether formula, $(K^2) + c_2(S) = 12\chi(S)$, is a special case of Hirzebruch's theorem of Riemann-Roch type (\rightarrow 366 Riemann-Roch Theorems B). Here, $c_2(S)$ denotes the second Chern number of S , which coincides with the Euler number of S if \mathbf{K} is the field of complex numbers.

Let $\text{Div}(S)$ denote the group of all divisors on S ; by linearity we can define the bilinear form $I(D \cdot D')$ on $\text{Div}(S)_0 = \text{Div}(S) \otimes_{\mathbf{Z}} \mathbf{Q}$. $J = \{D \in \text{Div}(S)_0 \mid I(D \cdot D') = 0 \text{ for all } D'\}$ is a subgroup and $X = \text{Div}(S)_0/J$ is a finite-dimensional vector space over \mathbf{Q} , on which the nondegenerate bilinear form I is induced. I has a unique positive eigenvalue; thus the other eigenvalues are all negative. This is called the **index theorem of Hodge**; it is derived from the Riemann-Roch theorem on S . From this, we infer that if $D^2 = I(D \cdot D) > 0$, then $I(D \cdot D')^2 \geq D^2 \cdot D'^2$ for any D' . X is said to be the **Neron-Severi group** of S and $\dim X$ is said to be the **Picard number** of S (\rightarrow 16 Algebraic Varieties P).

To study $l(mD)$ as a function of $m \gg 0$, O. Zariski writes an arbitrary effective divisor D as a sum of $D^{(+)}$ and $D^{(-)} \in \text{Div}(S)_0$ with non-negative rational coefficients such that (1) $D^{(+)}$ is **arithmetically effective** (or, numerically semipositive), i.e., $I(D^{(+)} \cdot C) \geq 0$ for any curve C on S ; (2) $D^{(-)} = 0$ or the intersection matrix of the support of $D^{(-)}$ is negative definite; and (3) $I(D^{(+)} \cdot D^{(-)}) = 0$. Such a decomposition is unique and is called the **Zariski decomposition** of D [7]. If $mD^{(+)}$ is a divisor for some $m > 0$, then $l(mD) = l(mD^{(+)})$.

E. Invariants of Algebraic Surfaces

There are many invariants besides the arithmetic genus discussed earlier. We set $h^{q,p} = \dim H^p(S, \Omega^q)$. Then $h^{2,0}$ is equal to the number of linearly independent holomorphic 2-forms; it is called the **geometric genus** and is usually denoted by p_g . Since $h^{0,1}$ gives the maximum among the deficiencies $\delta(\Sigma)$ of linear systems on S , it is called the **maximal deficiency** of S . For a divisor C such that $h^1(C) = 0$, we have $\delta(C) = h^{0,1}$. The number $h^{0,1}$ was formerly called the **irregularity** of S , because $h^{0,1}$ was considered to be a correction term in the equality $p_a(S) = p_g - h^{0,1}$. The study of higher-dimensional varieties showed, however, that it was unnatural to regard $h^{0,1}$ as a correction term. At present, by **irregularity** we mean the dimension of the Picard variety of S (\rightarrow 16 Algebraic Varieties P), and we denote this number by q .

When S is defined over the complex number field, we have $h^{p,q} = h^{q,p}$. In particular, $q = h^{0,1} = h^{1,0}$. This number is equal to the number of linearly independent \dagger Abelian simple integrals of the first kind; it is also equal to one-half the first Betti number of S . In cases with positive characteristic, these equalities do not hold in general. J.-P. Serre gave an example of an algebraic surface S such that $h^{0,1} \neq h^{1,0}$, and J. Igusa gave an example such that $q < h^{0,1} = h^{1,0}$. Let K be a canonical divisor of S . The number $P_i = l(iK)$ is called the **i -genus**, and P_i ($i = 2, 3, \dots$) are generally called **plurigenera**. If $P_n = 0$ and $d \mid n$, then P_d is also zero. The numbers $p_a(S) = h^{2,0} - h^{0,1}$, $p_g(S) = h^{2,0}$, $h^{1,0}$, $h^{0,1}$, P_i ($i = 2, 3, \dots$) ($P_1 = p_g$) are \dagger absolute invariants of S ; i.e., they take the same values for any nonsingular surface S' that is birationally equivalent to S . However, $h^{1,1}$ is not an absolute invariant. For a projective plane, all plurigenera P_n vanish and the irregularity $q = 0$. Thus if S is a **rational surface** (\rightarrow 16 Algebraic Varieties J), i.e., a surface which is birationally equivalent to \mathbf{P}^2 , all $P_n = q = 0$. Conversely, any surface with $q = P_2 = 0$ is a rational surface. This is called **Castelnuovo's criterion**. A **ruled surface** is defined to be a surface that is birationally equivalent to a product of the projective line and a curve. All P_n of a ruled surface equal 0 and any surface with $P_4 = P_6 = 0$ is a ruled surface. This is called the **criterion of ruled surfaces** (Enriques).

F. Characteristic Linear Systems of Algebraic Families

One of the central problems considered by the Italian school was to prove that the irregular-

ity q is equal to the maximal deficiency $h^{0,1}$. For that purpose, Severi introduced the notion of characteristic linear systems of algebraic families. Let Σ be an irreducible algebraic family of positive divisors on S such that a generic member C of Σ is an irreducible nonsingular curve, and let r be the dimension of Σ . Let Σ_1 be a 1-dimensional subfamily of Σ containing C as a simple member, and let C be a generic member of Σ_1 . Then the specialization of $C' \cdot C$ over the specialization $C' \rightarrow C$ is a well-defined C -divisor of degree $\eta = I(C \cdot C')$. The set of C -divisors thus obtained is called the **characteristic set**. The characteristic set forms an $(r-1)$ -dimensional linear system and contains $\text{Tr}_C[C]$ as a subfamily. This linear system is called the **characteristic linear system** of Σ . For any algebraic family of dimension r , we have $r \leq \dim C| + q$. In particular, there exists an algebraic family Σ that contains ∞^q linear systems and such that for a generic curve C we have $h^1(C) = 0$. For such an algebraic family, we have the equality $r = \dim C| + q$; hence the inequality $q \leq h^{0,1}$ follows. Moreover, if the characteristic linear system is complete, we have $q = h^{0,1}$. The proof of the completeness of characteristic linear systems given by Severi is valid only in some special cases (e.g., the case $p_g = 0$). For a complex algebraic manifold, a rigorous proof was given later. When the characteristic is positive, the completeness does not hold in general (Igusa); however, for the surface with $p_g = 0$, the completeness holds (Y. Nakai). The completeness holds if and only if the Picard scheme of S is reduced [14].

G. Birational Transformations of Algebraic Surfaces

Let S and S' denote nonsingular surfaces. If there exists a birational morphism $T: S \rightarrow S'$, we say that S dominates S' , and we write $S \geq S'$. In addition, if T is not an isomorphism, we write $S > S'$. In case there does not exist an S' with $S > S'$, S is said to be **relatively minimal**. On the other hand, if we have $S' > S$ for any S' which is birationally equivalent to S , S is said to be **minimal**. Any minimal surface is, by definition, relatively minimal. If a minimal (resp. relatively minimal) surface S is birationally equivalent to S' , we say that S is a **minimal** (resp. **relatively minimal**) **model** of S' or of the field $\mathbf{K}(S)$. A necessary and sufficient condition for S to have a minimal model is that S not be a ruled surface (Castelnuovo and Enriques).

Let S be a nonsingular surface and P be a point on S . Replacing P by a projective line \mathbf{P}^1 , we have a nonsingular surface S' and a birational morphism $T: S' \rightarrow S$ such that $T^{-1}(P)$

$= E \cong \mathbf{P}^1$ and $S' - E \cong S - \{P\}$ by $T: T: S' \rightarrow S$ (or T^{-1} in some references) is said to be a locally quadratic transformation. Any birational morphism between nonsingular surfaces is a composition of locally quadratic transformations and an isomorphism. Given a birational mapping $T: S \rightarrow S'$ and P on S' , $T^{-1}\{P\}$ is called an **exceptional curve** whenever it is not a point. Moreover, it is called an **exceptional curve of the first kind** if T is regular along $T^{-1}\{P\}$. Otherwise, it is of the **second kind**. Exceptional curves consist of irreducible rational curves. An irreducible curve E is an exceptional curve of the first kind if and only if $(E^2) = -1$ and $E \cong \mathbf{P}^1$. S is relatively minimal if and only if S has no exceptional curves of the first kind; S is minimal if and only if S has no exceptional curves at all. A relatively minimal surface that is not minimal is a ruled surface. Such a surface is either \mathbf{P}^2 or a \mathbf{P}^1 -bundle over a curve. In particular, a relatively minimal rational surface is either \mathbf{P}^2 or a \mathbf{P}^1 -bundle over \mathbf{P}^1 . Any surface of the latter type is occasionally called a **Hirzebruch surface** and its (K^2) is 8, where K denotes a canonical divisor. However, (K^2) of \mathbf{P}^2 is 9. Define the **linear genus** of a rational surface to be 10. If S is not a rational surface, taking a relatively minimal surface S' , we define the **linear genus** $p^{(1)}$ of S to be $(K^2) + 1$ of S' .

H. Examples of Algebraic Surfaces

Let S_m denote a nonsingular surface in \mathbf{P}^3 defined by a homogeneous polynomial of degree m . Let H denote a divisor on S_m induced from a (hyper)plane on \mathbf{P}^3 . Then the canonical divisor K is linearly equivalent to $(m-4)H$, i.e. $K \sim (m-4)H$. Hence, $p_g = (m-1)(m-2)(m-3)/6$. Moreover, $q = 0$ if \mathbf{K} is the field of complex numbers, S_m is simply connected. S_2 is isomorphic to the product of two copies of \mathbf{P}^1 , i.e. $S_2 \cong \mathbf{P}^1 \times \mathbf{P}^1$; hence, it is a rational surface. S_3 is also rational. There exist 27 lines on S_3 . Contracting 6 mutually disjoint lines among these 27 lines, we obtain a projective plane. Conversely, given 6 points on \mathbf{P}^2 in general position, by performing locally quadratic transformations with these points as centers we get a cubic surface S_3 and a birational morphism $T: S_3 \rightarrow \mathbf{P}^2$. The inverse images by T of the 6 given points, the proper transforms of 15 lines connecting every pair of points chosen from the 6, and 6 conics passing every 5 of the 6 points by T^{-1} , exhaust 27 lines on S_3 . If $m = 4$, then $K \sim 0$. In general, a nonsingular surface with $K \sim 0$ and $q = 0$ is said to be a **K3 surface** (- 72 Complex Manifolds J). K3 surfaces have certain properties similar to **Abelian surfaces** that are defined to be 2-

dimensional Abelian varieties (\rightarrow 3 Abelian Varieties). For $\mathbf{K} = \mathbf{C}$, the period mapping defined by integrating regular 2-forms has been studied extensively in connection with moduli theory.

In general, surfaces with the bigenus $P_2 = p_g = 1$ and $q = 0$ are birationally equivalent to $K3$ surfaces; surfaces with $P_4 = p_g = 1$ and $q = 2$ are birationally equivalent to Abelian surfaces. Every Abelian surface has the involution i defined by $i(x) = -x$ and the quotient surface by i is a singular surface with 16 ordinary double points. By performing 16 locally quadratic transformations successively with these singular points as centers we obtain a $K3$ surface. Such a $K3$ surface is called a **Kummer surface**. The original singular surface is also called a Kummer surface. A quartic surface in \mathbf{P}^3 with 16 double points is an example of a Kummer surface.

The theory of birational classification of surfaces was developed by Castelnuovo, Enriques, and others of the Italian school. This theory has been extensively enriched and generalized in various ways. Kodaira's theory of analytic surfaces includes classification of algebraic surfaces (\rightarrow 72 Complex Manifolds I, J), and classification of surfaces in the positive-characteristic case has been recently studied in detail [4, 5]. When the field $\mathbf{K}(S)$ is a subfield of a purely transcendental extension $\mathbf{K}(X, Y)$, S is said to be a unirational surface. If the extension $\mathbf{K}(X, Y)/\mathbf{K}(S)$ is separable, S is a rational surface. However, if it is inseparable, S may become nonrational, a $K3$ surface, an elliptic surface, or a surface of general type [5, 12]. Even for noncomplete surfaces, we have a classification theory [10] similar to the previous ones. The following result is one of the applications: whenever $S \times \mathbf{A}^n \cong \mathbf{A}^3$, S is isomorphic to \mathbf{A}^2 . Here \mathbf{A}^n means the affine n -space (M. Miyanishi, T. Sugie, T. Fujita; [7, 9, 13]).

Let I be the ring of integers of a real quadratic field of discriminant d . The Hilbert modular group $G = SL(2, I)/\{\pm 1\}$ acts on the product \mathcal{H}^2 , \mathcal{H} being the complex upper half-plane. The normal complex space \mathcal{H}^2/G can be compactified by adding a finite number of points and thus a compact normal surface is obtained. Resolving these singularities in the canonical minimal way, we have a nonsingular surface $Y(d)$ over \mathbf{C} , which is called the **Hilbert modular surface** with discriminant d . $Y(d)$ is simply connected; hence, $q(Y(d)) = 0$. If $d = 5, 8, 12, 13, 17, 21, 24, 28, 33, 60$, then $Y(d)$ is a rational surface. If $d = 29, 37, 40, 41, 44, 56, 57, 69, 105$, then $Y(d)$ is birationally equivalent to a $K3$ surface. If $d = 53, 61, 65, 73, 76, 77, 85, 88, 92, 93, 120, 140, 165$, then $Y(d)$ is an elliptic surface with $\kappa(Y(d)) = 1$. Otherwise, it is a

surface of general type (\rightarrow [19, 201 in 72 Complex Manifolds]).

16 (VIII.4) Algebraic Varieties

A. Affine Algebraic Varieties and Projective Algebraic Varieties

Fix a field k . A subset of the n -dimensional \dagger affine space k^n over k is called an **affine algebraic variety** (or simply **affine variety**) if it can be expressed as the set of the common zeros of a (finite or infinite) set of polynomials $F_i(X_1, \dots, X_n)$ with coefficients in k . Similarly, a subset of the n -dimensional \dagger projective space $P^n(k)$ over k that can be expressed as the set of the common zeros of a set of homogeneous polynomials $G_j(Y_0, \dots, Y_n)$ is called a **projective algebraic variety** (or simply **projective variety**). In this section, **variety** means either an affine or projective variety. A variety which is a subset of another variety is called a subvariety. These varieties are the forerunners of the modern, more general versions of algebraic varieties, which we will discuss later.

When V is an affine variety in k^n , the set of the polynomials in $k[X] = k[X_1, \dots, X_n]$ that vanish at every point of V form an ideal $I(V)$ of $k[X]$. The residue class ring $A_V = k[X]/I(V)$ is called the **coordinate ring** (or **affine ring**) of V . We can regard A_V as the ring of k -valued functions on V that can be expressed as polynomials of the coordinates of k^n . When V is a projective variety, the \dagger homogeneous ideal generated by the homogeneous polynomials in $k[Y] = k[Y_0, \dots, Y_n]$ that vanish at every point of V is denoted by $I(V)$, and the ring $A_V = k[Y]/I(V)$ is called the **homogeneous coordinate ring** of V .

A variety V is said to be **reducible** or **irreducible** according as it is the union of two proper subvarieties or not. A maximal irreducible subvariety of V is called an **irreducible component** of V . Any variety can be written uniquely as the union of a finite number of irreducible components. A variety V is irreducible if and only if $I(V)$ is a \dagger prime ideal. When that is the case, the field of quotients of A_V (when V is affine) or the subfield of the field of quotients

of A_V , consisting of the homogeneous elements of degree 0 (when V is projective) is called the **function field** of V and is denoted by $k(V)$. Elements of $k(V)$ are called **rational functions** (or simply **functions**) on the variety V . The field $k(V)$ is \dagger finitely generated over k . The transcendence degree of $k(V)$ over k is called the **dimension** of V . When V is reducible, the maximum of the dimensions of its irreducible components is called its dimension. If W is a subvariety of an irreducible variety V , then $\dim V - \dim W$ is called the **codimension** of W on V . A subvariety of pure codimension 1 of an affine or projective space can be defined by a single equation and is called a **hypersurface**. If the ideal $I(V)$ of a variety V of dimension r in a projective space $P^n(k)$ is generated by $n-r$ homogeneous polynomials, then V is called a **complete intersection**. Compared with general varieties, complete intersections have some simpler properties. On the other hand, many important varieties are not complete intersections, e.g., \dagger Abelian varieties of dimension ≥ 2 .

The intersections and finite unions of subvarieties on a variety V are also subvarieties. Thus the subvarieties can be taken as the \dagger system of closed sets of a topology on V (- 426 Topology), which is called the **Zariski topology of the variety V** . When k is the field of complex numbers, V can be viewed as an \dagger analytic space, and the topology of V as such (the "usual" topology) is much stronger than the Zariski topology. For the rest of this article, varieties will be considered as having Zariski topologies unless stated otherwise. Terms such as **Zariski open**, **Zariski closed**, and **Zariski dense** are used to mean open, closed, or dense in a Zariski topology. Suppose a condition (P) concerning the points of an irreducible variety V (concerning the elements of a set M parametrized by the points of V) is satisfied in a nonempty Zariski open set of V . Then we say that the condition (P) holds at **almost all points of the variety V** or at general points of V (almost all elements of the set M).

Let U and V be affine varieties in k^n and k^m , respectively. Then the product set $U \times V$ is an affine variety in k^{n+m} and is called the **product algebraic variety** (or simply the **product**) of U and V . Note that the Zariski topology on $U \times V$ is stronger than the product of the topologies of U and V . When k is \dagger algebraically closed, $U \times V$ is irreducible if U and V are irreducible.

Suppose that k is algebraically closed. Let \mathfrak{P} be a \dagger prime ideal of $k[X] = k[X_1, \dots, X_n]$, and let V be the affine variety in k^n defined as the zero points of \mathfrak{P} . Then $I(V) = \mathfrak{P}$ (\dagger Hilbert zero point theorem) (- 369 Rings of Polynomials D). Therefore there exists a one-to-one correspondence between the set of prime ideals of

$k[X]$ and the set of irreducible varieties in k^n . In particular, the \dagger maximal ideals correspond to the points of k^n . Similarly, there exists a one-to-one correspondence between the set of homogeneous prime ideals of $k[Y]$ other than $\sum_{i=0}^n Y_i k[Y]$ and the set of irreducible subvarieties in $P^n(k)$.

When we deal with nonlinear algebraic equations, we cannot expect a simple, clearcut theory without assuming that k is algebraically closed. Hence we take an algebraically closed field K containing k and regard a variety V in k^n as a subset of the variety V_K in K^n defined by the same equations. From now on, we suppose that k is algebraically closed. If the ideal $I(V)$ of $k[X]$ or $k[Y]$ determined by a variety V is generated by polynomials with coefficients in a subfield k' of k , we say that V is **defined over k'** or that k' is a **field of definition** for V . Any variety has the smallest field of definition, which is finitely generated over the prime field. In the theory of A. Weil [92], we fix an algebraically closed field K that has an infinite transcendence degree over the prime field. This K is called the **universal domain**. A point of V is called a **k' -rational point** of V if all of its coordinates belong to a subfield k' of K . Let K_1, K_2 be two extension fields of a field L , and let $(x) \in K_1^n, (y) \in K_2^n$. We say (y) is a **specialization** of the point (x) over L (notation: $(x) \xrightarrow{L} (y)$) if all polynomials $f(X) \in L[X_1, \dots, X_n]$ satisfying $f(x) = 0$ also satisfy $f(y) = 0$; in other words, if there exists a homomorphism of L -algebras $L[x_1, \dots, x_n] \rightarrow L[y_1, \dots, y_n]$ mapping x_i to y_i . Let K be the universal domain, V an irreducible variety in K^n , and $k' (\subset K)$ a field of definition for V having a finite transcendence degree over the prime field. Then there exists a point (x) of V such that all points of V are specializations of (x) over k' . Such a point (x) (in general not uniquely determined) is called a **generic point** of V over k' . The ring $k'[x]$ is isomorphic to $k'[X]/I(V) \cap k'[X]$ over k' . (Some authors use the term *generic point* to mean *almost all points* as defined earlier.)

B. Local Rings

Let V be an affine variety and let W be an irreducible subvariety of V . Let \mathfrak{P}_W be the subset of A , consisting of the elements that vanish identically on W . Then \mathfrak{P}_W is a prime ideal of A . The ring of \dagger quotients of A , with respect to \mathfrak{P}_W is denoted by $\mathfrak{D}_{V,W}$ or by \mathfrak{D}_W and is called the **local ring** of W on V (or of V at W). Suppose for simplicity that V is irreducible. Then \mathfrak{D}_W is the subring $\{f/g \mid f, g \in A_V, g \notin \mathfrak{P}_V\}$ of $k(V)$, and the \dagger residue field of \mathfrak{D}_W modulo the maximal ideal $\mathfrak{P}_W \mathfrak{D}_W$ can be

identified with $k(W)$. When a function φ on V ($\varphi \in k(V)$) belongs to \mathfrak{D}_W , it is said to be **regular** at W . For a given function $\varphi \in k(V)$, the set of the points of V where φ is regular is Zariski open. In the case of a projective variety, the local ring $\mathfrak{D}_{V,W}$ is defined as the subring of the ring of quotients of A , with respect to \mathfrak{P}_W , consisting of the homogeneous elements of degree 0.

A mapping from an open set U of a variety V to k that is regular at every point of U is called a **regular function** on U . The ring of regular functions on U is denoted by A_U . By assigning A_U to each open set U , we can define a \dagger sheaf of rings \mathcal{O}_V on V , of which the \dagger stalk $\mathcal{O}_{V,x}$ at a point $x \in V$ is the local ring $\mathfrak{D}_{V,x}$. The sheaf \mathcal{O}_V is called the **sheaf of germs of regular functions** on V (or the **structure sheaf** of V) (- 383 Sheaves H).

C. General Definition

Consider a pair (V, \mathcal{O}) of a topological space V and a sheaf \mathcal{O} of germs of mappings from V to k . If V has a finite open covering (U_i) such that each $(U_i, \mathcal{O}|U_i)$ is isomorphic to an affine variety V_i (in the sense that there exists a homeomorphism from U_i to V_i that transforms $\mathcal{O}|U_i$ to the structure sheaf of V_i), the pair (V, \mathcal{O}) is called a **prealgebraic variety over k** , and \mathcal{O} is called its **structure sheaf**. Usually (V, \mathcal{O}) is denoted simply by V .

A **regular mapping** between prealgebraic varieties is defined as a continuous mapping $g: V \rightarrow V'$ satisfying $\varphi \circ g \in \mathcal{O}_{V',x}$ for any $x \in V$ and $\varphi \in \mathcal{O}_{V',g(x)}$. Furthermore, if g is a homeomorphism and g^{-1} is also regular, then g is called an **isomorphism** or a **homeomorphism**. The Cartesian product $X \times Y$ of prealgebraic varieties X and Y is locally a product of affine varieties. Therefore $X \times Y$ has the structure of a prealgebraic variety. A prealgebraic variety X is called an **algebraic variety** if the image of the diagonal mapping $X \rightarrow X \times X$ is closed in the Zariski topology of the product variety $X \times X$ ("separation condition"). (This definition is due to J.-P. Serre [81]). The separation condition corresponds to \dagger Hausdorff's separation axiom. If W is a locally closed subset (i.e., the intersection of an open set and a closed set) of an algebraic variety V , then it becomes an algebraic variety in a natural manner (the germs of regular functions at $P \in W$ are taken to be the germs of functions induced on W by the functions in $\mathcal{O}_{V,P}$). Locally closed subvarieties of k^n or $P^n(k)$ are called **quasi-affine** or **quasiprojective algebraic varieties**, respectively. Definitions of irreducibility and local rings for general algebraic varieties are given in the same manner

as before. In this article, algebraic varieties will often be referred to simply as varieties.

The notion of an irreducible algebraic variety was developed from that of **abstract algebraic variety** (or simply **abstract variety**) defined by Weil.

D. Schemes

The set of prime ideals ($\neq (1)$) of a commutative ring A with unity element 1 is denoted by $\text{Spec}(A)$ and is called the **spectrum** of A . For any subset a of A , we denote by $V(a)$ the set of the prime ideals containing a . We define a topology on $\text{Spec}(A)$ in which the closed sets are $V(a)$. This, again, is called the **Zariski topology** of $\text{Spec}(A)$. For an element f of A , the open set $D(f) = \text{Spec}(A) - V(f)$ is called an elementary open set. The elementary open sets form a base of open sets in the Zariski topology of $\text{Spec}(A)$. The set of closed points is nothing but the set of maximal ideals of A . Assigning to each point \mathfrak{P} of $\text{Spec}(A)$ the \dagger ring of quotients $A_{\mathfrak{P}}$, we obtain a sheaf of rings \tilde{A} on $\text{Spec}(A)$. We have the equality $\Gamma(D(f), \tilde{A}) = A_f$, where A_f is the \dagger ring of quotients by the multiplicative system $\{f^n : n \geq 0\}$. In particular, we have $\Gamma(\text{Spec}(A), \tilde{A}) = A$. Regarded as a \dagger local-ringed space with \tilde{A} as the structure sheaf, $\text{Spec}(A)$ is called an **affine scheme**.

A local-ringed space X which is locally isomorphic to an affine scheme is called a **scheme**. A **morphism of schemes** is, by definition, a \dagger morphism between them as local-ringed spaces. Thus we obtain a \dagger category whose objects are schemes. We denote it by (Sch) . Giving a morphism $f: X \rightarrow \text{Spec}(A)$ is equivalent to giving a ring homomorphism $\Gamma(f): A \rightarrow \Gamma(X, 0)$. Hence the category of affine schemes (which is a \dagger full subcategory of (Sch)) is contravariantly equivalent to the category of commutative rings. If there is given a morphism of schemes $f: X \rightarrow S$, X is said to be an **S-scheme** or a **scheme over S** , and f is called the structure morphism and S the base scheme. For two S -schemes $f: X \rightarrow S$, $g: Y \rightarrow S$, a morphism of S -schemes is defined to be a morphism of schemes $h: X \rightarrow Y$ with $f = g \circ h$. Thus we obtain the category of S -schemes denoted by (Sch/S) . $\text{Spec}(\mathbb{Z})$ is the unique \dagger final object in (Sch) , hence (Sch) is nothing but $(\text{Sch}/\text{Spec}(\mathbb{Z}))$.

The \dagger fiber product always exists in (Sch) . In fact in the case of affine S -schemes $X = \text{Spec}(B)$ and $Y = \text{Spec}(C)$ with $S = \text{Spec}(A)$ we have $X \times_S Y = \text{Spec}(B \otimes_A C)$, and in the general case we construct $X \times_S Y$ by patching together fiber products of affine schemes.

A morphism $f: X \rightarrow S$ is called **separated** if the image of the diagonal morphism $\Delta_{X/S}$:

$X \rightarrow X \times_S X$ is closed. We also say that X is separated over S or X is a **separated S-scheme**. A scheme X is said to be **separated** if it is separated over $\text{Spec}(\mathbb{Z})$. All affine schemes are separated.

When K is a field, $\text{Spec}(K)$ is a space having only one point and equipped with K as the stalk of the structure sheaf. For a point x of a scheme X , denote by $k(x)$ the residue field of $\mathcal{O}_{X,x}$. For $f \in \mathcal{O}_{X,x}$ we call the residue class off in $k(x)$ the value off at x , denoted by $f(x)$. We have a natural morphism $i_x: \text{Spec}(k(x)) \rightarrow X$ whose image is $\{x\}$. More generally, we call a morphism i of a spectrum $\text{Spec}(K)$ of a field K to X a point of X with values in K . Such a point is determined by a point x in X and an embedding of $k(x)$ in K . A point of X with values in an algebraically closed field is called a **geometric point**. For a morphism $f: X \rightarrow S$ and a point s in S , the fiber product $X \times_S \text{Spec}(k(s))$ is called the **fiber** off over s and denoted by $f^{-1}(s)$. For a geometric point $\text{Spec}(K) \rightarrow S$, $X \times_S \text{Spec}(K)$ is called a **geometric fiber**.

A scheme X is called **reduced** if the local ring at each point of X has no \dagger nilpotent elements. A scheme is said to be **irreducible** if its underlying topological space is not a union of two proper closed subsets. A scheme is called **integral** if it is reduced and irreducible. Every local ring of an integral scheme is an \dagger integral domain. If a scheme X has an affine open covering $\{U_i = \text{Spec}(A_i)\}$ such that every A_i is a \dagger Noetherian ring, X is said to be **locally Noetherian**. A locally Noetherian scheme is called **Noetherian** if its underlying topological space is \dagger (quasi-)Compact.

A morphism $f: X \rightarrow Y = \text{Spec}(A)$ is said to be **locally of finite type (of finite type)** if X has an open affine covering (a finite open affine covering) $\{U_i = \text{Spec}(A_i)\}$ such that each A_i is a finitely generated A -algebra. A general morphism $f: X \rightarrow Y$ is said to be **locally of finite type (of finite type)** if there is an open affine covering $\{V_i\}$ of Y such that every restriction of $f: f^{-1}(V_i) \rightarrow V_i$ is locally of finite type (of finite type). If $f: X \rightarrow Y$ is (locally) of finite type we say that X is (locally) of finite type over Y .

A scheme of finite type over a field K (i.e., over $\text{Spec}(K)$) is called an **algebraic scheme** over K . There is a \dagger natural equivalence of categories between the category of reduced separated algebraic K -schemes (as a full subcategory of (Sch/K)) and the category of algebraic varieties over K (defined in Section C) equipped with regular mappings as morphisms. Hence we identify these categories from now on. Occasionally, algebraic variety means irreducible variety. Nonalgebraic schemes are also important as tools for the

study of algebraic varieties. For example, for a point x in a scheme X there is a canonical monomorphism $j_x: \text{Spec}(\mathcal{O}_{X,x}) \rightarrow X$ by which the unique closed point of $\text{Spec}(\mathcal{O}_{X,x})$ is mapped to x . If for two algebraic K -schemes X, Y and for two points $x \in X, y \in Y$ there is a K -isomorphism $\mathcal{O}_{X,x} \cong \mathcal{O}_{Y,y}$, then suitable neighborhoods of x and y are isomorphic over K .

Many concepts concerning varieties, e.g., dimension, generic points, specialization, can be naturally extended to the case of schemes by virtue of commutative ring theory.

A morphism of schemes $f: X \rightarrow Y$ is called **proper** if it satisfies the following two conditions: (1) f is separated and of finite type, (2) for every scheme T and for every morphism $T \rightarrow Y$, the morphism $X \times_Y T \rightarrow T$ obtained from f by the "change of base" is a closed mapping. We also say that X is a proper Y -scheme or X is proper over Y . A proper algebraic K -scheme is called **complete**. A projective variety is complete, while an affine variety over K is complete only when it is of dimension zero. Every algebraic variety can be embedded in a complete variety (M. Nagata [63]).

A morphism of schemes $f: X \rightarrow Y$ is called **affine** if every inverse image by f of an open affine subset of Y is again an affine scheme.

A morphism of schemes $f: X \rightarrow Y$ is called **finite** if it is of finite type and there is an affine open covering $\{U_i = \text{Spec}(A_i)\}$ of Y such that $f^{-1}(U_i) = \text{Spec}(B_i)$, where B_i is integral over A_i . For a locally Noetherian scheme Y and a morphism of schemes $f: X \rightarrow Y$ the following three conditions are equivalent: (i) f is finite; (ii) f is affine and proper; (iii) f is proper and every fiber off is a finite set. For a finite surjective morphism of Noetherian schemes $f: X \rightarrow Y$, X is an affine scheme if and only if Y is an affine scheme.

A morphism of schemes $f: X \rightarrow Y$ is said to be **flat** if for each point $x \in X$, $\mathcal{O}_{X,x}$ is a flat $\mathcal{O}_{Y,f(x)}$ -module. If, moreover, f is surjective, then f is called **faithfully flat**. Assume that $g: Y' \rightarrow Y$ is a faithfully flat morphism of finite type of locally Noetherian schemes and $f: X \rightarrow Y$ is a morphism of schemes. Then for many important properties of morphisms, f has these properties if and only if the pull-back $f_{Y'}: X \times_Y Y' \rightarrow Y'$ has the same properties (theory of descent [29, 30]).

E. Cohomology Theory

Let (X, \mathcal{O}) be a ringed space. An \mathcal{O} -Module (i.e., a sheaf of \mathcal{O} -modules) F is said to be **quasicoherent** if for each point x of X there exist a neighborhood U of x and an exact sequence $M \rightarrow N \rightarrow F|_U \rightarrow 0$, where M and N are free \mathcal{O}_U -Modules. An \mathcal{O} -Module F is said to

be **of finite type** if F is locally generated by a finite number of sections over \mathcal{O} ; F is **of finite presentation** if, locally, there exists an exact sequence $\mathcal{O}^p \rightarrow \mathcal{O}^q \rightarrow F \rightarrow 0$ where p and q are positive integers (they need not be globally constant); F is **coherent** if (i) F is of finite type and (ii) the kernel of any homomorphism $\mathcal{O}_U^n \rightarrow F|_U$ (where n is an arbitrary positive integer, and U is an open set) is of finite type. Obviously, if F is coherent, then F is of finite presentation, which implies that F is quasicoherent and of finite type. In the category of \mathcal{O} -Modules, the full subcategory of coherent sheaves is closed under almost all operations of sheaves. If \mathcal{O} itself is coherent as an \mathcal{O} -Module, \mathcal{O} is said to be a **coherent sheaf of rings**. In this case every \mathcal{O} -Module of finite presentation is coherent.

The structure sheaf of a locally Noetherian scheme is a coherent sheaf of rings. On a locally Noetherian scheme X , every quasicoherent sub- \mathcal{O}_X -Module or quotient \mathcal{O}_X -Module of a coherent \mathcal{O}_X -Module is coherent. A coherent \mathcal{O}_V -Module on an algebraic variety V is called a **coherent algebraic sheaf**.

Let $X = \text{Spec}(A)$ be an affine scheme. Then every quasicoherent \mathcal{O}_X -Module F on X is generated by its global sections. The correspondence $F \rightarrow \Gamma(X, F)$ defines an equivalence between the category of quasicoherent sheaves on X and the category of A -modules; if A is Noetherian, then the coherent sheaves and the finite A -modules correspond to each other under this equivalence.

Let X be a separated scheme, and $\mathcal{U} = \{U_i\}$ an affine open covering of X . For each quasicoherent \mathcal{O}_X -Module F , the cohomology group $H^q(X, F)$ is canonically isomorphic to the Čech cohomology $H^q(\mathcal{U}, F)$ (- 383 Sheaves F). If X is of dimension d , then $H^q(X, F) = 0$ for every sheaf F of Abelian groups on X and $q > d$.

For a scheme X we define the **cohomological dimension** $\text{cd}(X)$ to be the largest integer q such that $H^q(X, F) \neq 0$ for a quasicoherent \mathcal{O}_X -Module F on X [35]. The cohomological dimension $\text{cd}(X)$ does not exceed the dimension of X . If X is an affine scheme, then $\text{cd}(X) = 0$. The converse is true under the assumption that X is Noetherian (Serre's criterion [29, III]). For an algebraic scheme X of dimension n , $\text{cd}(X) = n$ if and only if X is complete (S. L. Kleiman).

Let $f: X \rightarrow Y$ be a proper morphism of Noetherian schemes. Then for every coherent \mathcal{O}_X -Module F and for every $q \geq 0$, $R^q f_*(F)$ (- 200 Homological Algebra) is also coherent. In the special case of $Y = \text{Spec}(k)$ with a field k this means that for an algebraic coherent sheaf F on a complete variety X the cohomology group $H^q(X, F)$ is a finite-dimensional vector space over k .

Let X be a scheme over k and let F be a locally free \mathcal{O}_X -Module of rank n (i.e., an \mathcal{O}_X -Module which is locally isomorphic to \mathcal{O}_X^n). If we take an open covering $\{U_i\}$ of X and isomorphisms $\varphi_i: F|_{U_i} \xrightarrow{\sim} \mathcal{O}_{X|U_i}^n$, then $\varphi_i \circ \varphi_j^{-1}$ defines a morphism $g_{ij}: U_i \cap U_j \rightarrow GL(n, k)$, which is called the coordinate transformation of F . If we construct a \dagger vector bundle B on X by the same coordinate transformations g_{ij} , then F can be regarded as the sheaf $\mathbf{B}(B)$ of germs of sections of B . By means of the canonical homomorphism $GL(n, k) \rightarrow PGL(n-1, k)$ we can construct a projective bundle $\mathbf{P}(F)$ on X (which is said to be associated with F). (Note that in [29], $\mathbf{P}(F)$ is defined to be a projective bundle with coordinate transformations ${}^t g_{ij}^{-1}$, i.e., associated with the dual of F in our sense.) This procedure of associating $\mathbf{P}(F)$ with a locally free \mathcal{O}_X -Module F can be generalized for any quasicoherent \mathcal{O}_S -Module of finite type on an arbitrary scheme S .

A closed (locally closed) S -subscheme $f: X \rightarrow S$ of $p: \mathbf{P}(F) \rightarrow S$ is called a **projective scheme** (quasiprojective scheme) **over** S , or f is said to be a **projective morphism** (quasiprojective morphism). A projective morphism is proper. A reduced projective scheme over a field k is nothing but a projective variety over k . We can develop the theory of projective schemes by means of \dagger graded rings in a way similar to affine schemes.

A locally free \mathcal{O}_X -Module of rank 1 is called an **invertible sheaf**. Invertible sheaves correspond to line bundles up to isomorphisms. Let $P = \mathbf{P}^N(k)$ be a projective space, (y_0, y_1, \dots, y_N) a system of homogeneous coordinates of P , and U_i the open subset of P defined by $y_i \neq 0$. Denote by $\mathcal{O}(n)$ the invertible sheaf on P defined by the coordinate transformation $g_{ij} = (y_j/y_i)^n$. More generally, let $p: P = \mathbf{P}(F) \rightarrow S$ be the projective bundle associated with a locally free \mathcal{O}_S -Module F of rank $N+1$ on a scheme S . Then there is an invertible sheaf $\mathcal{O}(n) = \mathcal{O}(1)^{\otimes n}$ on P with the properties: (i) for each $s \in S$ its restriction to the fiber $p^{-1}(s) = \mathbf{P}^N(k(s))$ is $\mathcal{O}(n)$ defined above; (ii) $p_*(\mathcal{O}(n)) = S^n(F)$ for $n > 0$ where $S^n(F)$ denotes the n th symmetric product of F . The invertible sheaf $\mathcal{O}(1)$ is called the **tautological line bundle** on P . (Note that $\mathcal{O}(1)$ in the sense of [29] is $\mathcal{O}(-1)$ in our sense, but since the definition of $\mathbf{P}(F)$ is also different, the above property (ii) holds without modification.)

For a quasiprojective S -scheme $f: X \rightarrow \mathbf{P}(E) \rightarrow S$, the restriction of $\mathcal{O}(1)$ to X is denoted by $\mathcal{O}_X(1)$ (or simply $\mathcal{O}(1)$). An invertible sheaf L on X is called **very ample over** S if there exist a locally free \mathcal{O}_S -Module of finite type E on S and an S -immersion $i: X \rightarrow \mathbf{P}(E)$ such that $\mathcal{O}_X(1) = L$; L is called **relatively ample** over S or S -ample if $L^{\otimes n}$ is very ample over S for a cer-

tain $n > 0$ (- Section N). When S is an affine scheme, an ample (very ample) sheaf over S is simply called **ample** (**very ample**). There is the following cohomological criterion of ampleness (generalized **Serre's theorem**).

Let Y be a Noetherian scheme, $f: X \rightarrow Y$ a proper morphism, and L an invertible \mathcal{O}_X -Module. Then the following four conditions are equivalent: (i) L is f -ample; (ii) for each coherent \mathcal{O}_X -Module F there is an integer N such that $R^q f_*(F \otimes L^{\otimes n}) = 0$ for all $n \geq N$ and $q > 0$; (iii) for each coherent sheaf of ideals \mathcal{I} of \mathcal{O}_X there is an integer N such that $R^1 f_*(\mathcal{I} \otimes L^{\otimes n}) = 0$ for all $n \geq N$. They imply the condition (iv): for each coherent \mathcal{O}_X -Module F there is an integer N such that the canonical homomorphisms $f_* f_*(F \otimes L^{\otimes n}) \rightarrow F \otimes L^{\otimes n}$ are surjective for all $n \geq N$.

Let X be a scheme proper over a field k (such an X is called a **k -complete scheme**), and let F be a coherent \mathcal{O}_X -Module. Then all $H^q(X, F)$ are finite-dimensional k -vector spaces (finiteness theorem), and $\chi(F) = \sum (-1)^q \dim H^q(X, F)$ is a finite number, called the **Euler-Poincaré characteristic** of F over X . For every invertible sheaf L , $\chi(F \otimes L^{\otimes m})$ is a polynomial in m , which is said to be the **Snapper polynomial** [48]. $\text{Supp } F$, defined to be the set $\{x \in X \mid F_x \neq 0\}$, is a closed subset of X and is called the **support** of F . The degree of the polynomial $\chi(F \otimes L^{\otimes m})$ is at most $\gamma = \dim \text{supp } F$, and we have $\chi(F \otimes L^{\otimes m}) = e \cdot m^\gamma / \gamma! + \text{lower terms in } m$ for some $e \in \mathbf{Z}$. e is said to be the **intersection number** of L with F [48]. When W is a closed subscheme of X defined by an \mathcal{O}_X -ideal I , $(L^\cdot \cdot W)$ is defined to be the intersection number of L with \mathcal{O}_X/I , where $r = \dim W$. If L is ample, then $(L^\cdot \cdot W) > 0$ for any W . In particular, when $W = X$, it follows that $(L^n) > 0$, where $n = \dim X$. The converse of this fact is the **Nakai-Moishezon criterion**, saying that if $(L^\cdot \cdot W) > 0$ for any closed subvariety W of X where $r = \dim W$, then L is ample [56, 64].

When L is ample, $H^q(X, F \otimes L^{\otimes m}) = 0$ for any $q > 0$ and for sufficiently large m ; hence $\chi(F \otimes L^{\otimes m}) = \dim H^0(X, F \otimes L^{\otimes m})$ and the Snapper polynomial $\chi(F \otimes L^{\otimes m})$ is also called the **Hilbert polynomial** or the **Hilbert characteristic function** of F . If L is the invertible sheaf defined by a hyperplane section of X in \mathbf{P}_k^N , i.e., $L = \mathcal{O}_X(1)$, then $\chi(L^{\otimes m}) = \dim H^0(X, L^{\otimes m}) = \dim R_m$ for sufficiently large m where $\bigoplus R_m$ denotes the homogeneous coordinate ring of X in \mathbf{P}_k^N .

In general, for a complete irreducible variety V of dimension γ , we put

$$\chi(V) = \chi(\mathcal{O}_V) = \sum_{q=0}^{\gamma} (-1)^q h^{0,q}$$

($h^{0,q} = \dim H^q(V, \mathcal{O}_V)$) and call it the **arithmetic**

genus of V . Classically, the number $p_a(V)$ defined by $p_a(V) = (-1)^r(\chi(V) - 1) = h^{0,r} - h^{0,r-1} + \dots \pm h^{0,1}$ was called the arithmetic genus of V , instead of $\chi(V)$. When V is a nonsingular irreducible curve, $p_a(V)$ is the usual \dagger genus. If V is a projective variety, the constant term of the Hilbert polynomial is $\chi(V)$ and the coefficient of its highest term is $(\deg V)/r!$.

Let V be a \dagger normal variety, and D a \dagger divisor on V . If, for each point $x \in V$, we denote by $\mathcal{O}(D)_x$ the set of the functions $f \in k(V)$ that satisfy $(f) + D \geq 0$ on some neighborhood of x , we obtain a coherent algebraic sheaf $\mathcal{O}(D)$, and we have $\dim H^0(V, \mathcal{O}(D)) = I(D)$. If, moreover, V is complete, we put $\chi_V(D) = \chi(V) - \chi(\mathcal{O}(-D))$ and call it the **virtual arithmetic genus** of D . Classically, the number $p(D) = (-1)^{r-1}(\chi_V(D) - 1)$ was called by that name. When D is effective and has no multiple components, $\chi_V(D)$ coincides with the arithmetic genus of D regarded as a variety. In general, $\chi_V(D)$ stays invariant if D is replaced by a divisor that is algebraically equivalent to D (\rightarrow Section N).

If D is a Cartier divisor, $\mathcal{O}(D)$ is an invertible sheaf. For two Cartier divisors D_1, D_2 , $\mathcal{O}(D_1 + D_2) = \mathcal{O}(D_1) \otimes \mathcal{O}(D_2)$, and D_1 and D_2 are linearly equivalent if and only if $\mathcal{O}(D_1) \cong \mathcal{O}(D_2)$.

Let V be an irreducible nonsingular variety and let Ω^p denote the sheaf of germs of regular differential forms of degree p ($\Omega^0 = \mathcal{O}_V$). If V is complete, then we denote $\dim H^q(V, \Omega^p)$ by $h^{p,q}$.

Serre's duality theorem: Let V be a nonsingular complete irreducible variety of dimension r , B an algebraic vector bundle over V , and B^* the dual vector bundle of B . Denote by \mathcal{B} and \mathcal{B}^* the sheaves of germs of sections of B and B^* , respectively. Then (i) $H^r(V, \Omega^r)$ is canonically isomorphic to k , and (ii) $H^q(V, \mathcal{B})$ and $H^{r-q}(V, \mathcal{B}^* \otimes \Omega^r)$ are dual to each other as linear spaces by means of the \dagger cup product of the above spaces with $H^r(V, \Omega^r) \cong k$. In particular, $H^q(V, \Omega^p)$ is dual to $H^{r-q}(V, \Omega^{r-p})$; hence we have $h^{p,q} = h^{r-p, r-q}$.

This theorem was extensively generalized by Grothendieck in the category of schemes [1, 331].

When the field k is of characteristic 0, we furthermore have $h^{p,q} = h^{q,p}$ by complex conjugation (\rightarrow 232 Kähler Manifolds C); but in characteristic p , there are examples for which this symmetry does not hold [61]. In general, $h^{p,q}$ is a \dagger relative invariant but not an \dagger absolute invariant; however, as $h^{p,0}$ is the dimension of the linear space of the differential forms of the first kind with degree p , $h^{p,0}$ is an absolute invariant. Hence $h^{0,p}$ is also an absolute invariant in the case of characteristic 0. When the characteristic is positive, the absolute invariance of $h^{0,p}$ has not yet been proved.

F. Simple Points and Singular Points

Let V be a variety over an algebraically closed field k . We say that a point P of V is **simple** or that V is **nonsingular** or **smooth** at P if the local ring \mathfrak{O}_P is a \dagger regular local ring. Since the problem is local, we may assume that V is an affine variety in k^n . Then the simplicity of P on V is equivalent to the following condition: P is contained in only one irreducible component of V , and if that component has dimension r there exist $n-r$ polynomials $F_i(X)$ in $I(V)$ such that $\text{rank}(\partial F_i / \partial X_j)_{(X)=P} = n-r$. A point of V that is not simple is called a **singular point** or a **multiple point**. The set of singular points on V (called the **singular locus** of V) is a proper closed subset of V . A variety with no multiple points is called **smooth** or **nonsingular**.

This notion can be made relative. A morphism $f: X \rightarrow Y$ of a locally Noetherian scheme is called **smooth** if f is flat and locally of finite type and all the geometric fibers off are nonsingular. In the case of an affine morphism $f: X = \text{Spec}(R[X_1, \dots, X_{r+s}]/(f_1, \dots, f_m)) \rightarrow Y = \text{Spec}(R)$ of relative dimension r (by which we mean the dimension of the general fiber) with a Noetherian ring R , the smoothness off amounts to a condition that $\text{rank}((\partial f_i / \partial X_j)(x)) = s$ at each point x of X .

When for a point P of a variety V the local ring \mathfrak{O}_P is \dagger normal, P is called a **normal point**. A simple point is normal. The set of normal points is a nonempty open subset of V . An irreducible variety whose points are all normal is called a **normal algebraic variety** (or simply **normal variety**). The singular locus of a normal variety has codimension ≥ 2 . For an irreducible variety V , there exists a pair (V', f) of a normal variety V' and a birational finite morphism $f: V' \rightarrow V$; V' is unique up to isomorphisms and is called the **derived normal model** or **normalization** of V .

Simplicity and normality for V at a subvariety W are defined in the same way as at a point by using the local ring $\mathfrak{O}_{V,W}$.

For a morphism $f: X \rightarrow Y$ of locally Noetherian schemes, locally of finite type, the following three conditions are equivalent: (i) f is smooth and every fiber off is a discrete set; (ii) f is flat and every geometric fiber over $\text{Spec}(K)$ off is a union of spectra of fields isomorphic to K ; (iii) f is flat and every fiber off over $y \in Y$ is a union of spectra of fields that are finite \dagger separable extensions of $k(y)$. These conditions are local with respect to X . If a morphism f satisfies these equivalent conditions, we say that f is **étale** or X is **étale** over Y . A morphism

$$f: X = \text{Spec}(R[X_1, \dots, X_n]/(f_1, \dots, f_n)) \rightarrow Y = \text{Spec}(R)$$

is étale if and only if $\det((\partial f_i / \partial X_j)(x)) \neq 0$ for all $x \in X$. Hence étale morphisms correspond to local isomorphisms in the analytic category. For a surjective étale morphism $f: X \rightarrow Y$ many important geometric properties (reduced, integral, normal, nonsingular, etc.) hold on X if and only if they hold on Y (theory of descent).

G. Dimension Theorems

Let V be an irreducible variety, and let U and W be irreducible subvarieties of V . Then any irreducible component of $U \cap W$ that is simple on V has dimension $\geq \dim U + \dim W - \dim V$. When the equality holds, the component is called a **proper component** of the intersection $U \cap W$. If every component of $U \cap W$ that is simple on V is proper, we say that U and W **properly intersect** on V . Any two subvarieties U and W of $\mathbb{P}^n(k)$ with $\dim U + \dim W \geq n$ intersect each other. When V is an irreducible r -dimensional variety in $\mathbb{P}^n(k)$, the number of points of intersection $V \cap L$ of V with an $(n-r)$ -dimensional linear variety L is independent of the choice of L as long as L is in a "general position." This number is called the **degree** of V and is denoted by $\deg(V)$. Letting $\mathcal{O}(1)$ be the fundamental sheaf of $\mathbb{P}^n(k)$, we have $\deg V = (\mathcal{O}(1)^r \cdot V)$ (- Section E).

H. Group Varieties

An algebraic variety G is called an **algebraic group** if it has a group structure and if the mapping $G \times G \rightarrow G$ sending (x, y) to xy^{-1} is a morphism. Every algebraic group is quasi-projective (Chow). If G is irreducible, then it is also called a **group variety**; a complete group variety is called an **Abelian variety** (- 3 Abelian Varieties B, 13 Algebraic Groups B). A scheme G over another scheme S equipped with morphisms over $S: G \times_S G \rightarrow G, G \rightarrow G$, and $S \rightarrow G$, called multiplication, inverse, and unit section, respectively, which satisfy the relations corresponding to the usual axioms of group, is called a **group scheme** (over S). As a point set, G is not a group, while, for any scheme T over S the set $G(T) = \text{Hom}_S(T, G)$ of the morphisms from T to G is a group (- 52 Categories and Functors M). Consider an algebraic group scheme G over $S = \text{Spec}(k)$. If the characteristic of k is zero, then G is necessarily reduced, so an algebraic group scheme over k is essentially the same as an algebraic group; if k has characteristic p , there exist algebraic group schemes over k that are not reduced.

I. Rational Mappings

Let $f: V \rightarrow V'$ be a morphism of varieties. If V is not complete, the image $f(V)$ is not always closed; the closure $\text{off}(V)$ (in V') is called the **closed image** of V . The image $f(V)$ contains an open dense subset of the closed image.

Let V and W be irreducible varieties. A closed subset T of $V \times W$ is called an **algebraic correspondence** of V and W . We say that points $P \in V$ and $Q \in W$ correspond to each other by T if $(P, Q) \in T$. If T is irreducible and the closed image of the projection $T \rightarrow V$ coincides with V , then the function field $k(V)$ can be identified with a subfield of $k(T)$; if we have $k(V) = k(T)$ with this identification, then T is called a **rational mapping** from V to W . Moreover, if the same conditions are satisfied for W , then T is called a **birational mapping** (of **birational correspondence** or **birational transformation**), and in this case we have $k(V) = k(W)$. A morphism can be considered a special kind of rational mapping by taking the graph. If T is a rational mapping from V to W and W_1 is the closed image of T in W , then $k(W_1)$ can be regarded as a subfield of $k(T) = k(V)$. If $k(V)$ is \dagger separably generated (\dagger purely inseparable) over $k(W_1)$, then T is said to be **separable** (purely inseparable).

Let T be a rational mapping from V to W , and let V' and W' be irreducible subvarieties of V and W , respectively. If there exists an irreducible subvariety T' of T whose projections have the closed images V' and W' , then we say V' and W' correspond to each other by T . The union of irreducible subvarieties of W that correspond to V' by T is a closed subset of W ; it is called the **proper transform** of V' by T and is denoted by $T[V']$. Note that $V' \supset V''$ does not imply $T[V'] \supset T[V'']$. The set of points of W that correspond to the points of V' is called the **total transform** of V' by T and is denoted by $T\{V'\}$. Identifying $k(T)$ with $k(V)$, we have $\mathfrak{O}_{T, T'} \supset \mathfrak{O}_{V', V'}$ in general; if the equality holds, we say that T is **regular** (or **defined**) **along** V' . In that case, W' is the unique irreducible subvariety of W corresponding to V' by T . If V' is simple and of codimension 1 in V , then T is always regular along V' . The set U of points of V at which T is regular is a nonempty open subset, and the restriction of T to U defines a morphism from U to W . A rational mapping can be defined as the closure of the graph of a morphism **defined** on an open subset of V . The study of a rational mapping can be reduced to that of the birational morphism $T \rightarrow V$. **Zariski's main theorem:** Let $S: X \rightarrow Y$ be a birational mapping, and assume that the inverse $S^{-1}: Y \rightarrow X$ is regular, and that X is normal along an irreducible subvariety X' . If there exists an irre-

ducible component Y' of $S[X']$ with $\dim X' \geq \dim Y'$, then S is regular along X' . It follows from the above main theorem that, if $T: V \rightarrow W$ is a rational mapping and if P is a normal point of V such that $T[P]$ contains an isolated point, then T is regular at P .

For a birational mapping $T: V \rightarrow W$ between complete irreducible varieties, a subvariety V' of V is said to be **fundamental** when $\dim T[V'] > \dim V'$. When V' is a point (curve) we say V' is a **fundamental point** (**fundamental curve**) with respect to T . The most classical example of a birational correspondence with fundamental points is the **quadratic transformation** T of a projective plane onto itself given by $(x_0: x_1: x_2) \rightarrow (x_1x_2: x_2x_0: x_0x_1)$ with a suitable coordinate system. In this case, $T^2 = \text{identity}$ and the points P_i defined by $x_j = 0$ for $j \neq i$ correspond to the lines $x_i = 0$ by T . Let Cr denote the group of birational transformations of $\mathbf{P}^n(\mathbf{k})$ into itself. These transformations are called **Cremona transformations** when $n \geq 2$. Cr is generated by linear transformations and quadratic transformations (M. Noether). Recently, Cr has been studied in detail by M. Demazure [21] and H. Umemura [91]. Let V be a complete nonsingular irreducible variety over k . It is called **relatively minimal** if every birational morphism from V to a complete nonsingular variety V' is an isomorphism. It is called **minimal** if every birational mapping from a nonsingular variety V' to V is a morphism. Replacing birational mapping by rational mapping, we can define **strong (absolute) minimality**. Abelian varieties and complete nonsingular curves with positive genera are strongly minimal. In general, minimality implies relative minimality.

Zariski's main theorem is closely related to the **general connectedness theorem** due to W. Fulton and J. Hansen stated as follows: Let P be the product of r copies of \mathbf{P}_k^m and A be the diagonal subvariety of P . If X is an irreducible projective variety and $f: X \rightarrow P$ is a morphism with $\dim f(X) > (r-1)m$, then $f^{-1}(\Delta)$ is connected [22]. The following results are derived from this theorem: (1) if X is singular with only normal crossings (- Section L), then X cannot be imbedded in \mathbf{P}^{2n-1} , where $n = \dim X$. (2) Let X be a nonsingular subvariety of \mathbf{P}^N which is not contained in any hyperplane. Suppose that by the projection $\pi_x: \mathbf{P}^N \rightarrow \mathbf{P}^{N-1}$ with center x , x being a general point of \mathbf{P}^N , X is isomorphic to $\pi_x(X)$. Then $3 \cdot \dim X \leq 2(N-2)$ (Zak's theorem). (3) Let X be a nonsingular subvariety of \mathbf{P}^N and H be an arbitrary hyperplane section of X . Then $\dim(\text{Sing } H) < \text{codim } X$ (J. Roberts).

By a similar connectedness theorem, it was proved that if C is a (reducible) curve with normal crossings on \mathbf{P}^2 over C , then the fun-

damental group of $\mathbf{P}^2 - C$ is commutative, which was conjectured by O. Zariski [20].

J. Rational Varieties

An irreducible algebraic variety V over k whose function field is purely transcendental over k is called a **rational variety**. A complete smooth surface S over an algebraically closed field is rational if and only if $P_2(S) = q(S) = 0$ (the Castelnuovo-Zariski criterion, \rightarrow 15 Algebraic Surfaces E).

If the function field of V has a finite algebraic extension which is purely transcendental over k , then V is called **unirational**. A unirational curve is in fact rational. More generally, if the function field $k(C)$ of a curve C over k is contained in a field finitely generated and purely transcendental over k , then C is rational (**Lüroth's theorem**). A unirational surface over an algebraically closed field of characteristic zero is rational by virtue of the above criterion, but in the case of positive characteristic there are unirational surfaces which are not rational (Zariski). There are nonrational unirational threefolds even of characteristic zero; for example, all smooth cubic hypersurfaces in \mathbf{P}^4 (C. H. Clemens and P. A. Griffiths [16]), and some smooth quartic hypersurfaces in \mathbf{P}^4 (V. A. Iskovskii and Yu. I. Manin [45]). See [6].

K. Monoidal Transformations

Let V be an irreducible variety and \mathcal{J} be a sheaf of ideals of \mathcal{O}_V . For any affine open set U of V , $\mathcal{J}|U$ is determined by an ideal a of the coordinate ring A of U . Let a, a_1, \dots, a_m be a system of generators of a , and let U' be the graph of a rational mapping from U to $\mathbf{P}^m(k)$ such that the points $P \in U$ and $(a_0(P): a_1(P): \dots : a_m(P)) \in \mathbf{P}^m(k)$ correspond to each other by U' . Then U' is uniquely determined (up to isomorphisms) by U and a only. Suppose V has a covering by affine open sets U_i . We obtain U'_i over U_i as before. By patching them together, we get a birational morphism $T: V' \rightarrow V$, which is unique up to isomorphisms. This T with V' is called the **monoidal transformation** or **blowing up** of V by the ideal sheaf \mathcal{J} . Note that in some references, the inverse transformation T^{-1} is said to be the monoidal transformation. The inverse image ideal $T^{-1}(\mathcal{J})$ is an invertible sheaf, that is relatively ample over V . If W is the support of $\mathcal{O}_V/\mathcal{J}$ and $W \neq V$, then $T^{-1}(W)$ has codimension 1 and T gives rise to the isomorphism from $V' - T^{-1}(W)$ onto $V - W$. Thus one can say that V' is obtained from V by replacing W with $T^{-1}(W)$, which is locally defined by prin-

principal ideals. If every point of W is a nonsingular point of V and W is itself nonsingular, $T^{-1}(W)$ is the projective bundle over W whose fiber is the projective r -space where $r = \dim V - \dim W - 1$. In general, if W is a subvariety defined by a sheaf of ideals \mathcal{J} , then T is said to be the **monoidal transformation with center W** . In particular, if W is a point, T is called the (locally) **quadratic transformation**.

L. Resolution of Singularities

Given an arbitrary irreducible variety V , we have the problem of finding out a nonsingular projective variety V' birationally equivalent to V . This is called the problem of **resolution of singularities**. In the case of characteristic zero, this problem was solved by Zariski (1944) for dimension ≤ 3 and by H. Hironaka (1964) [37] for any dimension. In the case of characteristic p , S. Abhyankar solved the 2-dimensional case (1956) and the 3-dimensional case (1966). Hironaka's theorem of resolution of singularities is stated as follows: Let V be a variety over a field of characteristic zero. Then there exists a finite sequence of morphisms of varieties: $V_r \rightarrow V_{r-1} \rightarrow \dots \rightarrow V_1 \rightarrow V_0 = V$ such that (1) V_r has no singular points, (2) each $V_{i+1} \rightarrow V_i$ is a monoidal transformation of V_i with center D_i , (3) each D_i is a nonsingular subvariety, (4) each V_i is normally flat along D_i . Here, V is said to be **normally flat** along a subscheme D of V defined by the sheaf of ideals \mathcal{J} , if the quotient modules $\mathcal{J}_x^p / \mathcal{J}_x^{p+1}$ are flat $\mathcal{O}_{D,x}$ -modules for all p and all points x of D .

Let V be a nonsingular variety and D an effective divisor on V . D is said to be a divisor with (only) **normal crossings** at $x \in V$, if D is defined by $f_1 \cdot f_s$ such that (f_1, \dots, f_s) is a part of a system of local coordinates around x . D is said to be a divisor with only normal crossings, if it is so everywhere. For any subvariety W on V , there exist $h: \tilde{V} \rightarrow V$ that is a composition of monoidal transformations with nonsingular centers, such that $h^{-1}(W)$ has only normal crossings. This results from Hironaka's main theorem II [37]. The normal crossing divisor is also defined for complex manifolds, and similar results hold.

M. Cycles and Divisors

Let V be an irreducible variety. We denote by \mathfrak{B}_r the set of r -dimensional irreducible subvarieties of V that are simple on V (i.e., are not contained in the singular locus of V), and by $\mathfrak{Z}_r(V)$ the free Abelian group with basis \mathfrak{B}_r . Elements of $\mathfrak{Z}_r(V)$ are called cycles of dimension r (or r -cycles) on V . Let A and B be r -

cycles; $A = \sum n_i A_i, B = \sum m_i A_i (A_i \in \mathfrak{B}_r, A_i \neq A_j \text{ if } i \neq j)$. If $n_i \geq m_i$ for all i , then we write $A \geq B$. If $A \geq 0$, then A is said to be a **positive cycle**. For a 0-cycle $A = \sum n_i P_i$ the integer $\deg(A) = \sum n_i$ is called the **degree** of A .

A cycle of codimension 1 is called a **divisor**. A divisor ≥ 0 is usually called **effective** instead of positive. If V is of dimension d and if $W \in \mathfrak{B}_{d-1}$, the local ring $\mathcal{O}_{V,W}$ is a discrete valuation ring. The normalized valuation defined by it is denoted by $v_W(\cdot)$. For a function $f \in k(V)$, we say that W is a **zero** of order n if $v_W(f) = n > 0$, and that W is a **pole** of order $-n$ if $v_W(f) = n < 0$. Any function $f \in k(V)$, other than the constant 0, has at most a finite number of zeros and poles. We denote by $(f)_0$ the sum $\sum v_W(f) W$ extended over all the zeros of f , and put $(f^{-1})_0 = (f)_\infty$ and $(f)_0 - (f)_\infty = (f)$. We call $(f)_0$, $(f)_\infty$, and (f) the **zero divisor**, the **pole divisor**, and the **divisor** of f , respectively. The divisor (f) is equal to $\sum v_W(f) W$, where the summation is taken over $W \in \mathfrak{B}_{d-1}$, and we have $(fg) = (f) + (g)$. When V is complete and the singular locus of V has codimension > 1 , then (f) is constant if and only if $(f) = 0$ (or $(f)_0 = 0$). Let D_1 and D_2 be divisors; if there exists a function $f (\neq 0) \in k(V)$ such that $D_1 - D_2 = (f)$, then D_1 and D_2 are called **linearly equivalent** to each other and we write $D_1 \sim D_2$. The **linear equivalence class** containing a divisor D is denoted by $\text{cl}(D)$. A divisor which is linearly equivalent to 0 on a neighborhood of each point of V is called a **Cartier divisor** (some authors call a Cartier divisor simply a divisor). If V is smooth, then any divisor is a Cartier divisor. If a divisor D can be written as $D = (f)$ on an open set U , then the function f is called a **local equation** of D on U . Let $T: V' \rightarrow V$ be a rational mapping from a normal variety V' to a complete variety V , let D be a Cartier divisor on V , and assume that the closed image of T is not contained in D . Since T is regular on some open set U such that $\text{codim}(V' - U) > 1$, we have a morphism $\varphi = T|_U$ and the pullback $\varphi^*(D)$ defined by composing the local equations of D with φ . Taking the closure of this divisor in V' , we obtain a divisor on V' , which is denoted by $T^*(D)$.

N. Divisors and Linear Systems

Let V be a complete irreducible variety, f_0, f_1, \dots, f_n be elements of the function field $k(V)$ of V , and D be a divisor on V satisfying (fi) $+ D \geq 0$ for each i . Then the set Σ of the divisors of the form $(\sum a_i f_i) + D$, where the a_i are elements of k and not all zero, is called a **linear system**. The linear space $kf_0 + kf_1 + \dots + kf_n$ is called a **defining module** of Σ . The divisors in

Σ are positive and are linearly equivalent to each other; if every positive divisor that is linearly equivalent to a member of Σ belongs to Σ , then Σ is said to be a **complete linear system**. For any linear system Σ , there exists a unique complete linear system containing it, which is denoted by $|\Sigma|$. The maximal positive divisor D_0 that is contained in all divisors of Σ is called the **fixed component** of Σ , and for each DEC we call $D - D_0$ the **variable component** of D (or of Σ). A point P of V is called a **base point** of a linear system Σ if P is on each variable component of Σ . A linear system Σ is called **irreducible** if its generic member is irreducible; otherwise it is called **reducible**. The dimension of a defining module of a linear system Σ is denoted by $l(C)$; we call $l(C) - 1$ the **dimension** of Σ and denote it by $\dim \Sigma$. A linear system of dimension 1 is called a **linear pencil**.

A defining module of a linear system Σ is determined uniquely up to k -isomorphisms. Let L be a defining module, and let f_0, f_1, \dots, f_n be a linearly independent basis of L over k . If we associate to each point P of V the point $Q = (f_0(P) : f_1(P) : \dots : f_n(P))$ of the n -dimensional projective space, then we obtain a rational mapping Φ_Σ from V to another variety V' . Outside the base points of Σ , the rational mapping Φ_Σ is regular; and the base points are the fundamental points of Φ_Σ . We say that Φ_Σ is the rational mapping defined by the linear system Σ . When Σ has no fixed components and Φ_Σ is a closed immersion, Σ is said to be **very ample** (or **ample**). For a divisor D , the set of positive divisors that are linearly equivalent to D is a linear system, which is called the **complete linear system** and is denoted by $|D|$. We usually write $l(D)$ instead of $l(|D|)$. If $|D|$ is very ample, we say that D is **very ample**. We say that D is **ample** (or **nondegenerate**) if mD is very ample for some $m > 0$.

0. Differential Forms

Let V be an n -dimensional irreducible variety, and let $A = k(V)$ be its function field. We denote by \mathfrak{D}^* the set of **derivations** of A over k , i.e., the k -linear mappings $D: A \rightarrow A$ satisfying $D(fg) = D(f)g + fD(g)$. Then \mathfrak{D}^* is an n -dimensional linear space over A . Let \mathfrak{D} denote the \dagger dual space of \mathfrak{D}^* over A . For each $f \in A$, let df be an element of \mathfrak{D} defined by $\langle df, D \rangle = D(f)$ ($D \in \mathfrak{D}^*$). Let x_1, x_2, \dots, x_n be a separating transcendence basis of A over k , in the sense that x_1, \dots, x_n are algebraically independent over k and A is a \dagger separable algebraic extension over $k(x_1, \dots, x_n)$. (Such a basis exists under the weaker hypothesis that k is \dagger perfect.)

Then dx_1, \dots, dx_n form a basis of \mathfrak{D} over A .

The homogeneous elements of degree r of the \dagger Grassmann algebra of \mathfrak{D} over A are called **differential forms of degree r** on V (or rational r -forms). The set of the differential forms of degree n is a 1-dimensional linear space over A spanned by $dx_1 \wedge \dots \wedge dx_n$.

A set of n functions f_1, \dots, f_n in A is called a system of **local coordinates** on an open set U of V if $f_1 - f_1(P), \dots, f_n - f_n(P)$ is a \dagger regular system of parameters of the local ring \mathfrak{O}_P for each $P \in U$. In that case, f_1, \dots, f_n is also a separating transcendence basis of A . If P is a simple point of V , then there exists a system of local coordinates on a suitable neighborhood of P . Let ω be a differential form of degree r on V , and write $\omega = \sum_{i_1 < \dots < i_r} \varphi_{(i)} df_{i_1} \wedge \dots \wedge df_{i_r}$, where (f_1, \dots, f_n) is a system of local coordinates around P . If the coefficients $\varphi_{(i)}$ are regular at P , then ω is said to be **regular** at P .

When V is a complete variety without singular points, a differential form that is everywhere regular on V is called a **differential form of the first kind** (or a **regular form**); the differential forms of the first kind are determined by the function field A and are independent of the choice of the nonsingular model V . The number of linearly independent differential forms of the first kind, of degree n , is denoted by p_g and is called the **geometric genus** of V .

Let V be a complete variety, W an irreducible subvariety of V of codimension 1, and P a point of W that is simple on V . Choose a system of local coordinates (f_i) . Given a differential form ω on V , we write it as a "polynomial" in the df_i , and denote by $v_W(\omega)$ the minimum of the values of the coefficients for the \dagger valuation $v_W(\cdot)$. The number $v_W(\omega)$ is determined by ω and W , and it is independent of the choice of P and of the local coordinates. Then ω defines a divisor $(\omega) = \sum_W v_W(\omega) W$ on V , which is called the **divisor of a differential form ω** . The divisor of a differential form of degree n ($= \dim V$) is called a **canonical divisor** and is usually denoted by K . The canonical divisors form a linear equivalence class of divisors.

P. Albanese Variety, Picard Variety, Néron-Severi Group

Let V be an irreducible variety. Then we can construct a couple (A, f) consisting of an \dagger Abelian variety called the **Albanese variety** of V and a rational mapping $f: V \rightarrow A$ (called an Albanese mapping) such that: (i) the image of f generates A , i.e., the sum of itself n times, $F: V^n \rightarrow A$, is generically surjective for sufficiently large n ; (ii) for every rational mapping $g: V \rightarrow B$ of V into an Abelian variety B ,

there exist a homomorphism $h: A \rightarrow B$ and a point $b \in B$ such that $g = h \cdot f + b$. The Albanese variety is uniquely determined up to isomorphisms and f is determined up to translations.

In the case of $k = \mathbb{C}$, if V is a complete nonsingular variety and if q is the dimension of the linear space of differential 1-forms of the first kind on V , then the first \dagger Betti number $i_1^?$, is equal to $2q$. Let $\omega_1, \dots, \omega_q$ be a basis of the linear space and let $\gamma_1, \dots, \gamma_{2q}$ be a basis of the first homology group modulo torsion. Put $\alpha_{ji} = \int_{\gamma_j} \omega_i$ and $\alpha_j = (\alpha_{j1}, \dots, \alpha_{jq})$. Then the period vectors α_j ($1 \leq j \leq 2q$) are linearly independent over \mathbb{R} in \mathbb{C}^q . If Γ denotes the discrete subgroup of \mathbb{C}^q generated by the α_j , then the quotient group \mathbb{C}^q/Γ is the Albanese variety of V . The Albanese mapping is given by the mapping $P \rightarrow (\int_Q^P \omega_1, \dots, \int_Q^P \omega_q) \pmod{\Gamma}$, where P is a variable point on V and Q is a fixed point on V (\rightarrow 232 Kähler Manifolds C).

Replacing the term "rational mapping" by "morphism" in the definition, we can define the **strict Albanese variety** of V and prove its existence. It is a quotient Abelian variety of the Albanese variety of V . If V is nonsingular, both coincide by virtue of the \dagger strong minimality of an Abelian variety (\rightarrow Section I).

Let V be a complete normal variety, U the set of the simple points of V , and D a divisor on V . Then D is said to be **algebraically equivalent to 0** if there exist a nonsingular curve C , a divisor Γ on $U \times C$, and two points P and Q on C such that D can be written as $D = \varphi_P^*(\Gamma) - \varphi_Q^*(\Gamma)$, where φ_P and φ_Q are the morphisms $\varphi_P: U \rightarrow U \times P \rightarrow U \times C$ and $\varphi_Q: U \rightarrow U \times Q \rightarrow U \times C$. We denote by $\mathfrak{G}(V)$, $\mathfrak{G}_a(V)$, and $\mathfrak{G}_l(V)$ the set of all divisors on V , the set of divisors that are algebraically equivalent to 0, and the set of divisors that are linearly equivalent to 0, respectively. We can introduce a canonical structure of an Abelian variety into $\mathfrak{G}_a(V)/\mathfrak{G}_l(V)$, which is called the **Picard variety** of V . The dimension q of the Picard variety is called the **number of irregularity** of V ; if $q = 0$ we say that V is **regular**.

The Albanese variety and the Picard variety of V are \dagger isogeneous to each other, and each one is the Picard variety of the other. If V is a curve, they are isomorphic and called the **Jacobian variety** (\rightarrow 9 Algebraic Curves E).

Using Cartier divisors instead of divisors, we get an analogous theory to construct another kind of Picard variety which turns out to be isomorphic to the Picard variety of the strict Albanese variety of V . The group of the linear equivalence classes of Cartier divisors can be identified with $H^1(V, \mathcal{O}_V^*)$, where \mathcal{O}_V^* is the sheaf of multiplicative groups of the invertible elements in \mathcal{O}_V . From this point of view, we can generalize the theory of Picard variety to the case of schemes also. The theory thus obtained

is called the theory of **Picard schemes** [60].

The quotient group $\text{NS}(V) = \mathfrak{G}(V)/\mathfrak{G}_a(V)$ is finitely generated [66] and is called the **Neron-Severi group** of V . We call the rank of $\text{NS}(V)$ the **Picard number** of V and denote it by $p(V)$. In the case of a nonsingular projective variety over $k = \mathbb{C}$ we have an inequality $p(V) \leq h^{1,1}(V) (= \dim, H^1(V, \Omega_V^1))$ and the **Lefschetz number** $B_2(V) - \rho(V)$ is a birational invariant (where $B_2(V)$ is the second Betti number of V) [39]. For the positive characteristic case, however, the above inequality does not hold in general [61].

The torsion part of $\text{NS}(V)$ is $\mathfrak{G}_n(V)/\mathfrak{G}_a(V)$, where $\mathfrak{G}_n(V)$ denotes the group of divisors numerically equivalent to zero (\rightarrow Section Q) (T. Matsusaka). The last fact cannot be generalized for higher codimensional cycles [25].

Q. General Intersection Theory

Let V be an irreducible variety of dimension n , and let A and B be irreducible subvarieties of V of dimension r and s , respectively. If C is a proper component of $A \cap B$, we can define the **intersection multiplicity** $i(A, B, C; V)$ of A and B along C on V , which has properties consistent with our geometric intuitions. In particular, it is invariant under biregular mappings. If A and B intersect properly on V and if C_1, \dots, C_N are the proper components of $A \cap B$, we define an $(r+s-n)$ -cycle $A \cdot B$ by $A \cdot B = \sum_v i(A, B, C_v; V) C_v$ and call it the **intersection product** of A and B . If each component X_α of an r -cycle $X = \sum_\alpha n_\alpha X_\alpha$ and each component Y_β of an s -cycle $Y = \sum_\beta m_\beta Y_\beta$ intersect properly, we define

$$X \cdot Y = \sum_\alpha \sum_\beta n_\alpha m_\beta X_\alpha \cdot Y_\beta.$$

Then we have the associative law $(X \cdot Y) \cdot Z = X \cdot (Y \cdot Z)$ for cycles X , Y , and Z whenever both sides are defined. Two r -cycles X_1 and X_2 are said to be **numerically equivalent** if for every $(n-r)$ -cycle Y that intersects them properly we have $\deg(X, Y) = \deg(X_2, Y)$.

The theory of intersection is one of the most basis theories in algebraic geometry, for the other theories can be constructed from it [92].

R. Chow Rings

Let U and T be nonsingular irreducible varieties. If Z is a cycle on $U \times T$ such that $Z \cdot (U \times t)$ is defined for every point t of T , we put $Z \cdot (U \times t) = X(t) \times t$, and we obtain a family $\{X(t)\}$ of cycles on U parametrized by the points of T . Such a family is called an **algebraic family** of cycles. Two cycles X_1 and X_2 whose difference is equal to the difference of two cycles in an algebraic family are said to

be **algebraically equivalent**. In particular, if $X_1 - X_2$ can be expressed as the difference of two cycles of an algebraic family parametrized by the points of the affine line, then X_1 and X_2 are said to be **rationally equivalent**. The set of the cycles that are algebraically (rationally) equivalent to 0 is a subgroup $\mathfrak{Z}_a(U)$ ($\mathfrak{Z}_{rat}(U)$) of $J(U)$. For divisors, rational equivalence coincides with linear equivalence.

Let $f: V \rightarrow U$ be a morphism between nonsingular irreducible varieties. For an irreducible subvariety W of V , let W' denote the closure of $f(W)$, and put $f_3(W) = 0$ if $\dim W > \dim W'$ and $f_3(W) = mW'$ if $\dim W = \dim W'$, where $m = [k(W): k(W')]$ is the degree of the morphism $W \rightarrow W'$. Extending f_3 by linearity, we obtain a module homomorphism $f_3: \mathfrak{Z}(V) \rightarrow \mathfrak{Z}(U)$. If f is proper, then f_3 induces a module homomorphism f_* from $\mathfrak{Z}(V)/\mathfrak{Z}_{rat}(V) = A(V)$ to $A(U)$.

Let U and V be nonsingular irreducible projective varieties, and $f: V \rightarrow U$ be a morphism with graph Γ . If $Y \in \mathfrak{Z}(U)$ is such that $\Gamma \cdot (V \times Y)$ is defined, we denote by $f_3^*(Y)$ the image of $\Gamma \cdot (V \times Y)$ under the induced isomorphism $\Gamma \rightarrow V$. Each class of the rational equivalence class group $A(U) = \mathfrak{Z}(U)/\mathfrak{Z}_{rat}(U)$ contains a cycle for which f_3^* is defined. Hence we can define $f^*: A(U) \rightarrow A(V)$. Let $\Delta: U \rightarrow U \times U$ be the diagonal morphism, and define $x \cdot y = \Delta^*(x \times y)$ for $x, y \in A(U)$. Then $A(U)$ is a ring with respect to this product; moreover, it is a \dagger graded ring with the grading by codimension. This graded ring $A(U)$ is called the **Chow ring** of U , and the mapping $f^*: A(U) \rightarrow A(V)$ is a ring homomorphism. If f is proper, we have $f_*(y \cdot f^*(x)) = f_*(y) \cdot x$ for $x \in A(U)$, $y \in A(V)$.

Zero Cycles. Let V be a nonsingular irreducible projective variety over an uncountable algebraically closed field of characteristic zero (say C). Denote by $A_0(V)$ the group of classes of 0-cycles of degree 0 on V modulo rational equivalence. We say $A_0(V)$ is finite-dimensional if the mapping $V^n \times V^n \rightarrow A_0(V)$ sending $(a_1, \dots, a_n, b_1, \dots, b_n)$ to $\sum a_i - \sum b_i$ is surjective for a certain n .

If $A_0(V)$ is finite-dimensional, then the canonical mapping $A_0(V) \rightarrow \text{Alb}(V)$ induced from $V \rightarrow \text{Alb}(V)$ is bijective (A. A. Rojzman). In general, the torsion part of $A_0(V)$ is isomorphic to that of $\text{Alb}(V)$ (Rojzman [75]). If $h^{p,0}(V) > 0$ for some $p > 1$, then $A_0(V)$ is not finite-dimensional (Mumford, Rojzman [74]). If V is a surface which is not of general type and with $h^{2,0}(V) = 0$, then $A_0(V)$ is isomorphic to $\text{Alb}(V)$ (S. Bloch, A. S. Kas, D. Lieberman [13]). There exist surfaces of general type with $h^{2,0} = 0$ such that $A_0(V) = 0$. For instance, Godeaux surfaces are such surfaces (H. Inose [43]).

One Cycles. Let V be a nonsingular projective irreducible variety and $N(V)$ denote the numerical equivalence classes of 1-cycles on V ($\otimes_{\mathbb{Z}} \mathbb{R}$). Via the intersection pairing, $N(V)$ is dual to the Neron-Severi group tensored by \mathbb{R} (Section P); and let $NE(V)$ denote the smallest cone in $N(V)$ containing all effective 1-cycles. S. Mori studied the structure of $NE(V)$ in detail. One of his results is stated as follows: If the anticanonical divisor is ample, then there exist rational irreducible curves l_1, \dots, l_r such that (1) $-(l_i \cdot K_V) < n + 1$ and (2) $NE(V) = \mathbb{R}_+[l_1] + \dots + \mathbb{R}_+[l_r]$, where $n = \dim V$, K_V is the canonical divisor on V , and $[l_i]$ denotes the class represented by l_i . Moreover, Mori has proved that (1) if K_V is not numerically effective, e.g., if $-K_V$ is ample, then V contains a rational curve, and (2) if the tangent bundle of V is \dagger ample, then V is isomorphic to the projective space [59]. (This is called the **Hartshorne conjecture**.)

S. Chow Coordinates, Hilbert Schemes

Consider an irreducible algebraic correspondence T between irreducible varieties V and W . Let V' and W' be the closed images of the projections of T to V and W , and let a and c be their dimensions, respectively. Take generic points P, Q of V', W' , and consider the total transforms $T\{P\}$ of P to W and $T\{Q\}$ of Q to V . Denoting the dimensions of $T\{P\}$ and $T\{Q\}$ by b and d , respectively, we have $a + b = c + d$, where both sides are equal to the dimension of T . This property is called the **principle of counting constants**.

This simple principle has wide application. For instance, let V be an r -dimensional variety in $\mathbb{P}^n(k)$, and let $\sum_j u_{ij} X_j = 0$ ($0 \leq i \leq r$) be the equations of $r + 1$ hyperplanes H_i . The condition $V \cap (H_0 \cap \dots \cap H_r) \neq \emptyset$ defines an irreducible algebraic correspondence T between V and the multiprojective space $W = F^{r+1}(k) \times \mathbb{P}^n(k)$ with u_{ij} as coordinates: $T = \{(x, u) \mid x \in V, \sum u_{ij} X_j = 0\}$. In this case, we have $a = r, b = (n - 1)(r + 1)$, and $d = 0$ in the notation introduced previously, so that $c = n(r + 1) - 1$. This implies that W' is of codimension 1 in W ; hence W' is defined by a single equation $F(u_{ij}) = 0$. This form F is the **associated form** of V of B. L. van der Waerden and W. L. Chow. It is a homogeneous form of degree d ($d = \deg(V)$) in each (u_{i0}, \dots, u_{in}) and is symmetric in the indices i . More generally, for a positive cycle $X = \sum n_x V_x$ of dimension r and of degree d ($= \sum n_x \deg(V_x)$) in $\mathbb{P}^n(k)$, the product $\prod F_x^{n_x}$ of the associated forms F_x of V_x is called the **associated form** of X . The coefficients of F , arranged in a fixed order and regarded as the homogeneous coordinates of a point of a pro-

jective space, are called the **Chow coordinates** of X . This is a natural generalization of the \dagger Plücker coordinates. Given r , d and a projective variety $U (\subset \mathbf{P}^n(k))$, the set of Chow coordinates of the positive cycles that are contained in U , whose dimension is r and whose degree is d , is a projective variety called a **Chow variety**.

In scheme theory, the Hilbert scheme is introduced in the following way [60]. Let \mathbf{P}_Z^n be the n -dimensional projective space over $\text{Spec } \mathbf{Z}$. For a locally Noetherian scheme S , and for a closed subscheme Z of $\mathbf{P}_Z^n \times S$, we have the composition of the immersion of Z and the projection $\mathbf{P}_Z^n \times S \rightarrow S$; this is denoted by $f_Z: Z \rightarrow S$. For any point s of S , $f_Z^{-1}(s)$ is a closed subscheme of $\mathbf{P}_{k(s)}^n$ and the restriction of $\mathcal{O}(1)$ to $f_Z^{-1}(s)$ is denoted by L_s . Put $\mathcal{M}(S) = \{Z \subset \mathbf{P}_Z^n \times S \mid f_Z \text{ is flat}\}$. Then M becomes a contravariant functor to the category of sets, which is representable, i.e., there exists a locally Noetherian scheme M such that \mathcal{M} is naturally isomorphic to the functor $\text{Hom}(-, M)$. M is written as $\text{Hilb}(\mathbf{P}_Z^n)$ and is called the **Hilbert scheme**. There exists a closed subscheme W of $\mathbf{P}_Z^n \times \text{Hilb}(\mathbf{P}_Z^n)$ with flat f_W such that for any $Z \in M(S)$, there exists a unique $\varphi: S \rightarrow M = \text{Hilb}(\mathbf{P}_Z^n)$ in such a way that $Z = W \times_M S$. In particular, if X is a closed subscheme of \mathbf{P}_Z^n over a field k , there exist $\text{SE } \text{Hilb}(\mathbf{P}_Z^n)$ and a field extension $k/k(s)$ such that $X = f_W^{-1}(s) \otimes_{k(s)} k$. Thus $\text{Hilb}(\mathbf{P}_Z^n)$ parametrizes all closed subschemes of \mathbf{P}_k^n . Fix a polynomial P and define $\mathcal{M}^P(S)$ to be $\{Z \in M(S) \mid \chi(L_s^{\otimes m}) = P(m) \text{ for all } s\}$. \mathcal{M}^P is also a contravariant functor, represented by a scheme $\text{Hilb}^P(\mathbf{P}_Z^n)$ which is projective over $\text{Spec } \mathbf{Z}$. The direct sum of all $\text{Hilb}^P(\mathbf{P}_Z^n)$ is just $\text{Hilb}(\mathbf{P}_Z^n)$.

T. Algebraic Geometry and Complex Analytic Geometry

When $k = \mathbf{C}$, an algebraic variety is called a **complex algebraic variety**, and it has the structure of a \dagger complex analytic manifold or (if it has singular points) of a \dagger analytic space. If we denote by $\mathcal{O}_{V,x}^h$ the ring of holomorphic functions at a point x of V , then $\mathcal{O}_{V,x} \subset \mathcal{O}_{V,x}^h$, and their \dagger completions coincide. If x is a simple point of V , then $\mathcal{O}_{V,x}^h$ is the \dagger ring of convergent power series, and its completion is the \dagger ring of formal power series. The prime ideals of $\mathcal{O}_{V,x}^h$ remain prime under completion (M. Nagata). Because of this, the analytic behavior of V in a neighborhood of x can be investigated algebraically through the completion of $\mathcal{O}_{V,x}$. If V is complete, then the analytic coherent sheaves on V and the algebraic coherent sheaves on V correspond to each other bijectively; consequently, for propositions that can

be stated in terms of coherent sheaves, the results in the analytic sense remain valid in the algebraic sense also, and vice versa (J.-P. Serre [82]) (- 72 Complex Manifolds E).

U. Topology of Algebraic Varieties

Every algebraic variety defined over \mathbf{R} (or \mathbf{C}) can be triangulated by real analytic cells [46]. Let V be a nonsingular connected algebraic variety defined over \mathbf{C} . For an algebraic automorphism σ of \mathbf{C} we can define V^σ by letting σ operate on the coefficients of the defining equations of open affine coverings of V . V and V^σ are not necessarily homeomorphic or even of the same homotopy type [83]. Grothendieck has shown that there is a \dagger spectral sequence $E_1^{p,q} = H^p(V, \Omega_V^q) \Rightarrow H^{p+q}(V, \mathbf{C})$, called a **Hodge spectral sequence**. This spectral sequence can be defined in a purely algebraic way and $H^{p+q}(V, \mathbf{C})$ can be considered as the \dagger hypercohomology of the de Rham complex $\{\Gamma(V, \Omega_V^q), d\}$ of V . If V is projective, V carries a Kähler metric and by the theory of harmonic integrals the Hodge spectral sequence degenerates and $E_1^{p,q}$ is \mathbf{C} -isomorphic to the complex conjugate of $E_1^{q,p}$ (- 232 Kähler Manifolds B). This is also the case if V is complete.

The topology of a nonsingular projective surface was studied by Lefschetz using the method of Lefschetz pencils. For a projective nonsingular irreducible variety V of dimension n defined over \mathbf{C} , a **Lefschetz pencil** $\{W_t\}_{t \in \mathbf{P}^1}$ of V is, by definition, a linear pencil consisting of hyperplane sections W_t of V such that: (i) for all $t \in U = \mathbf{P}^1 - \{t_1, t_2, \dots, t_d\}$, W_t is nonsingular; (ii) each W_{t_i} has only one singular point that is an ordinary double point; and (iii) $W_0 \cap W_\infty$ is nonsingular, where we assume $0, \infty \in U$. Embed V into \mathbf{P}^N by a high multiple of a hyperplane of V and take a generic linear pencil $\{H_t\}$ of hyperplanes in \mathbf{P}^N . Then $\{W_t = H_t \cap V\}$ is a Lefschetz pencil of V . By blowing up V along $W_0 \cap W_\infty$ we obtain a smooth variety \tilde{V} and a surjective morphism $\pi: \tilde{V} \rightarrow \mathbf{P}^1$. Let $W = \pi^{-1}(0)$, $\pi_U = \pi|_{\pi^{-1}(U)}$. $R^p \pi_{U*} \mathbf{Q}$ is a local system attached to the monodromy representation $\varphi_p: \pi_1(U, 0) \rightarrow GL(H^p(W, \mathbf{Q}))$. φ_p is trivial if $p \neq n-1$. For each point t_i there corresponds a cocycle δ_i of $H^{n-1}(W, \mathbf{Q})$ called a **vanishing cocycle** such that if γ_i is a loop based at 0 going once (counterclockwise) around t_i , we have, for each $x \in H^{n-1}(W, \mathbf{Q})$, $\varphi_p(\gamma_i)(x) = x \pm (x, \delta_i) \delta_i$, where $(\ , \)$ is the intersection pairing of $H^{n-1}(W, \mathbf{Q})$. $\varphi_p(\gamma_i)$ is called a **Picard-Lefschetz transformation**. The main results due to Lefschetz are restated as follows. (1) (**Weak Lefschetz theorem**). The natural homomorphism $H^i(V, \mathbf{Q}) \rightarrow H^i(W, \mathbf{Q})$ is an isomorphism for $0 \leq i \leq n-2$ and is an injection for

$i = n - 1$, or equivalently $H_i(V, \mathbf{W}, \mathbf{Q}) = 0$ for $0 \leq i \leq n - 1$. (2) (Strong Lefschetz theorem). Let ξ be the cohomology class of $H^2(V, \mathbf{Q})$ corresponding to the hyperplane section \mathbf{W} , and let $L: H^*(V, \mathbf{Q}) \rightarrow H^{*+2}(V, \mathbf{Q})$ be the homomorphism defined by the cup product with ξ . Then for each $i \leq n$, $L^{n-1}: H^i(V, \mathbf{Q}) \rightarrow H^{2n-i}(V, \mathbf{Q})$ is an isomorphism. The weak Lefschetz theorem is true for a cohomology with integral coefficients. In fact, V-W has the homotopy type of a real n -dimensional finite CW complex, and $\pi_r(V, \mathbf{W}) = 0$ for $r < n$. The strong Lefschetz theorem is equivalent to the statement that $H^{n-1}(W, \mathbf{Q})$ is the direct sum of the vector space spanned by the vanishing cocycles δ_i and the vector space spanned by the invariant cocycles (i.e., $\varphi_{n-1}(\gamma_i)x = x, i = 1, \dots, d$). Lefschetz's original proof of this statement is incomplete, and no direct topological proof is known. The transcendental proof of (2) is given by the theory of harmonic integrals. A version of Lefschetz pencils is a proper morphism $f: X \rightarrow D = \{z \mid |z| < \varepsilon\}$ of a complex manifold X onto a disk D such that $f^* = f \circ f^{-1}(D^*)$, $D^* = D - \{0\}$, is of maximal rank at every point of $f^{-1}(D^*)$. Fix a point $s \in D^*$. $\pi_1(D^*, s)$ operates on $H^j(W, \mathbf{Z}, \mathbf{W} = f^{-1}(s))$, and we have a representation $\varphi_j: \pi_1(D^*, s) \rightarrow GL(H^j(W, \mathbf{Z}))$. For a loop γ based at s and going once around 0 the Picard-Lefschetz transformation $\varphi_j(\gamma)$ is quasiunipotent (i.e., for a certain integer m , $\varphi_j(\gamma)^m$ is unipotent).

For a nonsingular projective variety defined over a field k with characteristic $p > 0$, the above Lefschetz theorems hold for an l -adic cohomology ($l \neq p$) [19, 30 (SGA 7)] (Section AA). Using the theory of finite étale coverings of an algebraic variety defined over a field k , we can define the algebraic fundamental group and the algebraic homotopy groups, which are profinite completions of the topological fundamental group and the topological homotopy groups, respectively, where $k = \mathbb{C}$ [5, 30 (SGA 1)]. Let (X, x) be a germ of a complex space with isolated singular point x . (X, x) is always algebraizable, i.e., the completion $\hat{\mathcal{O}}_{X, x}$ of the analytic local ring $\mathcal{O}_{X, x}$ is isomorphic to the completion of the local ring of a closed point of an algebraic variety defined over \mathbb{C} [3]. For topological type of algebraic surfaces \rightarrow Moishezon [57].

V. Hodge Theory

Let $H_{\mathbf{R}}$ be a finite-dimensional real vector space containing a lattice $H_{\mathbf{Z}}$, and let $\mathbf{H} = H_{\mathbf{R}} \otimes_{\mathbf{R}} \mathbf{C}$ be its complexification. A Hodge structure of weight m on \mathbf{H} (or $H_{\mathbf{R}}$) is, by definition, a direct sum decomposition $\mathbf{H} = \bigoplus_{p+q=m} H^{p,q}$, $\bar{H}^{p,q} \cong H^{q,p}$, where $H^{p,q}$ is a

complex vector subspace and the overbar denotes complex conjugation. If \mathbf{H} and \mathbf{H}' carry Hodge structures of weight m and m' , respectively, then $\mathbf{H} \otimes \mathbf{H}'$, $\text{Hom}_{\mathbf{C}}(\mathbf{H}, \mathbf{H}')$, $\wedge^p \mathbf{H}$, and \mathbf{H}^* carry Hodge structures of weight $m + m'$, $m' - m$, pm , and $-m$, respectively. For a Hodge structure \mathbf{H} of weight m , $F^p \mathbf{H} = \bigoplus_{k \geq p} H^{k, m-k}$, $p = 0, 1, \dots, m$, induces a decreasing filtration. Let \mathbf{H} be a Hodge structure of weight m , and let Q be a bilinear form on \mathbf{H} . If the following three conditions are satisfied, the Hodge structure \mathbf{H} is said to be polarized by Q . (i) Q is defined over \mathbf{Q} and is symmetric (skew-symmetric) if m is even (odd). (ii) $Q(H^{p,q}, H^{p',q'}) = 0$ unless $p = p', q = q'$. (iii) $(\sqrt{-1})^{p-q} Q(v, \bar{v}) > 0$ for nonzero $v \in H^{p,q}$. Let \mathbf{V} be a compact Kähler manifold. Then $\mathbf{H} = H^*(V, \mathbb{C})$ carries the Hodge structure induced by the type (p, q) -decomposition (\rightarrow 232 Kähler manifolds B). This is also the case if \mathbf{V} is a compact complex manifold which is the image of a holomorphic mapping from a compact Kähler manifold of the same dimension. Moreover, if \mathbf{V} is projective, the Hodge-Riemann bilinear relations define a natural polarization on the subspace P of \mathbf{H} consisting of all primitive cohomology classes.

Each algebraic cycle \mathbf{W} of codimension s determines a cohomology class $[\mathbf{W}] \in H^{2s}(V, \mathbf{Q})$, which belongs to $H^{s,s}(V)$. (Such a class is called an algebraic cycle.) The converse of this fact is called the Hodge conjecture, which says that $H^{2s}(V, \mathbf{Q}) \cap H^{s,s}(V)$ is spanned by algebraic cycles. The case $s = 1$ has been verified by Hodge, Lefschetz, and Kodaira.

Let $\mathbf{V}(\mathbf{W})$ be a smooth irreducible algebraic variety defined over \mathbb{C} (complex manifold), and let $\varphi: V \rightarrow \mathbf{W}$ be a projective smooth morphism with connected fibers. Then $\mathbf{H} = R^m \varphi_* \mathbf{C}$ is a flat vector bundle on \mathbf{W} with the flat connection ∇ . \mathbf{V} is often called the Gauss-Manin connection, and it can be defined algebraically if \mathbf{W} is also algebraic.

For each fiber $V_s = \varphi^{-1}(s)$, $s \in \mathbf{W}$, the filtration $F^p H^m(V_s, \mathbb{C}) = \bigoplus_{k \geq p} H^{k, m-k}(V_s)$ induces a complex subbundle \mathbf{F}^p and the connection ∇ has the property $\nabla(\mathcal{O}(\mathbf{F}^p)) \subset \mathcal{O}(\mathbf{F}^{p-1} \otimes \mathbf{T}^*)$, where \mathbf{T} is the tangent bundle of \mathbf{W} [26]. Moreover, if \mathbf{W} is algebraic, \mathbf{V} is a differential equation with regular singular points on \mathbf{W} where \mathbf{W} is a smooth compactification of \mathbf{W} , such that $\mathbf{W} - \mathbf{W}$ is a divisor with normal crossings (\rightarrow Section L). If we consider the subbundle \mathbf{P} of \mathbf{H} consisting of all primitive cohomology classes, the polarization on each fiber induces a Hermitian pseudometric on \mathbf{P} . Curvatures of bundles $\mathbf{P} \cap \mathbf{F}^p$ have been studied by Griffiths [26]. There exists a classifying space D for polarized Hodge structures and there exists a holomorphic mapping of the universal covering \tilde{W} of \mathbf{W} into D , usually

called a period mapping. D may not be a bounded symmetric domain but has several interesting properties [24, 27]. In some cases D/Γ with a suitable discrete subgroup Γ is the moduli space of polarized algebraic varieties (e.g., curves, Abelian varieties).

P. Deligne [18] has generalized Hodge theory to arbitrary algebraic varieties (more generally schemes of finite type over \mathbb{C}). The simplest case is the Hodge theory of a smooth noncomplete irreducible variety X . By Nagata's embedding theorem [63] there exists a complete algebraic variety \bar{X} such that $Y = \bar{X} - X$ is a subvariety. By virtue of Hironaka's resolution theorem we can assume that \bar{X} is nonsingular and that Y is a divisor with normal crossings. Let $\Omega_X^1(\log Y)$ be a sheaf of germs of meromorphic 1-forms with logarithmic pole along Y , i.e., locally written as $\sum_{i=1}^k a_i(x)(dx_i/x_i) + \sum_{j=k+1}^n a_j(x)dx_j$, where (x_1, \dots, x_n) is a system of local coordinates with center $p \in Y$ in X such that $x_k = 0$ is a local equation of Y and $a_i(x), a_j(x)$ are holomorphic at p . Using the complex $\{\Omega_X^p(\log Y) = \bigwedge^p \Omega_X^1(\log Y), d\}$, with a suitable filtration, Deligne has shown that $H = H^m(X, \mathbb{C})$ carries a mixed Hodge structure and this structure is independent of the choice of X . The mixed Hodge structure on H consists of two finite filtrations, i.e., $\text{Oc.} \subset W_{n-1} \subset W_n \subset \dots \subset H$, the weight filtration which is defined over \mathbb{Q} , and $\dots \subset F^p \subset F^{p+1} \subset \dots \subset H$, the Hodge filtration such that F^p induces on W_n/W_{n-1} a Hodge structure of weight n . As a corollary he has shown that a meromorphic p -form on \bar{X} with logarithmic pole along Y (i.e., a section of $\Omega_X^p(\log Y)$) is d -closed on X , and $\omega = 0$ if and only if $\omega|_X$ is zero in $H^p(X, \mathbb{C})$. An important application of the theory of this mixed Hodge structure on $H^m(X, \mathbb{C})$ is the following. Let V and W be smooth irreducible varieties, and let $\varphi: V \rightarrow W$ be a smooth projective morphism. If \bar{V} is a smooth compactification of V , the canonical homomorphism $H^m(V, \mathbb{Q}) \rightarrow H^0(W, R^m\varphi_*\mathbb{Q})$ is surjective. Fix a point $s \in W$. $\pi_1(W, s)$ operates on $H^m(V_s, \mathbb{Q})$. Then this action is semisimple [18].

W. Deformations, Moduli, Algebraic Spaces

In this section for simplicity the field k is assumed to be algebraically closed. Let X be an algebraic scheme over k . A (flat) **deformation of X over a connected scheme S** over k with base point s_0 consists of the following data: (1) A morphism $p: \mathfrak{X} \rightarrow S$ that is flat and of finite type. If X is complete, p is also proper. (2) A closed point $s_0 \in S$ such that the fiber $\mathfrak{X} \times_S k(s_0)$ is isomorphic to X . For any closed point $s \in S$, the fiber $X_s = \mathfrak{X} \times_S k(s)$ is called a **flat deforma-**

tion of X . If X is smooth and complete, we assume further that p is smooth. Similarly, we can define a deformation of a polarized algebraic manifold, an embedding deformation of X in an algebraic scheme Y over k , a deformation of an affine scheme with isolated singular points, and a deformation of vector bundles on a fixed algebraic scheme over k , etc. The theory has two aspects: local theory and global theory.

Let (R, \mathfrak{m}) be a complete Noetherian local ring such that $R/\mathfrak{m} = k$. Set $R_n = R/\mathfrak{m}^n$. A formal deformation X_R of X is a sequence $\{X_n\}$ such that (i) X_n is a deformation of X over $\text{Spec}(R_n)$ and (ii) there is a compatible sequence of isomorphisms $X_n \otimes_{R_n} R_{n-1} \xrightarrow{\sim} X_{n-1}$ for any n . Let (FLA/k) be the category of finite-dimensional commutative local k -algebras. The local theory of deformation is the study of the covariant functor F of (FLA/k) to (Set) , where, for $A \in (\text{FLA}/k)$, $F(A)$ is the set of isomorphism classes of deformations of X over $\text{Spec}(A)$. The functor is in general neither representable nor prorepresentable (i.e., there exists a formal deformation X_R of X such that $F(A) = \text{Hom}_{k\text{-alg}}(R, A)$). But, under reasonably mild conditions on F , F has the hull R [78]. That is, there is a formal deformation X_R of X and a natural transformation $j: G \rightarrow F$, where $G(A) = \text{Hom}_{k\text{-alg}}(R, A)$, such that j is formally smooth (i.e., for any surjection $A' \twoheadrightarrow A$ in (FLA/k) , $G(A') \rightarrow G(A) \times_{F(A)} F(A')$ is surjective) and $G(k[\varepsilon]) \rightarrow F(k[\varepsilon])$ is bijective for the ring of dual numbers $k[\varepsilon]$. The formal deformation X_R is called a **versal deformation** of X . The hull R is unique up to noncanonical isomorphism. The deformation functor F has the hull R if X is (i) a complete algebraic scheme over k , (ii) an affine scheme with isolated singular points, (iii) a polarized algebraic variety over k , or (iv) a vector bundle on a complete algebraic scheme over k , etc. If there exists a deformation $\pi: \mathfrak{X} \rightarrow S$ of X over a scheme S with base point s_0 over k such that $R = \hat{\mathcal{O}}_{S, s_0}$, $X_n \cong \mathfrak{X} \otimes_S R_n$, the formal deformation $\{\pi_n: X_n \rightarrow \text{Spec}(R_n)\}$ is called **algebraizable**. Algebraizability of the versal deformation has been studied by M. Artin. Since the assumption that S is a scheme is rather restrictive, Artin has introduced the notion of algebraic spaces and has considered algebraizability in the category of algebraic spaces [2–4]. For a complete algebraic variety, the versal deformation is not necessarily algebraizable and we need to consider deformations of polarized algebraic varieties. The versal deformation of an affine variety with an isolated singularity is algebraizable in the category of algebraic spaces. For the global theory of deformations, we need the projectivity assumption, and the theory is essentially reduced to the theory of

Hilbert schemes (or Chow varieties) (\rightarrow Section S). The problem of moduli is considered as the study of the set A_4 of all isomorphism classes of deformations of X . Usually we consider the moduli of polarized varieties.

Let (Sch) be the category of Noetherian schemes and \mathcal{M} a contravariant functor from (Sch) to (Set) defined by $\mathcal{M}(X) = \{\text{isomorphism classes of families of polarized varieties parametrized by } X \in \text{Ob}(\text{Sch}), \text{ e.g., families of polarized Abelian varieties with(out) additional conditions}\}$. The functor \mathcal{M} is called a moduli functor. If it is represented by a scheme M , \mathcal{M} is called a **fine moduli scheme** [60]. In this case there is the universal family $\pi: \mathcal{V} \rightarrow M$. In many cases the moduli functor is not representable. A **coarse moduli scheme** for a given moduli problem is a scheme A_4 together with a natural transformation $\phi: \mathcal{M} \rightarrow \text{Hom}(-, M)$ such that (1) $\phi(\text{Spec}(k)): M(\text{Spec}(k)) \rightarrow \text{Hom}(\text{Spec}(k), M)$ is bijective for any algebraically closed field k , and (2) for any scheme N and any natural transformation $\psi: \mathcal{M} \rightarrow \text{Hom}(-, N)$, there is a unique natural transformation $\lambda: \text{Hom}(-, M) \rightarrow \text{Hom}(-, N)$ with $\psi = \lambda \cdot \phi$. A coarse moduli scheme is called a **moduli space** or a **moduli scheme**.

In many cases, the moduli space can be obtained as the quotient space of a certain (locally closed) subset H of a Hilbert scheme by the following equivalence relation: $s \sim s'$ $\Leftrightarrow H$ if and only if $X_s \cong X_{s'}$ as polarized varieties, where $\pi: \tilde{X} \rightarrow H$, $\pi^{-1}(s) = X_s$ (T. Matsusaka [53]). This equivalence relation is often induced by an action of a \dagger reductive algebraic group G . Suppose that a reductive algebraic group G operates on an algebraic k -scheme Z . A G -invariant morphism $f: Z \rightarrow Y$ (i.e., for the trivial action of G on Y , f is a G -equivariant morphism) is called a **geometric quotient** if (1) f is a surjective affine morphism and $f_*(\mathcal{O}_Z)^G = \mathcal{O}_Y$, (2) if X is a G -stable closed subset of Z , then $f(X)$ is closed in Y , and (3) for $x_1, x_2 \in Z$, $f(x_1) = f(x_2)$ if and only if the G -orbits of x_1 and x_2 are the same. Let G be a reductive algebraic group, $\chi: G \rightarrow \text{Aut}(V)$ a rational representation on a finite-dimensional vector space V over k , and $v_0 \neq 0$ a G -invariant point. Then there exists a G -invariant homogeneous polynomial F of degree ≥ 1 on V such that $F(v_0) \neq 0$ (W. J. Haboush [32]). This implies that if a reductive group G operates on an algebraic k -affine scheme $\text{Spec}(A)$, then the invariant ring A^G is a finitely generated k -algebra and, moreover, if any G -orbit in $\text{Spec}(A)$ is closed, the natural morphism $\text{Spec}(A) \rightarrow \text{Spec}(A^G)$ is a geometric quotient. For a quasiprojective scheme Z over k with an action of a reductive group G we need a notion of stable points [60, 62]. The subset of stable points of Z consists of all geometric

points of a G -stable open subscheme Z^s of Z , and there exists a geometric quotient $f: Z^s \rightarrow Y$ where Y is quasiprojective (Mumford [60], C. S. Seshadri [79], Haboush [32]). In this way Mumford has shown the existence of coarse moduli schemes of nonsingular complete irreducible algebraic curves and polarized Abelian varieties. But, in general, analysis of stable points is very difficult and it is desirable to extend the category of schemes so that it becomes easier to obtain a quotient. Matsusaka has introduced the notion of a Q -variety [52]. M. Artin has introduced the notion of an algebraic space (D. Knutson [49]).

An **algebraic space** X of **finite type** consists of an affine scheme U and a closed subscheme $R \subset U \times U$ such that (1) R is an \dagger equivalence relation, and (2) the projections $p_i: R \rightarrow U$ ($i = 1, 2$) are étale. (These are often written as $R \rightrightarrows U \rightarrow X$.) A morphism $g: V \rightarrow X$ of an affine scheme V to an algebraic space X consists of a closed subscheme $W \subset U \times V$ such that (1) the projection $W \rightarrow V$ is étale and surjective, and (2) the two closed subschemes $R \times_V W$, $W \times_V W$ of $U \times U \times V$ are equal. Let $S \rightrightarrows V \rightarrow Y$ be an algebraic space. Then $\text{Hom}(Y, X)$ is defined as the kernel of $\text{Hom}(V, X) \rightrightarrows \text{Hom}(S, X)$. If Y is an affine scheme, this definition of $\text{Hom}(Y, X)$ is equivalent to the previous definition by virtue of the étale descent. Thus algebraic spaces form a category which contains the category of schemes. We can define the structure sheaf of an algebraic space and construct a cohomology theory. Many important notions and theorems for schemes can be generalized to those for algebraic spaces. Every algebraic space has a dense open subset that is an affine scheme. A group algebraic space is a group scheme (J. P. Murre). Suppose $k = \mathbb{C}$. If an algebraic group G operates on an algebraic k -scheme properly with a finite stabilizer group, the quotient space exists as an algebraic space. In this way H. Popp has shown the existence of moduli spaces of algebraic surfaces of general type as algebraic spaces [70, 71] (- 15 Algebraic Surfaces; also [54]). Moreover, every separated algebraic space X of finite type over \mathbb{C} carries a natural structure X^{an} of an analytic space. If there exists a proper modification morphism $f: X^{\text{an}} \rightarrow Y$ of a separated algebraic space X onto an analytic space Y , then Y carries a structure of an algebraic space and f becomes a morphism of algebraic spaces (Artin [2]). For any algebraically closed field k , Artin has introduced the notion of formal algebraic space and formal contraction and has obtained results similar to those for algebraic spaces [49]. An irreducible compact complex space X whose algebraic dimension (\rightarrow 72 Complex Manifolds F) is equal to $\dim X$ is called a

Moishezon space. As a corollary of the above theorem, any Moishezon space X carries a structure M of a compact algebraic space such that $X \cong M^{\text{an}}$.

X. Formal Schemes

Let A be a ring which we assume to be Noetherian, for simplicity, and I an ideal of A . Taking $\{I^n\}_{n>0}$ as a fundamental system of neighborhoods of 0, we can introduce a structure of a topological ring into A called **I -adic topology**. The completion of A with I -adic topology is isomorphic to the projective limit $\hat{A} = \varprojlim_{n>0} A/I^n$ (here A/I^n are regarded as discrete topological rings) and called the **completion of A along I** . If A is Noetherian, then \hat{A} is again Noetherian. There is a canonical continuous homomorphism $i: A \rightarrow \hat{A}$ whose kernel comprises the zero divisors a with $a \cdot 1 \in I$ (intersection theorem of Krull; → 284 Noetherian Rings B). If i is an isomorphism, we say A is **complete** with respect to I . The topology of \hat{A} is the \hat{I} -adic topology where $\hat{I} = i(I)\hat{A}$ and \hat{A} is complete with respect to \hat{I} . Take a Noetherian ring A complete with respect to I which we consider as an I -adic topological ring by identifying its completion along I with A . On $\mathfrak{X} = V(I) \subset \text{Spec}(A)$ we can define a sheaf of topological rings $\mathcal{O}_{\mathfrak{X}}$ by $\Gamma(\mathcal{D}(f), 0) = \varprojlim_{n>0} A_f/I^n A_f$ for $\mathcal{D}(f) = D(f) \cap \mathfrak{X}$ with $f \in A$. We call $(\mathfrak{X}, \mathcal{O}_{\mathfrak{X}})$ the **formal spectrum** of A and write $\text{Spf}(A)$. I is called a **defining ideal** of $\text{Spf}(A)$. A (locally Noetherian) **formal scheme** is by definition a topological local ringed space which is locally isomorphic to a formal spectrum (of a Noetherian ring). If we define morphisms between two formal schemes by those in the category of topological local ringed spaces, the formal schemes form a category.

For two formal spectra $\text{Spf}(A)$ and $\text{Spf}(B)$ with defining ideals I and J , respectively, the direct product $\text{Spf}(A) \times \text{Spf}(B)$ in the category of formal schemes is the formal spectrum of the completion of $A \otimes B$ along the image of $I \otimes B + A \otimes J$. Similarly, we can construct a fiber product of formal schemes. A formal scheme \mathfrak{X} is called **separated** if the image of the diagonal morphism $\Delta_{\mathfrak{X}}: \mathfrak{X} \rightarrow \mathfrak{X} \times \mathfrak{X}$ is closed (→ Section D).

For a Noetherian ring A with an ideal I , the formal spectrum $\text{Spf}(\hat{A})$ (with a defining ideal \hat{I}) is called the **completion of $\text{Spec}(A)$ along $P(I)$** . Similarly for a Noetherian scheme X and a closed subscheme X' we can define the **completion $X_{|X'}$ of X along X'** . Every completion of a separated scheme is separated. For a coherent sheaf F on X one can define its **completion $F_{|X'}$ along X'** , which is again coherent (under the assumption that X is locally Noetherian).

Thus we can develop a theory of formal schemes in a way similar to that of schemes, which we call **“formal geometry”** (for the more general definitions and further discussions see [2; 29, I, III; 303]). Roughly speaking, a function on $X_{|X'}$ is a formal Taylor series with respect to the direction normal to X' whose coefficients are regular functions on X' . The method of formal completion enables us to introduce “analytic” or “infinitesimal” methods in algebraic geometry. Among many important theorems, we state here the following two theorems. (1) **The fundamental theorem of proper mapping:** Let $f: X \rightarrow Y$ be a proper morphism of locally Noetherian schemes, Y' a closed subscheme of Y , and $X' = X \times_Y Y'$ the inverse image of Y' . Denote the respective completions of X and Y along X' and Y' by \hat{X} and \hat{Y} , respectively. We have the induced proper morphism of formal schemes $\hat{f}: \hat{X} \rightarrow \hat{Y}$. Then we have canonical isomorphisms, $(R^n f_*(F))_{|Y'} \cong R^n \hat{f}_*(F_{|X'})$, $n \geq 0$, for every coherent, \mathcal{O}_X -Module F on X . This theorem can be applied to prove **Zariski’s connectedness theorem:** for a proper morphism $f: X \rightarrow Y$ of locally Noetherian schemes with $f_*(\mathcal{O}_X) = \mathcal{O}_Y$, every fiber $f^{-1}(y)$ off is connected and non-empty for $y \in Y$. (2) We use the same notation as in (1) and assume, moreover, that $Y = \text{Spec}(A)$ for a Noetherian ring A , complete with respect to an ideal I , and $Y' = V(I)$. Then the correspondence $F \rightarrow F_{|X'}$ gives an equivalence between the category of coherent \mathcal{O}_X -Modules with proper support over Y and the category of coherent $\mathcal{O}_{\hat{X}}$ -Modules with proper support over \hat{Y} . This theorem plays an important role in the theory of \dagger deformations of algebraic varieties.

Y. Algebraic Vector Bundles

In this section a **vector bundle** is a locally free sheaf of finite constant rank (→ Section E). A quotient sheaf of a vector bundle is called a **quotient bundle** if it is a vector bundle. A subsheaf F of a vector bundle E is a **subbundle** when both F and E/F are vector bundles. A vector bundle is said to be **indecomposable** unless it is a direct sum of proper subbundles. Every vector bundle E on \mathbf{P}^1 is a direct sum of line bundles, that is, $E \cong \bigoplus \mathcal{O}(a_i)$ (Grothendieck). This property characterizes \mathbf{P}^1 in the category of nonsingular projective varieties. In fact, if X is a nonsingular projective variety with $\dim X > 0$ and $X \not\cong \mathbf{P}^1$ and if r is an integer with $r \geq \dim X$, there are stable (see below), a fortiori, indecomposable vector bundles on X of rank r (J. Simonis and M. Maruyama). Vector bundles are closely related to subschemes of the base variety. Let E be a

vector bundle of rank 2 on a nonsingular quasiprojective variety X and $\mathcal{O}(1)$ an ample invertible sheaf on X . For $n \gg 0$ and general $s \in H^0(X, E(n))$, $E(n)/s\mathcal{O}_X \cong L \otimes I$ with L a line bundle and I an ideal in \mathcal{O}_X which defines a smooth subscheme $Y = (s)_0$ of codimension 2. When X is, for example, \mathbf{P}^n ($n \geq 3$) or affine, the converse holds. Let Y be a subscheme of X purely of codimension 2 and locally of complete intersection. If $\omega_Y \cong A^4 \otimes \mathcal{O}_Y$ for an invertible sheaf M on X , there is a vector bundle E of rank 2 and $s \in H^0(X, E)$ with $(s)_0 = Y$. Moreover, E is decomposable if and only if Y is globally a complete intersection. An Abelian surface can be embedded in $\mathbf{P}^4(\mathbf{C})$, and hence we have an indecomposable vector bundle of rank 2 on $\mathbf{P}^4(\mathbf{C})$ [40]. For $n \geq 5$, we have no examples of indecomposable vector bundles of rank 2 on $\mathbf{P}^n(\mathbf{C})$ [36]. Every vector bundle on $A^n = k^n$ is trivial (D. Quillen [72], A. Suslin). From this and the fact stated above several results can be deduced; every nonsingular curve in A^3 is set-theoretically a complete intersection (L. Szpiro).

For a vector bundle E on a complete scheme, the following are equivalent: (i) for every coherent \mathcal{O}_X -module F , $F \otimes S^n(E)$ is generated by its global sections for $n \gg 0$, (ii) for every coherent sheaf F on X , $H^i(X, F \otimes S^n(E)) = 0$ for all $i > 0$ and $n \gg 0$, (iii) the tautological line bundle $\mathcal{O}(1)$ on $\mathbf{P}(E)$ is ample. A vector bundle having these properties is said to be **ample**. This is a generalization of the notion of ampleness of invertible sheaves (- Section E). The set of ample vector bundles is closed under several operations [34]. No good criterion such as Nakai-Moishezon's for the ampleness of invertible sheaves (- Section E) is yet known. The tangent bundle of a nonsingular complete variety X is ample if and only if $X \cong \mathbf{P}^n$ (- Section R; S. Mori [59]).

Let Y be a nonsingular projective variety over an algebraically closed field and $\mathcal{O}_Y(1)$ an ample invertible sheaf on Y . A coherent sheaf E on Y is said to be **stable** (or, **semistable**) with respect to $\mathcal{O}_Y(1)$ if E is torsion-free and if for every coherent subsheaf F of E with $0 \neq F \neq E$, $\chi(F(m))/r(F) < (\leq) \chi(E(m))/r(E)$ for all $m \gg 0$, where $r(*)$ denotes the rank. If E is stable (or semistable) and locally free, it is called a **stable** (resp. **semistable**) **vector bundle**. Let $f: X \rightarrow S$ be a smooth, projective, geometrically integral morphism and $\mathcal{O}_X(1)$ an f -ample invertible sheaf on X . For a numerical polynomial H and an S -scheme T , set $\Sigma_{X/S}^H(T) = \{E \mid E \text{ is a coherent sheaf on } X_T \text{ with the properties (a) and (b)}\} / \sim$; (a) E is T -flat, (b) for every geometric fiber X_t , $E_t = E|_{X_t}$ is stable with respect to $\mathcal{O}_{X_t}(1)$ and $\chi(E_t(m)) = H(m)$, and if

$E_1 \cong E_2 \otimes f_T^*(L)$ with L an invertible sheaf on T , $E_1 \sim E_2$. $\Sigma_{X/S}^H$ is a contravariant functor of the category of locally Noetherian S -schemes to the category of sets. If S is of finite type over a universally Japanese ring A , $\Sigma_{X/S}^H$ has a coarse moduli scheme $M_{X/S}(H)$ (- Section W) and it is locally of finite type over S (D. Mumford, Seshadri, D. Gieseker, Maruyama [23, 51]). The set of the classes of semistable sheaves under a suitable equivalence relation (S -equivalence) on geometric fibers of X over S also has a coarse moduli scheme $M_{X/S}(H)$ and $M_{\text{ss}}(H)$ is its open subscheme. Moreover, it is known that $M_{\text{ss}}(H)$ is projective over S in some cases, for example, when A is a field of characteristic zero. When $\dim X/S = 1$, $X \cong \mathbf{P}^2$ or \mathbf{P}^3 , the structures of $M_{\text{ss}}(H)$ have been extensively studied [11, 69]. Theories of vector bundles are used in theoretical physics [9].

Z. Torus Embeddings

Over an algebraically closed field k , a **torus embedding**, or a **toric variety**, is a normal scheme X locally of finite type over k on which an algebraic torus T acts with a dense open orbit isomorphic to T . Such X 's, as well as many of their algebrogeometric properties, can be described very simply in terms of cones in real affine spaces, as Demazure [21] first saw in the nonsingular case in connection with algebraic subgroups of the Cremona transformation group, and then as D. Mumford et al. [47] as well as K. Miyake and T. Oda [67] saw in the general case immediately after H. Sumihiro [SS] proved a basic theorem on linear algebraic group actions.

The group N , written additively, of one-parameter subgroups of an r -dimensional algebraic torus T is a free Abelian group of rank r . A **convex rational polyhedral cone** σ in $N_{\mathbf{R}} = \mathbf{R} \otimes_{\mathbf{Z}} N$ with 0 as the vertex is the set of nonnegative linear combinations of a finite number of elements of N such that $\sigma \cap (-\sigma) = \{0\}$. A subset τ of σ is called a **face**, and is denoted by $\tau < \sigma$, if there exists a linear functional m on $N_{\mathbf{R}}$ having nonnegative values on σ and $\tau = \{y \in \sigma \mid m(y) = 0\}$. A **fan** Δ in $N_{\mathbf{R}}$ is a collection of such σ 's satisfying the conditions (i) $\Delta \ni \sigma, \sigma > \tau \Rightarrow \Delta \ni \tau$ and (ii) $\Delta \ni \sigma, \sigma' \Rightarrow \sigma > \sigma \cap \sigma' < \sigma'$.

Each $\sigma \in \Delta$ gives rise to an affine torus embedding U_{σ} as follows: Let M be the \mathbf{Z} -module dual to N ; hence A^4 is the group of characters of T . For $\sigma \in \Delta$, the set $M \cap \sigma = \{m \in M \mid m(y) \geq 0 \text{ for all } y \in \sigma\}$ is seen to be a finitely generated additive subsemigroup of M containing 0 and generating M as a group. U_{σ} is then the spectrum of the semigroup algebra $k[M \cap \sigma]$.

Thanks to the condition (ii) above, the U_σ 's can be naturally pasted together to produce a torus embedding $X = \bigcup_{\sigma \in \Delta} U_\sigma$.

Every torus embedding is obtained in this way. Equivariant dominant morphisms between torus embeddings can be described in terms of \mathbb{Z} -linear maps between N 's which send a fan to another.

Many algebrogeometric properties of X can be described in terms of A , e.g., X is nonsingular if and only if every $\sigma \in A$ can be spanned by a part of a \mathbb{Z} -basis of N . X is complete (proper over k) if and only if the union of σ 's in A coincides with N . X has at worst cyclic quotient singularities if and only if every $\sigma \in A$ is simplicial, i.e., if it is spanned by R -linearly independent elements of N . An equivariant resolution of singularities of X exists and is obtained by a suitable subdivision of A (Mumford et al. [47]). X has only rational singularities, hence is Cohen-Macaulay (M. Hochster [38] and Mumford et al. [47]). The set of T -orbits in X is in one-to-one correspondence with $\sigma \in \Delta$. A reduced T -invariant subscheme Y of X is the union of T -orbits, and hence corresponds to a subset Σ of A . M.-N. Ishida [44] determined when Y is Cohen-Macaulay or Gorenstein in terms of the combinatorics of Σ .

A T -invariant Cartier divisor D on X corresponds to a support function h , which is a continuous R -valued function on the union $\bigcup_{\sigma \in \Delta} \sigma$ which is (i) positively homogeneous, i.e., $h(\lambda y) = \lambda h(y)$ for $\lambda > 0$ and $y \in \bigcup_{\sigma \in \Delta} \sigma$, (ii) \mathbb{Z} -valued on $N \cap (\bigcup_{\sigma \in \Delta} \sigma)$ and (iii) linear when restricted to each $\sigma \in \Delta$. Various properties of the invertible sheaf $\mathcal{O}_X(D)$ (\rightarrow Section E) can be described in terms of h . For instance, when X is complete, $\mathcal{O}_X(D)$ is t ample if and only if h is upper convex, i.e., $h(y) + h(y') \leq h(y + y')$, and moreover, A is the coarsest fan with the property (iii) above. The cohomology of $\mathcal{O}_X(D)$ can be calculated by means of h (Demazure [21] and V. Danilov [17]).

A support function h , on the other hand, gives rise to a convex polyhedron in M_R with vertices in M . In this way, certain aspects of the geometry of convex sets can be thought of as a part of the theory of projective varieties (R. Stanley [87], B. Teissier [89]).

Mumford et al. [47] introduced a more general concept of **toroidal embedding**: A normal algebraic variety Y and a nonsingular Zariski open subset U such that $Y \supset U$ is formally isomorphic at each point to a torus embedding $X \supset T$. This concept has been used very effectively to prove important theorems: (1) Systematic nice compactifications of arithmetic quotients of bounded symmetric domains (D. Mumford et al. [7], I. Satake [77]). Y. Nami-kawa [65] worked out the details in the case

of the Siegel upper planes, improving their earlier Satake compactifications studied by I. Satake, W. Baily, J.-I. Igusa, and A. Borel [12].

(2) **Semistable reduction theorem** (Mumford et al. [47]). Let $f: V \rightarrow C$ be a flat morphism from a nonsingular variety V to a nonsingular curve C in characteristic 0. After a finite base extension $C' \rightarrow C$ and a modification $V' \rightarrow V \times_C C'$, we can get $f': V' \rightarrow C'$ whose singular fibers are reduced with only nonsingular components crossing normally with each other (\rightarrow Section L). Without the reducedness requirement, the existence is derived from a result of Hironaka [37].

AA. Etale Topology

Let \mathcal{S} be a category. We say that a **Grothendieck topology** on Y is given if, for each $S \in \text{Ob}(\mathcal{S})$, families of morphisms (**covering families** of S) are given and satisfy the following conditions: (1) If $\varphi: T \rightarrow S$ is an isomorphism, $\{\varphi: T \rightarrow S\}$ is a covering family, (2) if $\{\varphi_i: R_i \rightarrow S\}_{i \in I}$ is a covering family, for any morphism $\varphi': S' \rightarrow S$, the fiber product $R'_i = R_i \times_S S'$ exists and the induced family $\{\varphi'_i: R'_i \rightarrow S'\}$ is a covering family of S' , (3) if $\{\varphi_i: R_i \rightarrow S\}_{i \in I}$ is a covering family and if for each $i \in I$, $\{s_{i,a}: S_{i,a} \rightarrow R_i\}_{a \in A_i}$ is a covering family, then $\{\varphi_i^0 s_{i,a}: S_{i,a} \rightarrow S\}_{i \in I, a \in A_i}$ is a covering family. In general, it is more convenient to use a notion of sieves to define a Grothendieck topology [30 (SGA 4)]. A category with Grothendieck topology is called a **site**. Let X be a scheme and Et/X the category whose objects consists of schemes étale over X . If we choose a family of morphisms $\{\phi_i: Y_i \rightarrow Y\}_{i \in I}$, with $\bigcup_{i \in I} \phi_i(Y_i) = Y$, as a covering family of $Y \in \text{Ob}(\text{Et}/X)$, this defines the **étale topology** on X and the **étale site** $X_{\text{ét}}$. Similarly, one can define the **Zariski site** X_{Zar} (resp. the **flat site** X_{fl}), using open immersions (resp. flat morphisms locally of finite type). A **presheaf** on a **site** Y is a contravariant functor from Y to (Set) . A presheaf F is a **sheaf** if, for any covering family $\{\phi_i: R_i \rightarrow R\}_{i \in I}$, $F(R) \rightarrow \prod_{i \in I} F(R_i) \rightrightarrows \prod_{i,j \in I} F(R_i \times_R R_j)$ is exact. If Y has a final object X , the functor $F \mapsto F(X)$ is left exact on the category of Abelian sheaves on \mathcal{S} and the cohomology groups $H^*(X, F)$ are defined as the right derived functors. Using covering families, one can define the Čech cohomology $\check{H}^*(X, F)$ as usual. In the following, a sheaf means an Abelian sheaf. For a t geometric point $i: x \rightarrow X$ of a scheme, an étale neighborhood U of x consists of an étale morphism $f: U \rightarrow X$ and a morphism $j: x \rightarrow U$ such that $f \circ j = i$. For a sheaf F on $X_{\text{ét}}$, the stalk F_x at a geometric point x is defined by $F_x =$

$\lim \Gamma(U, F)$, U being the étale neighborhoods of x . On $X_{\text{ét}}$ the sheaf \mathbf{G}_m is defined by $G_i(S) = \Gamma(S, \mathcal{O}_S)^*$ for each $S \in \text{Ob}(\text{Et}/X)$. The kernel of the n th power homomorphism $\mathbf{G}_m \xrightarrow{f_n} \mathbf{G}_m$ is denoted by μ_n . The sequence $1 \rightarrow \mu_n \rightarrow \mathbf{G}_m \xrightarrow{f_n} \mathbf{G}_m \rightarrow 1$ is exact in $X_{\text{ét}}$ if p is prime to residual characteristics of X , but not necessarily exact in X_{zar} . There are canonical isomorphisms $\text{Pic}(X) = H^1(X_{\text{zar}}, \mathcal{O}_X^*) \simeq H^1(X_{\text{ét}}, \mathbf{G}_m) \simeq H^1(X_{\text{fl}}, G_i)$. For $X = \text{Spec}(k)$, k a field, the étale cohomology theory of sheaves on $X_{\text{ét}}$ is equivalent to the \dagger Galois cohomology theory over k ; hence $H^i(X_{\text{ét}}, F) \simeq H^i(G, F_k)$, where $G = \text{Gal}(k/\bar{k})$, \bar{k} the \dagger separable closure of k and F_k is the stalk of F at the geometric point \otimes_k of X . For a morphism $f: X \rightarrow Y$ of schemes and a sheaf F on $X_{\text{ét}}$, the direct image sheaf $f_* F$ of F is defined by $f_* F(S) = F(X \times_Y S)$, $S \in \text{Ob}(\text{Et}/Y)$, and higher direct-image sheaves $R^i f_* F$ are defined by the right-derived functor. Let X be a separated scheme of finite type over a field k . By a theorem of Nagata [63], there exists a scheme X proper over k and an open immersion $j: X \rightarrow \bar{X}$. For a torsion sheaf F on $X_{\text{ét}}$, let $j_! F$ be a sheaf on $\bar{X}_{\text{ét}}$ extended by 0 outside X . The cohomology with compact support $H_c^q(X_{\text{ét}}, F)$ is defined by $H_c^q(X_{\text{ét}}, F) = H^q(\bar{X}_{\text{ét}}, j_! F)$. This is independent of compactifications. Similarly, for a separated morphism $f: X \rightarrow S$ of finite type of schemes and a torsion sheaf F on $X_{\text{ét}}$, one can define higher direct image sheaf with compact support $R^q f_! F$. For the étale topology, torsion sheaves are important. All torsion sheaves on $X_{\text{ét}}$ on a Noetherian scheme X are inductive limits of constructible sheaves. A sheaf F on $X_{\text{ét}}$ is called **locally constructible (constant)** if F is represented by an étale covering of X . A sheaf F on $X_{\text{ét}}$ is called **constructible** if there exists a finite surjective family of subscheme X_i of X such that the restriction of F to X_i is locally constructible (constant). This is equivalent to saying that every irreducible closed subscheme Z of X contains a nonempty open subscheme U such that the restriction F to U is locally constant and has finite stalks, i.e., there is a covering family $\{\phi_i: U_i \rightarrow U\}$ such that $F|_{U_i}$ is constant and the stalk F_x is a finite Abelian group for all geometric points x of U . The cohomology of a torsion sheaf or a constructible sheaf has properties similar to those of the classical cohomology. Let $f: X \rightarrow S$ be a proper morphism and F a torsion sheaf on $X_{\text{ét}}$. Then the stalk $R^q f_* F$ at a geometric point s of S is isomorphic to $H^q(X_{s, \text{ét}}, F)$, where $X_s = X \times_S \text{Spec } k(s)$. If f is a separated morphism of finite type of Noetherian schemes, a similar fact holds for the cohomology with compact support. Moreover, if F is a constructible sheaf, $R^q f_! F$ is also constructible (**finiteness theorem**). For an affine scheme X of

finite type over a separably closed field and F a torsion sheaf on $X_{\text{ét}}$, one has $H^q(X_{\text{ét}}, F) = 0$ for $q > \dim X$. Let $f: X \rightarrow S$ be a separated morphism of schemes of finite type on C , F a torsion sheaf on $X_{\text{ét}}$. One has a canonical isomorphism $(R^q f_! F)^{an} \simeq R^q f_!^{an} F^{an}$. In particular, if X is proper over C , one has $H^q(X_{\text{ét}}, \mathbf{Z}/(n)) \simeq H^q(X^{an}, \mathbf{Z}/(n))$. On the other hand, for a nonsingular complete curve C over an algebraically closed field, one always has $H^1(C_{\text{ét}}, \mathbf{Z}) = 0$. For a geometric point s of S the **strict localization** of S at s is the ring $\mathcal{O}_{S, s} = \varinjlim \Gamma(U, \mathcal{O}_U)$, U being étale neighborhoods of s . A geometric point t of S is called a **generalization** of s if t is defined by an algebraic closure of the residue field of a point of $\text{Spec } \mathcal{O}_{S, s}$. In this case, s is called a **specialization** of t . If $f: X \rightarrow S$ is a proper smooth morphism the sheaf $R^q f_* \mathbf{Z}/(n)$ is locally constructible (constant), and if s is a specialization of t one can define a **cospecialization** of $H^q(X_{t, \text{ét}}, \mathbf{Z}/(n))$ to $H^q(X_{s, \text{ét}}, \mathbf{Z}/(n))$ which is bijective. Let X be a scheme of finite type over a field k . If $l \nmid \# \text{ch}(k)$ is prime, one can define the l -adic cohomology $H^q(X, \mathbf{Q}_l) = \varinjlim_n H^q(X, \mathbf{Z}/(l^n)) \otimes_{\mathbf{Z}_l} \mathbf{Q}_l$. The l -adic cohomology has as many good properties as the classical cohomology (\rightarrow Section U).

17 (X1.11) Algebroidal Functions

A. General Remarks

If an analytic function f satisfies an \dagger irreducible algebraic equation

$$A_0(z)f^k + A_1(z)f^{k-1} + \dots + A_k(z) = 0 \quad (1)$$

with single-valued \dagger meromorphic functions $A_j(z)$ in a domain G in the complex z -plane, then f is called a **k -valued algebroidal function** in G . With no loss of generality, we can assume that there is no common zero among the $A_j(z)$ and that all the $A_j(z)$ are \dagger holomorphic in G . When $k = 1$, the solution of (1) is a single-valued meromorphic function in G . If all the $A_j(z)$ are polynomials, then f is an \dagger algebraic function. Thus algebroidal functions can be regarded as extensions of single-valued to multiple-valued functions and also as extensions of algebraic to \dagger transcendental functions. Since (1) is irreducible, its discriminant $D(z)$ does not vanish identically. For all the points a satisfying $D(a) \neq 0$, $A_0(a) \neq 0$, $a \in G$, equation (1) determines k holomorphic function ele-

ments $f_1(z), f_k(z)$ in a suitable neighborhood of a that determine the analytic function f . They can be \dagger prolonged analytically in G in the wider sense. At any point satisfying $A_0(z) = 0$, at least one element has a pole; and at any point satisfying $D(z) = 0$, there may appear ramified elements. Therefore an algebroidal function can be defined as a finitely multiple-valued analytic function in G with the exception of poles and \dagger algebraic branch points. Every algebroidal function $f(z)$ determines a \dagger Riemann surface, which may be considered a \dagger covering surface \mathfrak{Z} of G . This surface \mathfrak{Z} is a k -sheeted \dagger covering surface over G with no singular point except for algebraic branch points. Also, f reduces to a single-valued meromorphic function on \mathfrak{Z} , and all the function elements over a point z are different. A k -valued algebroidal function can also be characterized by this property.

These two (equivalent) definitions of algebroidal functions give rise to two distinct methods of studying these functions. In adopting the first definition, we can make use of results in the single-valued case, as did G. Rémoundos and G. Valiron. When the latter definition is adopted, we can use several methods that are also applicable in the single-valued case, as did H. Selberg and E. Ullrich.

Research on algebroidal functions has been carried out mainly for the case where G is the finite plane $|z| < \infty$ or the unit disk $|z| < 1$. Almost all the known results for algebroidal functions are extensions of those on single-valued functions, but several results particularly relevant to algebroidal functions have been discovered. The existence of branch points makes it difficult to investigate algebroidal functions in some cases.

B. Absolute Value

Among several results on the absolute values of algebroidal functions, the \dagger maximum principle, one of the basic principles, holds on the Riemann surface \mathfrak{Z} . The following relation holds among the $A_j(z)$ and $|f_v(z)|$. Assume that (1) has the form

$$f^k + A_1(z)f^{k-1} + \dots + A_k(z) = 0. \quad (1')$$

Then $\log(1 + A(z))/\log(1 + F(z))$ is bounded, where $A(z) = \max |A_j(z)|$ and $F(z) = \max |f_v(z)|$.

An algebroidal function that has no pole in $|z| < \infty$ is called an **entire algebroidal function**. The successive derivatives of an entire algebroidal function may have poles at every branch point, which is a departure from the case of single-valued integral functions. An algebroidal function defined by (1) or (1') with entire functions $A_j(z)$ and zero-free $A_0(z)$ is

entire. Dividing both sides of (1) by $A(z)$, we obtain equation (1'), and all its coefficients are entire. In equation (1'), the order, type, and class of an entire algebroidal function coincide with those of the largest $A_j(z)$ (429 Transcendental Entire Functions).

For an entire algebroidal function of order less than $1/2$, $F(z)$ tends to infinity uniformly along a sequence of concentric circles $|z|=r_n$ ($r_n \rightarrow \infty$). However, it can be shown that not all the branches of $f(z)$ necessarily tend to infinity on the Riemann surface \mathfrak{Z} ; in this sense, Wiman's theorem does not remain true. But, using $\min_{|z|=r} \max_v |f_v(z)|$, one can obtain some extensions of the generalized Wiman theorem.

C. Picard's Theorem and Its Extension

Rémoundos first extended Picard's theorem and Borel's theorem to an algebroidal function. Every k -valued transcendental algebroidal function in the finite plane takes on every value infinitely often with at most $2k$ exceptional values. There are examples where $2k$ values are actually omitted. Hence the theorem is the best one possible in this sense. T. Varopoulos (*Bull. Soc. Math. France*, 53 (1925), 23-34) introduced the **degeneracy index**

$$\lambda = \dim \{ (c_0, c_1, \dots, c_k) \in C^{k+1} \mid c_0 A_0 + c_1 A_1 + \dots + c_k A_k = 0 \}$$

($0 \leq \lambda \leq k-1$) into equation (1) and showed that the number of Picard's exceptional values off is at most $k + \lambda + 1$. There is no single-valued meromorphic function with $A > 0$, so this result is relevant only for algebroidal functions. Extending this idea further, J. Dufrénoy and others obtained more precise results. The situation is the same for the Borel exceptional values. That is, the convergence exponent of $f(z) = w = 0$ coincides with the order off except for at most $2k$ values, for which the convergence exponents off are less than the order off (E. Borel). There are at most $2k$ polynomials $P(z)$ for which $f(z) = P(z) = 0$ has at most a finite number of roots (Borel), and furthermore, using the degeneracy index, we can give more precise results.

Selberg was the first to extend the Nevanlinna theory of meromorphic functions to algebroidal functions (272 Meromorphic Functions). Almost simultaneously, Valiron obtained the same results starting from the coefficients of (1); then Ullrich improved the results by considering the effect of branch points of \mathfrak{Z} .

Let \mathfrak{Z}_r be the part of \mathfrak{Z} over $|z| < r$, let $n(r, w)$ be the number of roots of $f(z) = w = 0$ in \mathfrak{Z}_r , and let $n(r, \mathfrak{Z})$ be the number of branch points

of \mathfrak{Z}_r . With these notations we write

$$N(r, w) = \frac{1}{k} \int_0^r (n(t, w) - n(0, w)) \frac{dt}{t} + \frac{n(0, w)}{k} \log r,$$

$$m(r, w)$$

$$= \frac{1}{2k\pi} \int_{|z|=r} \log^+ \frac{1}{|f(re^{i\varphi}) - w|} d\varphi, \quad w \neq \infty,$$

$$T(r, w) = m(r, w) + N(r, w).$$

Let $T(r, f)$ be the logarithmic integral of the spherical area of the image of \mathfrak{Z}_r under $w = f(z)$,

$$T(r, f) = \frac{1}{k} \int_0^r \frac{dt}{t} \int_{\mathfrak{Z}_t} \frac{|f'(te^{i\varphi})|^2}{(1 + |f(te^{i\varphi})|^2)^2} t d\varphi,$$

and let $N(r, \mathfrak{Z})$ be the logarithmic integral of $n(r, \mathfrak{Z})$. Then we have $T(r, w) = T(r, f) + O(1)$ and the **ramification theorem**:

$$N(r, \mathfrak{Z}) < (2k-2)T(r, f) + O(1).$$

Also, $T(r, f) = O(\log r)$ holds if and only if f is algebraic. Let $A(z)$ be the maximum of $|A_j(z)|$, and let

$$\mu(r) = \frac{1}{2k\pi} \int_0^{2\pi} \log A(re^{i\varphi}) d\varphi.$$

Then $T(r, f) = \mu(r) + O(1)$. As the second fundamental theorem we have

$$\begin{aligned} \sum_{v=1}^q N(r, w_v) &> (q-2)T(r, f) - N(r, \mathfrak{Z}) \\ &\quad + \sum_{v=1}^q N_1(r, w_v) + O(\log r T) \\ &> (q-2k)T(r, f) \\ &\quad + \sum_{v=1}^q N_1(r, w_v) + O(\log r T), \end{aligned}$$

where $N_1(r, w)$ is the logarithmic integral of $n_1(r, w)$ which is the sum of the multiplicity minus one of all the roots of $f(x) - w = 0$ in \mathfrak{Z}_r . Furthermore, the **deficiency**, **ramification index** of $f(z)$, and **ramification index** of the surface \mathfrak{Z} are defined by

$$\delta(w) = 1 - \limsup N(r, w)/T(r, f)$$

$$= \liminf m(r, w)/T(r, f),$$

$$\mathfrak{D}(w) = \liminf N_1(r, w)/T(r, f),$$

$$\xi = \liminf N(r, \mathfrak{Z})/T(r, f).$$

With these notations, we have

$$\sum \delta(w_v) + \sum \mathfrak{D}(w_v) \leq 2 + \xi \leq 2k.$$

These results contain the Picard theorem and the Borel theorem. Furthermore, by considering the effect of branch points, the Ahlfors theory of covering surfaces can be extended to algebroidal functions (Y. Tsumura). By using this result, Bloch's theorem can be obtained very simply.

But these results do not contain the Varopoulos result. Taking into consideration the degeneracy index λ , H. Cartan proved the following inequality when $\lambda = 0$:

$$(q - k - 1)T(r, f) < \sum_{v=1}^q N_k(r, w_v) + S(r),$$

and for general λ he conjectured that the number $q - k - 1$ may be changed to the number $q - k - \lambda - 1$. This conjecture is still unsolved except for some special cases where for example, $q = k + \lambda + 2$ (N. Toda, *Nagoya Math. J.*, 91 (1983), 37–47).

Interesting results follow upon a study of this degeneracy index. For example, when f is an entire algebroidal function, if $\sum_{v=1}^{2k-1} \delta(w_v) > 2k - 2$ ($w_v \neq \infty$), there are at least $k - 1$ \dagger Picard's exceptional values in $\{w_v\}$ (Niino, Ozawa, and Toda).

With respect to the relation between the number of exceptional values and the order of fin $|z| < \infty$, there are some results similar to those for single-valued functions. For example, if f has $k + 1$ Picard's exceptional values, the order ρ must be a positive integer or ∞ .

D. Asymptotic Values and Other Results

In the single-valued case, Valiron, L. Ahlfors, W. H. J. Fuchs, A. Edrei, W. K. Hayman, and others studied the \dagger Borel direction, the number of \dagger asymptotic values, the relation between the deficiency values and the asymptotic values, etc. However, almost none of the corresponding results holds for the algebroidal case as shown by several counterexamples.

There is no relationship between the order of an entire algebroidal function and the number of its finite \dagger asymptotic values, which is quite different from the single-valued case. Furthermore, it is possible to have an infinite number of asymptotic values even if the order is equal to zero. If an algebroidal function f satisfies $\liminf T(r, f)/(\log r)^2 < +\infty$, then it has at most k asymptotic values (Valiron-Tumura). The Ahlfors theorem, which is concerned with the number of \dagger direct transcendental singular points of the inverse function and the order of a meromorphic function in the single-valued case, was extended to the algebroidal function by Lü Yinian (*Scientia Sinica*, 23 (1980)).

The \dagger Julia direction or the Borel direction for an algebroidal function is defined not on \mathbb{C} but on $|z| < cc$ because of the appearance of branch points. With respect to the Julia direction, there are results similar to those for the single-valued case, but it is unknown in general whether the Borel direction exists. A. Rauch proved that if $\int^\infty T(r, f)/r^{\rho+1} dr = \infty$,

18 B

Almost Periodic Functions

then there is a sector with an angle of at least π/ρ in which $L(\varphi) = \int^\infty \log^+ F(re^{i\varphi})/r^{\rho+1} dr$ diverges. Apart from the theory of distribution of values, Selberg obtained some conditions under which the inverse functions of \dagger Abelian integrals of a special kind reduce to algebroidal functions.

Almost Periodic Functions

A. History

The theory of almost periodic functions was originated by H. Bohr in 1924 as a result of his study of \dagger Dirichlet series. The theory provides a method of studying a wide class of trigonometric series (\rightarrow 159 Fourier Series) of general type. Further generalizations were made by N. Wiener, V. V. Stepanov, A. S. Besikovich, S. Bochner, and others. H. Weyl, J. von Neumann, and others clarified the relations between this theory and \dagger representation of groups, specifically, the relations between almost periodic functions in a \dagger topological group and representation theory of a \dagger compact group.

B. Almost Periodic Functions in the Sense of Bohr

Let $f(x)$ be a complex-valued continuous function defined for all real values of x . A number τ is called a **translation number** of $f(x)$ belonging to $\varepsilon > 0$ if

$$\sup_{-\infty < x < \infty} |f(x + \tau) - f(x)| \leq \varepsilon.$$

If for any $\varepsilon > 0$ there exists a number $l(\varepsilon) > 0$

such that any interval of length $l(\varepsilon)$ contains a translation number off belonging to ε , then $f(x)$ is called **almost periodic in the sense of Bohr**. We denote by \mathbf{B} the set of all almost periodic functions in the sense of Bohr.

If $f(x)$ is \dagger periodic with a period p , then $f \in \mathbf{B}$, because each number $l \geq p$ plays the role of $l(\varepsilon)$ for any $\varepsilon > 0$. Any $f \in \mathbf{B}$ is bounded and uniformly continuous. A necessary and sufficient condition for a bounded continuous function on $(-\infty, \infty)$ to belong to \mathbf{B} is that for any given sequence $\{h_n\}$ of real numbers, there exist a subsequence $\{h_{n_k}\}$ such that the sequence of functions $\{f(x + h_{n_k})\}$ is uniformly convergent in $(-\infty, \infty)$; i.e., the set $\{f(x + h) \mid h \in (-\infty, \infty)\}$ is \dagger totally bounded with respect to the uniform norm $\|f\| = \sup |f(x)|$ in the space of bounded continuous functions in $(-\infty, \infty)$.

If $f(x) \in \mathbf{B}$, then $f(-x)$, $f(x)$, $\alpha f(x)$ (where α is a complex number), and $f(x + h)$ (where h is a real number) $\in \mathbf{B}$. If $f(x)$, $g(x) \in \mathbf{B}$, then $f(x) \pm g(x)$ and $f(x)g(x) \in \mathbf{B}$. If $f_n(x) \in \mathbf{B}$ and $\{f_n(x)\}$ converges uniformly to $f(x)$, then $f(x) \in \mathbf{B}$. For any real number A , $\exp i\lambda x$ (where i is the \dagger imaginary unit) is continuous and periodic. Hence the polynomial function $\sum_{n=1}^m \alpha_n \exp i\lambda_n x \in \mathbf{B}$. Moreover, if the latter function converges uniformly to $\sum \alpha_n \exp i\lambda_n x$ as m tends to ∞ , then the limit function is also an element of \mathbf{B} . The polynomial $\sum_{n=1}^m \alpha_n \exp i\lambda_n x$ and the series $\sum_{n=1}^{\infty} \alpha_n \exp i\lambda_n x$ are called a **generalized trigonometric polynomial** and a **generalized trigonometric series**, respectively.

For any $f \in \mathbf{B}$, its **mean** exists:

$$M[f] = \lim_{T \rightarrow \infty} \frac{1}{T} \int_a^{a+T} f(x) dx.$$

The convergence of the right-hand formula is uniform in $a \in (-\infty, \infty)$, and the limit is independent of the choice of a . Thus $M[f]$ is a \dagger linear functional defined on \mathbf{B} . Since $M[\exp i\lambda x] = 1$ for $\lambda = 0$ and $= 0$ for $\lambda \neq 0$, the family $\{\exp i\lambda x \mid -\infty < \lambda < \infty\}$ is an \dagger orthonormal system with respect to the \dagger inner product $(f, g) = M[f(x)g(x)]$ defined on \mathbf{B} . Let $\alpha(\lambda) = M[f(x)\exp(-i\lambda x)]$ for any $f \in \mathbf{B}$; then there exist countably many values of λ for which $\alpha(\lambda)$ differs from zero. Denote these values of λ by $\lambda_1, \lambda_2, \dots$ and write $\alpha(\lambda_n) = \alpha_n$. We call the numbers $\alpha_1, \alpha_2, \dots, \alpha_n$, the **Fourier coefficients** of $f(x)$. The formal series $\sum_{n=1}^{\infty} \alpha_n \exp i\lambda_n x$ is called the **Fourier series** of $f(x)$. Moreover, the **Parseval equality** $M[|f(x)|^2] = \sum_{n=1}^{\infty} |\alpha_n|^2$ is valid for any $f \in \mathbf{B}$. For every periodic function, these definitions coincide with the ordinary Fourier coefficients and the Fourier series (\rightarrow 159 Fourier Series). Any almost periodic function in the sense of Bohr is uniquely determined by its Fourier

coefficients; i.e., if two almost periodic functions have the same Fourier series, then they are identical. For any $f \in \mathbf{B}$, its Fourier series does not always converge uniformly, but $f(x) \in \mathbf{B}$ can be approximated uniformly by a sequence of trigonometric polynomials. Hence the almost periodic functions in the sense of Bohr are also called **uniformly almost periodic functions**.

C. Generalizations of Almost Periodic Functions

Let $C(-\infty, \infty)$ be the space (- 168 Function Spaces) of all bounded continuous functions on $(-\infty, \infty)$ with distance $\rho(f, g) = \sup_{-\infty < x < \infty} |f(x) - g(x)|$. Then a uniformly almost periodic function is the limit of a sequence of trigonometric polynomials with respect to this distance. Generally, let ρ be a \dagger distance function introduced in a function space (whose elements are not necessarily continuous in $(-\infty, \infty)$). Then the limit of a sequence of generalized trigonometric polynomials with respect to the distance ρ is called an **almost periodic function with respect to ρ** . For example, for $p \geq 1$, we set

$$D_{Sp}[f, SI] = \sup_{-\infty < a < \infty} \left\{ \int_a^{a+1} |f(x) - g(x)|^p dx \right\}^{1/p},$$

$$D_{Wp}[f, SI] = \lim_{l \rightarrow \infty} \sup_{-\infty < a < \infty} \left\{ \frac{1}{l} \int_a^{a+l} |f(x) - g(x)|^p dx \right\}^{1/p}$$

These are distance functions. The properties of the corresponding almost periodic functions and their relations to other classes of almost periodic functions have been studied by Besikovich [1].

D. Analytic Almost Periodic Functions

Let D be a strip domain, $a < \operatorname{Re} z < b$, defined in a complex plane. For any \dagger holomorphic function $f(z)$ in D and $\varepsilon > 0$, a real number τ is called a **translation number** off belonging to $\varepsilon > 0$ if $\sup_{z \in D} |f(z + i\tau) - f(z)| \leq \varepsilon$. If for any $\varepsilon > 0$ there exists a number $l(\varepsilon) > 0$ such that any interval of length $l(\varepsilon)$ contains a translation number off belonging to ε , then $f(x)$ is called an **analytic almost periodic function** in D . We denote the set of all analytic almost periodic functions in $D = \{a < \operatorname{Re} z < b\}$ by $\mathbf{A}(a, b)$. If we fix an x in $a < x < b$, then $g(y) = f(x + iy)$ for any $f(z) \in \mathbf{A}(a, b)$ belongs to \mathbf{B} .

For any $f \in \mathbf{A}(a, b)$ there corresponds a \dagger Dirichlet series $\sum_{n=1}^{\infty} \alpha_n \exp \lambda_n z$ such that two analytic almost periodic functions are identical if the corresponding Dirichlet series are

identical. Here the coefficients

$$\alpha_n = M_y[f(x+iy)\exp(-iy, y)]$$

are determined independently of x ($a < x < b$), and Parseval's identity

$$M_y[|f(x+iy)|^2] = \sum_{n=1}^{\infty} |\alpha_n|^2 \exp 2\lambda_n x$$

holds (Bohr [3]). If the series

$$\sum \alpha_n \exp \lambda_n x \exp i\lambda_n y$$

at $x = a$ and $x = b$ represent the Fourier series of $f_a(y)$ and $f_b(y) \in \mathbf{B}$, respectively, then there exists $f \in \mathbf{A}(a, b)$ such that $f(z)$ is continuous on \bar{D} and

$$f(a+iy) = f_a(y), \quad f(b+iy) = f_b(y).$$

The behavior of $f \in \mathbf{A}(a, b)$ at the boundary or exterior points of the domain $D = \{a < \operatorname{Re} z < b\}$ has also been investigated by Besikovich [1].

E. Almost Periodic Functions on Groups

Von Neumann defined almost periodic functions on any group, generalizing the characterization of uniformly almost periodic functions on $(-\infty, \infty)$. Let $B(G)$ be the set of all complex-valued bounded functions on a group G . Then $B(G)$ is a metric space with the distance $\rho(f, g) = \sup_{x \in G} |f(x) - g(x)|$. If for any $f \in B(G)$ the set $A_f = \{f_{a,b}(x) = f(axb) | a, b \in G\}$ is totally bounded in the metric space $B(G)$, we call f an **almost periodic function on the group** G . This condition is equivalent to the total boundedness of $B_f = \{f_a(x) = f(xa) | a \in G\}$ or $C_f = \{f_a(x) = f(ax) | a \in G\}$. We denote the set of almost periodic functions on G by $\mathcal{A}(G)$.

For $f(x), g(x) \in \mathcal{A}(G)$, the linear combinations $a \cdot f(x) + b \cdot g(x)$ ($a, b \in \mathbb{C}$) and the product $f(x)g(x)$ are both contained in $\mathcal{A}(G)$. If $f_n \in \mathcal{A}(G)$ and $\{f_n\}$ converges to f uniformly on G , then $f \in \mathcal{A}(G)$. If $f \in \mathcal{A}(G)$, then $f_{a,b}, f_{a,b}f \in \mathcal{A}(G)$ also. Hence $\mathcal{A}(G)$ is a closed subalgebra invariant under two-sided translation in the † Banach algebra $l^{\infty}(G)$. For any $f \in \mathcal{A}(G)$ there exists only one number $M[f]$ in the closure (with respect to the distance ρ in $B(G)$) of

$$A'_f = \left\{ \sum_{i=1}^n c_i f(a_i x b_i) \mid c_i > 0, \sum c_i = 1, a_i, b_i \in G \right\}$$

(= the least closed † convex set including A_f). We call $M[f]$ the **mean** off on G . The mapping $f \rightarrow M[f]$ is a linear functional on $\mathcal{A}(G)$, and we have $M[f] \geq 0$ if $f \geq 0$.

F. Relation to Bounded Representation

Suppose that we are given a finite-dimensional matrix representation $\mathbf{D}(x) = (d_{ij}(x))$ of a group

G . Then the following three conditions are equivalent: (i) All the $d_{ij}(x)$ are bounded on G . (ii) All the $d_{ij}(x)$ are almost periodic in G . (iii) The representation D is † equivalent to a representation by unitary matrices. The inner product $(f, g) = M[f(x)g(x)]$ provides the algebra $\mathcal{A}(G)$ with the structure of a † pre-Hilbert space. Let $H(G)$ be the Hilbert space that is the completion of $\mathcal{A}(G)$. If we select $D''(x) = (d''_{ij}(x))$ from each L , where L is an equivalence class of bounded irreducible representations of G , and if n_{λ} is the order of D^{λ} , then $\{(1/\sqrt{n_{\lambda}})d''_{ij}(x) | 1 \leq i, j \leq n_{\lambda}, \lambda \in L\}$ is a † complete orthonormal system in the Hilbert space $H(G)$. Any $f(x) \in \mathcal{A}(G)$ can be approximated uniformly in G by a finite linear combination of the $d_{ij}(x)$.

G. Almost Periodic Functions on Topological Groups

When G is a † separated topological group, we denote the set of all continuous functions on G contained in $\mathcal{A}(G)$ by $\mathcal{A}_{*}(G)$. The statements of the theorems in the previous section concerning $\mathcal{A}(G)$ and the representation D remain valid if we replace $\mathcal{A}(G)$ by $\mathcal{A}_{*}(G)$ and replace D by a continuous representation of G . In particular, if G is the additive group of real numbers \mathbf{R} , then $\mathbf{d}(\mathbf{R})$ is exactly \mathbf{B} .

H. Relation to Compact Groups

Every continuous function on a compact group G is almost periodic; i.e., $\mathcal{A}_{*}(G) = C(G)$. The mean value $M[f]$ of $f \in \mathcal{A}_{*}(G)$ is identical to $\int_G f(x) dx$, where the † Haar measure dx is normalized so that $\int_G dx = 1$. In this case, the theory of bounded representations discussed above is the Peter-Weyl theory (- 69 Compact Groups).

In general, let G be a separated topological group. There exists a continuous homomorphism φ of G onto a compact group $K = K(G)$ with the following two properties: (i) For any compact group K' and a continuous homomorphism $\varphi': G \rightarrow K'$, there exists a continuous homomorphism $\psi: K \rightarrow K'$ such that $\varphi' = \psi \circ \varphi$. (ii) Such a pair $\mathbf{K} = (K, \varphi)$ is unique up to isomorphism. K is called the **Bohr compactification** of G , and φ is called the canonical mapping. In particular, suppose that G is a locally compact Abelian group and G^* is its † character group. We denote by G' the group G^* with discrete topology. Let K be the character group of G' , and let φ^* be the identity mapping $G' \rightarrow G^*$ and φ be its conjugate mapping $G \rightarrow K$, which is a continuous homomorphism. Then K is the Bohr compactification of G with the canonical mapping φ . A necessary and sufficient condition for f on G to be con-

tinuous almost periodic is that a continuous function f' on K such that $f' = f' \circ \varphi$ must exist. If this condition is satisfied, then the mean $M[f]$ is identical to $\int_K f'(x) dx$. For any finite-dimensional continuous unitary representation D' of K , $D = D' \circ \varphi$ is a finite-dimensional continuous unitary representation of G , and vice versa. Hence there exists a canonical isomorphism (determined by $D = D' \circ \varphi$) between the equivalence classes of finite-dimensional unitary representations of a separated topological group G and the equivalence classes of finite-dimensional unitary representations of its Bohr compactification K . The kernel of the canonical mapping $\varphi: G \rightarrow K$ is identical to the intersection of all the kernels of finite-dimensional continuous unitary representations of G .

1. Maximally Almost Periodic Groups

Let G be a topological group. If for each pair a, b of distinct elements of G there exists a continuous almost periodic function f on G such that $f(a) \neq f(b)$, then G is called a **maximally almost periodic group**. This is the case if and only if G has sufficiently many finite-dimensional unitary representations. For a connected locally compact group G , the following six conditions are equivalent: (1) G is a maximally almost periodic group. (2) There is a one-to-one continuous homomorphism from G into a compact group. (3) G is the direct product of a compact group and a vector group \mathbf{R}^n . (4) G is the projective limit of Lie groups that are locally isomorphic to compact groups. (5) The quotient group G/Z is compact, where Z is the center of G . (6) The system of all neighborhoods that are invariant under the inner automorphisms constitutes a basis for the neighborhood system of the unit [7].

Moreover, any discrete free group is maximally almost periodic. If there is no continuous almost periodic function except constant functions, the topological group is called **minimally almost periodic**. Any noncompact connected simple Lie group is minimally almost periodic.

19 (XV.1 0) Analog Computation

A. History

The term **analog computation** is a generic term describing various techniques of computation employing diagrams, or physical systems whose equations are similar to the mathematical problems in question. The history of analog computation is probably as old as that of digital computation; for example, the ancient Greeks tried to solve cubic equations using diagrams, and the astrolabe widely used by astronomers through the medieval period is also a kind of analog computer. Soon after the discovery of logarithms, the **slide rule** was invented. In the 18th Century, the **planimeter**, used to measure plane areas, was introduced, and in the 19th Century, the **nomogram** appeared (- Section D). In the first half of 20th Century, a large electronic analog computer was developed, thus predating the first practical digital computer.

However, analog computation has an essential defect, namely, the limitation of accuracy. Today it is useful for simple calculation, but is rapidly becoming less important as the development of digital computers, including pocket calculators, advances.

B. Graphical Calculation

Graphical calculation is a method of computation by means of geometric constructions using common drawing tools. Some typical examples of practical graphical calculation are the following: evaluation of linear functions of several variables (J. Massau, 1887), of systems of linear equations (F. J. van den Berg, 1888), of polynomials (J. A. Segner, 1761), of algebraic equations (Lill, 1867), **graphical integration**, **graphical differentiation**, and the solu-

tion of ordinary differential equations of the first order (J. Massau, 1878), of linear differential equations (Czuber), and of ordinary differential equations of the second order (Lord Kelvin, 1892).

Using bisquare-root graph paper, sold under the names of **binomial probability paper** or **stochastic paper**; we can handle F -distributions or other probability distributions reducible to F -distributions, such as binomial or normal distributions, to a fairly good degree of approximation. This **graphical method of statistical inference** is, even now, a powerful method of statistical quality control.

C. Graphical Mechanics

Graphical mechanics is the graphical treatment of mechanical problems, especially problems of equilibrium. In this method, the fundamental constructions are the composition and resolution of forces by means of force polygons (Fig. 1). This method is also applicable to problems in dynamics when they can be reduced to problems of equilibrium by means of d'Alembert's principle.

Fig. 1

An example of the graphical method of constructing the composite and the line of action of three given forces F_1 , F_2 , and F_3 . In the force polygon in (b), the vector $\vec{03}$ represents the composite R . On the link polygon in (a), the point d is a point on the line of action of the force. If the fourth force F_4 has the same magnitude as R with opposite direction, both polygons are closed, and the four forces F_1 , F_2 , F_3 , and F_4 are in equilibrium.

Graphical mechanics is most convenient when applied to problems reducible to 2-dimensional structural mechanics. But we can also use it for 3-dimensional problems if we work on projections, e.g., on the plan and the elevation, of the original body. In recent years, however, the amount of work involved in geometric construction has been deemed non-negligible, and the technique of computer

graphics is now considered to be much more convenient. Here the computation is done by a digital computer, and the result is displayed in a convenient graphical form.

D. Nomograms

Nomograms are charts in which we can easily read off the corresponding value u_n from given values u_1, \dots, u_{n-1} when there is a relation $F(u_1, \dots, u_n) = 0$ among n real variables u_1, \dots, u_n . The construction of nomograms has been thoroughly investigated by M. d'Ocagne [5].

A function of two variables $F(u_1, u_2) = 0$ can be represented by a **two-sided scale** or by **functional paper**. The most useful nomograms are those for functions of three variables, $F(u_1, u_2, u_3) = 0$. Changing this into $f_i(x, y, u_i) = 0$ ($i = 1, 2, 3$) and drawing the curves $f_i(x, y, u_i) = 0$ for fixed values of u_i , we have an **intersection chart**, where three curves for the corresponding values u_1, u_2, u_3 meet at a point. In practice, however, it is much more convenient to use the **alignment chart**, which is a dual of the intersection chart. It is especially useful when the relation $F(u_1, u_2, u_3) = 0$ can be decomposed into an equation of the form

$$\begin{vmatrix} f_1(u_1) & g_1(u_1) & h_1(u_1) \\ f_2(u_2) & g_2(u_2) & h_2(u_2) \\ f_3(u_3) & g_3(u_3) & h_3(u_3) \end{vmatrix} = 0. \quad (1)$$

Putting $x_i = f_i/h_i$, $y_i = g_i/h_i$ ($i = 1, 2, 3$) and drawing the curves (x_i, y_i) with the parameter u_i scaled on it (u_i -scaled), the corresponding values u_1, u_2 , and u_3 satisfying relation (1) lie on a straight line (Fig. 2). Using this property we can easily read off the corresponding values (by laying down a ruler). In the strict sense, the term "nomogram" usually refers specifically to an alignment chart.

Fig. 2

For four or more variables, we can apply similar techniques if the function is **separable** into functions of three variables. If it is not separable, we can sometimes apply such techniques such as two-functional scales with functional networks, cocircular charts, coplanar charts, or moving charts. Using func-

tional approximations, an approximate nomogram has recently been constructed with errors considered to be admissible in practical use.

Historically, the origin of Hilbert's 13th problem, which asks if it is possible to represent a function of many variables as the composite of functions of two variables, comes from a study of nomograms with many variables.

E. Analog Computers

The **analog computer** is a special purpose machine designed for a specified analog computation. In a wider sense it includes special devices that perform [†]analog simulation. The following mechanical devices are well known: the **pantograph** for copying plans, the **harmonic analyzer** for obtaining the Fourier expansion of a periodic function, and V. Bush's **differential analyzer**. Since about 1940 large **electronic analog computers** for solving differential equations have been extensively developed.

Analog computers have up to recently had the advantages of ease of construction, simplicity, and inexpensive operation, and they were also considered to be fast enough for use in **real-time** computation. To compensate for the limitations of analog computers in comparison to digital ones, several **hybrid computers** have also been used. However, with the rapid progress of digital computers and digital-analog converters, the analog computers are now considered less important than in the past.

F. Curve Fitting

Curve fitting is a method of finding a simple curve $y = f(x)$ supplying the best possible approximation to the values y_1, y_2, \dots, y_n for discrete values x_1, x_2, \dots, x_n of the independent variable. A polynomial passing through all the given points is constructed by means of [†]tinterpolation. For experimental data we usually construct a curve by using methods, such as the [†]method of least squares, that take the errors due to observation into account.

A function constructed to best fit the observed values of the function $y = f(x)$ expressing some physical law is called an **empirical formula**, in contrast to the **theoretical formula**. Usually, we first assume that the function contains several **empirical constants**, which are then determined to fit the experimental data.

The most common case is a linear approximation (using a linear function) with a suitable change of variables. **Semilogarithmic**

paper, **logarithmic paper**, or **probability paper** are used to facilitate transformations in terms of logarithms or normal distributions.

We also frequently use polynomials or trigonometric polynomials of lower degree. To determine the empirical constants the following methods are used: the graphing method, the selection of certain points, the mean value method, or the method of least squares.

G. Orthogonal Polynomials

Let there be given the values y_0, y_1, \dots, y_{n-1} for discrete values $x = 0, 1, \dots, n-1$ with equal differences. A polynomial $f(x)$ of degree k ($\leq n$) that minimizes the sum of the squares $G_k(n) = \sum (y_m - f(m))^2$ is given by

$$f(x) = \sum_{v=0}^k a_v q_v(n, x),$$

$$a_v = \sum_{m=0}^{n-1} y_m q_v(n, m) / S_v(n),$$

$$S_v(n) = \sum_{m=0}^{n-1} (q_v(n, m))^2,$$

and we have $G_k(n) = \sum_{m=0}^{n-1} y_m^2 - \sum_{v=0}^k a_v^2 S_v(n)$. Here the function $q_v(n, x)$, called a **Chebyshev q-function**, is defined by

$$q_v(n, x) = \sum_{m=0}^v \binom{v+m}{m} \binom{v-n}{v-m} \binom{x}{m}$$

In practical applications, it is better to replace $q_v(n, x)$ by the function

$$q_v^*(n, x) = q_v(n, x) / 2^{-v} v! M_v(n),$$

where $M_v(n)$ is the greatest common divisor of

$$\binom{v+m}{m} \binom{n-1-m}{v-m} \quad (m=0, 1, \dots, v).$$

The values $q_v^*(n, m)$ ($m=0, 1, \dots, n-1$) are mutually coprime integers. The function $q_v^*(n, m)$ is called the **simplest Chebyshev q-function** or **simplest orthogonal polynomial**, and is sometimes denoted by $X_{n,v}(x)$, $\xi'_{n,m}(x)$, or $\varphi_{n,m}(x)$.

When two functions satisfy the condition

$$(f, g)_n = \sum_{m=0}^n f(m)g(m) = 0,$$

they are called **orthogonal for a finite sum**. If from $1, x, x^2, \dots, x^v$ we construct a system orthogonal with respect to this definition, then we have the polynomial

$$P_{v,n}(x) = \sum_{m=0}^v (-1)^m \binom{v}{m} \binom{v+m}{m} \binom{x}{m} / \binom{n}{m},$$

which has the following connection with q_v :

$$q_v(n, x) = ((-1)^v (n-1)! / 2^v (n-v-1)!) P_{v,n-1}(x).$$

The polynomial $P_{v,n}(x)$ is called a **Chebyshev orthogonal polynomial** or sometimes simply an **orthogonal polynomial**. The polynomials $P_{v,n}(x)$ are orthogonal for the finite sum. If $n \rightarrow \infty$ and $0 \leq x \leq 1$, the function $P_{v,n}(x)$ tends to $P_v(1 - 2x)$, where P_v is the \dagger Legendre polynomial. These functions may be conveniently used in least-squares curve fitting.

20 (X.1) Analysis

The origin of analysis can be traced back to the time when Eudoxus (4th century B.C.) and Archimedes (3rd century B.C.) devised the so-called method of exhaustion for calculating the area of a plane figure and the volume of a solid. Their objects of investigation were restricted, however, to particular types of figures or solids. In the 16th and 17th centuries, F. Viète, J. Kepler, and B. Cavalieri again took up this problem. In the 17th Century, the problem of drawing a tangent to a given curve was studied by R. Descartes, P. de Fermat, B. Pascal, and J. Wallis. Fermat, in particular, applied the result to find the maxima and minima of certain functions. It is worth noting that a certain type of mathematics powerful enough to produce similar results was independently developed in Japan around that time. In 1684, G. Leibniz in Germany introduced the symbols dx and dy in treating the same problem. He proved that dy/dx represents the slope of the tangent to the curve at a given point and discovered a new operation to calculate it. In 1686, he established the "inverse tangent method," which is what we now call integral calculus. He also introduced the notation \int . On the other hand, I. Newton in England developed his "method of fluxions," corresponding to our differential and integral calculus, from the viewpoint of mechanics. But neither Leibniz nor Newton formulated the fundamental concepts rigorously, and therefore they were criticized severely by many contemporary scholars. The new calculus gained ground in Great Britain rather slowly. B. Taylor in England and C. MacLaurin in Scotland demonstrated its usefulness in 1715 and in 1745, respectively. On the continent, however, Leibniz's symbolic calculus was taken up by mathematicians of the Bernoulli family, G. F. A. de l'Hôpital, G. Fagnano, and many others; with it, they solved many scientific problems which until then had remained intractable. This motivated subsequent researchers to pose new problems in the form of differential equations.

One of these problems, treated by J. le Rond d'Alembert in relation to the vibration of a chord, concerns the \dagger partial differential equation

$$\partial^2 y / \partial t^2 = a^2 \partial^2 y / \partial x^2 \quad (1)$$

for $y = y(t, x)$ with the boundary conditions $y = 0$ for $x = 0$ and $x = l$. He obtained the solution $y = f(at + x) - f(at - x)$, where f is an arbitrary function of period $2l$. In 1753, D.

Bernoulli showed that solutions of equation (1) are given by functions of the form

$$y = \frac{a_0}{2} + \sum_{k=1}^{\infty} \left(a_k \cos \frac{k\pi x}{l} + b_k \sin \frac{k\pi x}{l} \right)$$

These two kinds of solutions gave rise to the question of whether an arbitrary function can be expressed by a [†]trigonometric series. This problem was studied by A. C. Clairaut, J. L. Lagrange, and L. Euler. In 1807, J. Fourier in France, in treating a problem on the conduction of heat, claimed that an arbitrary function of period 2π can be expressed as

$$y = \frac{a_0}{2} + \sum_{k=1}^{\infty} (a_k \cos kx + b_k \sin kx), \quad (2)$$

where the coefficients a_k and b_k are given by

$$a_k = \frac{1}{\pi} \int_{-\pi}^{\pi} f(x) \cos kx \, dx, \\ b_k = \frac{1}{\pi} \int_{-\pi}^{\pi} f(x) \sin kx \, dx. \quad (3)$$

This series is now called the [†]Fourier series, but Fourier never verified the fact that the series (2) with coefficients (3) converges and represents $f(x)$. It was only as late as 1820 that A. L. Cauchy in France first noted that to treat a series properly, one must examine its convergence.

In the 19th Century, the concept of [†]functions, which had been taken in the sense of “analytic expressions,” came to be defined by the correspondence relation. Cauchy clarified the ideas of [†]limit and [†]continuity, [†]differentiability and [†]integrability. He showed that a function that is continuous in a bounded closed interval is integrable in that interval. But his proof was not rigorous, as he lacked the notion of [†]uniform continuity. In his 1854 paper on the trigonometric series, B. Riemann in Germany considered the integrability of functions that might be discontinuous and introduced the concept of what we now call the [†]Riemann integral.

The theory of [†]sets, initiated by G. Cantor in Germany in his paper of 1874, revolutionized analysis. R. Baire, E. Borel, and H. Lebesgue in France contributed to the establishment of analysis on the basis of set theory. Baire made a classification of discontinuous functions. Generalizing his results, Lebesgue gave a definition of analytic expressions, thus clarifying the term that had been used vaguely since the time of Euler. Lebesgue also tried to define the concepts of the integral of a function, the length of a curve, and the area of a surface from the most general viewpoint. In generalizing the notion of [†]measure introduced by Borel, he established in 1902 the theory of [†]Lebesgue measure with which he laid the

foundations of the theory of [†]Lebesgue integrals. The introduction of this theory gave to the theory of Fourier series a new turn in the direction of functional analysis. Measure theory was also employed by A. N. Kolmogorov of the Soviet Union to lay a solid foundation for [†]probability theory in 1933.

The study of functions of a complex variable was originated by Cauchy in the first half of the 19th Century. He began his research by introducing the notion of “monogenic functions”; a function which is monogenic at every point of a domain is what we now call a [†]holomorphic function. He established [†]Cauchy’s integral theorem and integral formulas for these functions, and deduced from these theorems the [†]residue theorem for functions with [†]poles. Making use of the integral formula, Cauchy proved that a function that is holomorphic at a point a can be expanded in a power series of the form $\sum_{k=0}^{\infty} a_k(z-a)^k$ in a neighborhood of this point.

Riemann considered a complex variable w as a function of another complex variable z when dw/dz is independent of the value of the differential dz . This amounts to the same thing as a “monogenic function” of Cauchy. Riemann’s mapping theorem became a model for subsequent developments. Riemann introduced the concept of [†]Riemann surfaces in order to [†]uniformize multivalued functions. This important idea was basic to the progress of analysis and [†]topology in the 20th Century.

K. Weierstrass, who was a contemporary of Riemann, developed the theory of functions of a complex variable from a purely analytic viewpoint. He defined an element of a function to be a power series $\sum_{k=0}^{\infty} a_k(z-a)^k$ of $z-a$, representing a holomorphic function in the interior of its [†]circle of convergence, and defined an analytic function to be an aggregate of such elements that are derived from one of them by means of [†]analytic continuations, along all curves having the point a as the initial point.

Riemann and Weierstrass constructed their theory to complete the theory of [†]elliptic functions and [†]Abelian functions that was initiated by N. H. Abel and C. G. J. Jacobi. Their results were a high point of 19th-century classical mathematics. H. Poincaré in France built upon their work. Another high point in the theory of functions of a complex variable was reached when J. Hadamard and C. de La Vallée Poussin in France made use of it to prove the [†]prime number theorem in 1896.

Weierstrass also initiated the study of functions of several complex variables and was succeeded by Poincaré, P. Cousin, and E. Picard in France. They tried to extend the theory of functions of one complex variable to

that of many variables. F. Hartogs, however, discovered a phenomenon quite different from the case of one variable. Cousin posed in 1895 the problem of constructing a function of several complex variables that has assigned poles. This problem was pursued by A. Weil in France and solved by K. Oka in Japan in 1936. Also, the problem of characterizing domains of holomorphy was investigated by E. E. Levi in Italy, H. Cartan in France, and P. Thullen and K. Stein in Germany and was finally solved by Oka in 1953. H. Cartan and J.-P. Serre reformulated these results in terms of cohomology with coefficients in sheaves. This considerably influenced the formulations of mathematics thereafter. These results were further generalized to analytic space by H. Grauert, R. Remmert, and Stein in Germany. The theory of complex manifolds, which are generalizations of Riemann surfaces to several variables, was initiated by W. V. D. Hodge in England and K. Kodaira in Japan and continued by F. Hirzebruch in Germany, M. F. Atiyah in England, and I. M. Singer in the United States.

Differential calculus gives a general method of finding extreme values of a given function. Likewise, in order to find a function that produces an extremal of the given functional, the calculus of variations was created in the 18th Century. For example, Euler considered the problem of finding a particular function $y(x)$ that renders the functional $\int_a^b F(x, y, y') dx$ an extreme value among all those functions $y(x)$ for which the plane curve $y = y(x)$ passes through two given points (a, A) and (b, B) of the plane; he showed that this $y(x)$ must satisfy the differential equation $dF_y/dx = F_y = 0$ (1744). Lagrange, W. R. Hamilton, and others developed this result into a general variational principle that governs not only classical mechanics but also quantum mechanics.

From research on the continuity or differentiability of the functional with respect to y emerged the idea of considering a function as a "point" in a function space. This gave rise to functional analysis, a branch of analysis that treats functions as elements of certain spaces and utilizes the methods of algebra and topology. The first result in this regard was the theory of integral equations of V. Volterra in Italy and E. I. Fredholm in Sweden in the beginning of the 20th Century. Fredholm's work was motivated by his desire to solve the Dirichlet problem, the solution of which had been used by Riemann in the proof of his mapping theorem, etc. However, Riemann's own proof of existence of the solution, called the Dirichlet principle, was not rigorous, and attempts to save the proof provided one of the central problems of analysis for some time.

Fredholm's solutions were different from Riemann's but D. Hilbert in Germany was able to justify Riemann's original proof. Hilbert's proof was later simplified and generalized by R. Courant, H. Weyl, and others. Hilbert also introduced the function spaces l_2 and L_2 to study the eigenvalue problem of integral equations with symmetric kernels. Later J. von Neumann in Germany established spectral theory in abstract Hilbert spaces and applied it to the mathematical foundations of quantum mechanics (1929). S. Banach in Poland created the theory of linear operators in Banach spaces (1932). This theory was further generalized to that of linear topological spaces and was applied to the theory of distributions.

In their study of partial differential equations and Fourier analysis, Hadamard, J. Leray, S. L. Sobolev, T. Carleman, and many others had to extend the notion of functions; they also enlarged the notion of derivatives. L. Schwartz in France introduced distributions and defined derivatives in the sense of distributions to unify these generalizations (1945). M. Sato in Japan defined more general generalized functions, called hyperfunctions (1958). It has become evident that both distributions and hyperfunctions have provided the most powerful tools in recent research in the general theory of partial differential equations, to which L. Hormander in Sweden has made outstanding contributions.

Analytic Functions of Several Complex Variables

A. Holomorphic Functions

As in the case of holomorphic functions of one complex variable, the definition of holo-

morphic functions can be given in two ways: the first definition utilizes differentiability, following the approach of B. Riemann; and the second method utilizes the notion of power series expansion as developed by K. Weierstrass. In this article, $N = \{0, 1, 2, \dots\}$.

B. Power Series

Let z be an n -tuple of complex variables z_1, \dots, z_n , and $c = (c_1, \dots, c_n)$ a point of \mathbb{C}^n . An infinite sum P of monomials $a_k(z - c)^k = a_{k_1, \dots, k_n}(z_1 - c_1)^{k_1} \dots (z_n - c_n)^{k_n}$ ($k = (k_1, \dots, k_n) \in \mathbb{N}^n$), where $a_k \in \mathbb{C}$, is called a **power series** with center c and coefficients a_k . If, for a bijection φ of \mathbb{N} onto \mathbb{N}^n , the simple series $\sum_{p \in \mathbb{N}} |a_{\varphi(p)}| (z - c)^{\varphi(p)}$ is convergent at $z = z^0$, we say that P is **absolutely convergent** at z^0 . Its sum at z^0 , denoted by $\sum a_k(z^0 - c)^k$, is defined as the sum $\sum a_{\varphi(p)}(z^0 - c)^{\varphi(p)}$, which is independent of the choice of φ . If P is uniformly bounded at z^0 , then P is absolutely convergent at every point of the open **polydisk** $S = \{z \mid |z_j - c_j| < |z_j^0 - c_j|, j = 1, \dots, n\}$. Furthermore, in this case P converges absolutely and uniformly on every compact set in S (N. H. Abel).

The **convergence domain** of a power series P is the set D of points z^0 such that P is absolutely convergent at every point in a neighborhood of z^0 . The interior of the set B of points at which the infinite sum P is uniformly bounded is equal to D . A **(complete) Reinhardt domain** with center c is a domain D in \mathbb{C}^n such that whenever D contains z_0 , the domain D also contains the torus $\{z \mid |z_j - c_j| = |z_j^0 - c_j|, j = 1, \dots, n\}$ (the closed polydisk $\{z \mid |z_j - c_j| \leq |z_j^0 - c_j|, j = 1, \dots, n\}$). If the convergence domain D of the power series P is not empty, it is a complete Reinhardt domain and is also **logarithmically convex**; that is, the set $D - \bigcup_j \{z \mid z_j = c_j\}$ is mapped onto a convex domain in \mathbb{R}^n by the mapping $z_j \rightarrow \log |z_j - c_j|$ ($j = 1, \dots, n$). The set \tilde{D} of points at which P is absolutely convergent is, in general, greater than D , and it is possible that \tilde{D} contains exterior points of D . A **thorn** of D is the set of exterior points of D contained in \tilde{D} that are located on the planes $\{z \mid z_j = c_j\}$ ($j = 1, \dots, n$). An n -tuple $r \in \mathbb{R}_+^n$ is called a set of **associated convergence radii** if P is absolutely convergent at every point of $\{z \mid |z_j - c_j| < r_j, j = 1, \dots, n\}$ but not of $\{z \mid |z_j - c_j| > r_j, j = 1, \dots, n\}$. An n -tuple of associated convergence radii may not be uniquely determined, but it satisfies

$$\limsup_{|k| \rightarrow +\infty} (|a_k| r^k)^{1/|k|} = 1, \quad |k| = k_1 + \dots + k_n$$

(E. Lemaire).

Let f be a complex-valued function defined in a neighborhood of $z^0 \in \mathbb{C}^n$. If there exists a

convergent power series P with center z^0 such that at every point of a neighborhood of z^0 the value off and the sum of P coincide, then f is called **analytic** at z^0 in the sense of Weierstrass, and P is the **Taylor expansion** of f at z^0 .

C. Differentiability

Let f be a complex-valued function defined in a neighborhood of $z^0 \in \mathbb{C}^n$. If in a neighborhood of z^0 we have

$$f(z) - f(z^0) = \alpha_1(z_1 - z_1^0) + \dots + \alpha_n(z_n - z_n^0) + \varepsilon, \\ \text{with } \alpha_1, \dots, \alpha_n \in \mathbb{C} \text{ and} \\ \lim_{z \rightarrow z^0} \varepsilon / (|z_1 - z_1^0| + \dots + |z_n - z_n^0|) = 0, \quad (1)$$

then we say that f is **(totally) differentiable** at z^0 . The function f is then continuous at z^0 , and the partial derivatives $\partial f / \partial z_j$ ($j = 1, \dots, n$) exist. Furthermore, the Cauchy-Riemann differential equations $\partial f / \partial \bar{z}_j = 0$ ($j = 1, \dots, n$) hold, where $\partial f / \partial z_j = (1/2)(\partial f / \partial x_j - i \partial f / \partial y_j)$ and $\partial f / \partial \bar{z}_j = (1/2)(\partial f / \partial x_j + i \partial f / \partial y_j)$ with $z_j = x_j + iy_j$. We say that f is **holomorphic** at z^0 in the sense of Riemann if f is differentiable at every point in a neighborhood of z^0 . Analyticity in the sense of Weierstrass is equivalent to holomorphy in the sense of Riemann. Furthermore, if the partial derivatives $\partial f / \partial z_j$ ($j = 1, \dots, n$) exist at every point in a neighborhood of z^0 , then f is, without assuming continuity, proved to be holomorphic. Thus the holomorphy off in each variable z_j implies the holomorphy off in $z = (z_1, \dots, z_n)$ (**Hartogs's theorem of holomorphy**, 1906).

A complex-valued function in a domain $G \subset \mathbb{C}^n$ is called **holomorphic** or **analytic** in G if it is holomorphic at every point of G . Let $H(G)$ be the ring of holomorphic functions in G . For $f = u + iv \in N(G)$, u and v satisfy in G the differential equations $\partial^2 u(z, \bar{z}) / \partial z_j \partial \bar{z}_k = 0$; that is,

$$\frac{\partial^2 u}{\partial x_j \partial x_k} + \frac{\partial^2 u}{\partial y_j \partial y_k} = 0, \quad (2) \\ \frac{\partial^2 u}{\partial x_j \partial y_k} - \frac{\partial^2 u}{\partial x_k \partial y_j} = 0, \quad j, k = 1, \dots, n.$$

A \dagger distribution $\text{TED}'(G)$ is called **pluriharmonic** in G if it satisfies (2) in G . Then T is harmonic and hence a real analytic function by \dagger Weyl's lemma.

Let G_j be a domain in the z_j -plane with piecewise smooth boundary C_j . If $f \in H(G)$ ($G = \prod_{j=1}^n G_j$) is continuous on \bar{G} , then

$$\frac{1}{(2\pi i)^n} \int_{C_1 \times \dots \times C_n} \frac{f(\zeta)}{(\zeta_1 - z_1) \dots (\zeta_n - z_n)} \\ d\zeta_1 \wedge \dots \wedge d\zeta_n = \begin{cases} f(z), & z \in G, \\ 0, & z \notin \bar{G} \end{cases} \quad (3)$$

(**Cauchy's integral representation**). Thus if $n \geq 2$, then f is determined by its values only on the proper subset $C = C_1 \times \dots \times C_n$ of ∂G , which is called the **skeleton** (or **determining set**) of G . For (pluriharmonic) functions of several complex variables, the boundary value problem, not necessarily solvable in its classical form, is not so effective as the Dirichlet problem in one complex variable.

As in the case of one variable, the \dagger Laurent expansion is valid for every holomorphic function in a domain of the form $G = \prod_{j=1}^n G_j$, where the G_j are circular annuli $\subset \mathbb{C}$. Suppose that we are given $f_1 \in H(G_1)$ and $f_2 \in H(G_2)$, where G_1, G_2 are domains in \mathbb{C}^n such that $G_1 \cap G_2$ is nonempty and connected. If $f_1 = f_2$ on $\{z \mid |z_j - z_j^0| < r_j, y = y^0, j = 1, \dots, n\}$, where $z^0 = x^0 + iy^0 \in G_1 \cap G_2$, then there exists a unique $f \in H(G_1 \cup G_2)$ such that $f|_{G_1} = f_1$ and $f|_{G_2} = f_2$ (**theorem of identity**). Thus \dagger analytic continuation proceeds as in the case of one variable. Similarly, some fundamental theorems in one variable, such as \dagger Liouville's theorem on \dagger entire functions and the \dagger maximum principle, hold also for several variables. However, there are some properties that reveal the differences between the cases of one and several variables. For instance, the set of zeros of a holomorphic function (\rightarrow 23 Analytic Spaces B) has no isolated point for $n \geq 2$. The investigation of these remarkable differences is one of the purposes of the theory of analytic functions of several complex variables.

D. Shilov Boundaries

While the maximum principle holds for a holomorphic function in a domain G , the set of points where the maximum is attained may be a proper subset S of ∂G . For instance, if G is the product of annuli as before, then the skeleton of G can be taken as S . In connection with the theory of \dagger normed rings, G. E. Shilov proved that there exists a unique smallest member S_0 (called the **Shilov boundary** of G) in the family of closed subsets S such that $\sup\{|f(z)| \mid z \in S\} = \sup\{|f(z)| \mid z \in G\}$ for every $f \in H(G)$ continuous on G . The structure of S_0 is investigated in detail together with the pseudoconvexity of G connected with it. Applying \dagger Perron's method for the Dirichlet problem to \dagger plurisubharmonic functions and the Shilov boundary, H. J. Bremermann solved one type of boundary problem.

E. Local Theory

Let f and g be two functions defined in neighborhoods of a set $S \subset \mathbb{C}^n$. If $f = g$ in a neighborhood of S , then f and g are called **equiva-**

Analytic Functions, Several Complex Variables

lent with respect to S . The germ off on S , denoted by f_S , is the equivalence class off: A **germ of a holomorphic function** on S is the germ on S of a holomorphic function defined in a neighborhood of S , and $H(S)$ denotes the ring of germs of holomorphic functions on S . Given a point 0 in \mathbb{C}^n , $H(0) = H(\{0\})$ is isomorphic to the ring H_n of convergent power series at 0 , i.e., the power series that are absolutely convergent in some neighborhoods of 0 . For every nonzero function $f \in H(0)$, there exists a system of coordinates (z_1, \dots, z_n) centered at 0 such that $f(0, \dots, z_n) \neq 0$ for every $z_n \neq 0$ in a neighborhood of $z_n = 0$. In a neighborhood of 0 , f is then equal to the product of an invertible element of H_n and a **distinguished pseudopolynomial**

$$P(z_n) = z_n^p + a_1(z_1, \dots, z_{n-1})z_n^{p-1} + \dots + a_p(z_1, \dots, z_{n-1}) \in H_{n-1}[z_n],$$

with $a_1(0, \dots, 0) = \dots = a_p(0, \dots, 0) = 0$, and $P(z_n)$ is uniquely determined by f and the coordinates z_1, \dots, z_n (**Weierstrass's preparation theorem**). It follows from this that H_n is an n -dimensional \dagger regular local ring. Considering $H(0)$ as the \dagger inductive limit of \dagger locally convex rings $H(U)$, where U ranges over a base for a neighborhood system of 0 , H. Cartan proved the preparation theorem in a more precise form in which the association $f \rightarrow a_j$ is continuous with respect to the supremum norm. Based on a deep consideration of this situation, K. Oka proved a theorem of fundamental importance: The \dagger sheaf $\mathcal{O}_{\mathbb{C}^n}$ defined by $\mathcal{O}_{\mathbb{C}^n, z} = H(z) (z \in \mathbb{C}^n)$ is \dagger coherent.

F. Domains of Holomorphy

Given a domain $G \subset \mathbb{C}^n$ for $n \geq 2$, it may be that there exists a domain G' strictly greater than G such that all the functions that are holomorphic in G extend to holomorphic functions in G' . For instance, let $S = S' \times \sigma$, where S' and σ are open polydisks in (z_1, \dots, z_{n-1}) -space and z_n -space, respectively, and let $T \subset \mathbb{C}^n$ be an open set. If there exists an open set $U (\neq \emptyset) \subset S'$ such that $(U \times \sigma) \cup (S' \times \partial\sigma) \subset T$ and if $S \cap T$ is connected, then all the functions that are holomorphic in T extend uniquely to holomorphic functions in $S \cup T$ (**Hartogs's continuation theorem**). In particular, if A is an \dagger analytic set in a domain $G \subset \mathbb{C}^n$ with $\dim A \leq n - 2$, then all the functions that are holomorphic in $G - A$ extend uniquely to holomorphic functions in G . Furthermore, if A is an analytic set in G with $A \neq G$, then every $f \in H(G - A)$ that is locally bounded at the points of A extends uniquely to a holomorphic function in G (**Riemann's continuation theorem**

for $n \geq 2$). The domain \tilde{G}_f of holomorphy for f is defined to be the maximal domain to which f may be continued analytically. A domain G is called a **domain of holomorphy** if $G = \tilde{G}_f$ for some $f \in H(G)$. However, \tilde{G}_f is, in general, not a subdomain of \mathbb{C}^n . \tilde{G}_f is, generally, a manifold spread over \mathbb{C}^n ; i.e., \tilde{G}_f is a connected n -dimensional \dagger complex analytic manifold with a holomorphic mapping $\varphi: \tilde{G}_f \rightarrow \mathbb{C}^n$ of maximum Jacobian rank (φ is then an open mapping). The same is true for the common existence domain of functions in a subfamily of $H(G)$. The common existence domain \tilde{G} of all the functions in $H(G)$ is called the **envelope of holomorphy**. A **holomorphically complete domain** is a domain G such that $G = \tilde{G}$. These notions carry over to the case where G is a manifold spread over \mathbb{C}^n . The (general) Levi problem of determining the conditions for a given domain to be holomorphically complete is fundamental to the theory of analytic functions of several complex variables (\rightarrow Section I). In connection with this problem, various notions of pseudoconvexity of holomorphically complete domains are defined.

G. Pseudoconvexity

An upper semicontinuous real-valued function $u (-\infty \leq u < +\infty)$ in a domain $G \subset \mathbb{C}^n$ is said to be **plurisubharmonic** if for every $z^0 \in G$ and every $a \in \mathbb{C}^n$ the function $u(z^0 + ta)$ of t is \dagger subharmonic (including the constant $-\infty$) in all the connected components of $\{t \mid z^0 + ta \in G\}$. A domain G is said to be **pseudoconvex** (or **d-pseudoconvex**) if $u = -\log d$, is plurisubharmonic in G , where $d(z)$ is the distance from $z \in G$ to ∂G with respect to any norm in \mathbb{C}^n . Every connected component of the interior of the intersection of a family of pseudoconvex domains is pseudoconvex, and the union of an increasing sequence of pseudoconvex domains is pseudoconvex. Suppose that we are given a domain G and a function u of class C^2 in a neighborhood of \bar{G} such that $G = \{z \mid u(z) < 0\}$ and, for some $\varepsilon > 0$, $\sum_{j,k} (\partial^2 u / \partial z_j \partial \bar{z}_k) a_j \bar{a}_k \geq \varepsilon |a|^2$ for every $a \in \mathbb{C}^n$. Then the domain G is said to be **strongly pseudoconvex**. Strong pseudoconvexity implies pseudoconvexity. Every pseudoconvex domain is exhausted by an increasing sequence of strongly pseudoconvex domains. An open set $P \subset \mathbb{C}^n$ is called an **analytic polyhedron** if $P = \{z \mid |\chi_\alpha(z)| < 1, \alpha = 1, \dots, N\}$, $\chi_\alpha \in H(\bar{P})$ ($\alpha = 1, \dots, N$). Then every connected component of P is pseudoconvex. A **Weil domain** is a connected and bounded analytic polyhedron P defined by $\chi_\alpha (\alpha = 1, \dots, N)$ with $N \geq n$, such that for every k ($1 \leq k \leq n$) the intersection of the hypersurfaces $|\chi_{\alpha_i}(z)| = 1$ ($1 \leq i \leq k$) is of dimension $\leq 2n - k$.

H. Holomorphic Convexity

A domain $G \subset \mathbb{C}^n$ is called **holomorphically convex** if for every compact set $K \subset G$, $\hat{K} = \bigcap_{f \in H(G)} \{z \mid |f(z)| \leq \sup_{\omega \in K} |f(\omega)|\}$ (the **holomorphic hull** of K) is a compact set contained in G . (For a domain G contained in an \dagger analytic set we can similarly define holomorphic convexity of G .) Every connected component of the intersection of a family of holomorphically convex domains is holomorphically convex, and a holomorphically convex domain is exhausted by an increasing sequence of Weil domains. Holomorphic completeness implies holomorphic convexity. The converse is true for domains in \mathbb{C}^n . If G is holomorphically convex, then for every point ζ of ∂G there exists an $f \in H(G)$ such that f is not locally bounded at ζ (H. Cartan and P. Thullen, 1932). Hence a holomorphically convex domain is a domain of holomorphy. Thus a domain in \mathbb{C} is holomorphically convex if and only if it is a domain of holomorphy. (The same is true for unramified covering domains over \mathbb{C}^n (Oka, 1953).) The union of an increasing sequence of domains of holomorphy is a domain of holomorphy (H. Behnke and K. Stein [2], 1939). Suppose that we are given a domain G and domains S_α , T_α ($\alpha = 1, 2, \dots$) such that $S_\alpha \cup T_\alpha \subset G$ and $\sup_{T_\alpha} |f| = \sup_{S_\alpha \cup T_\alpha} |f|$ for every $f \in H(G)$. Suppose also that $S_0 = \lim S_\alpha$ is bounded. We say that the **continuity principle** holds in G if $\bar{T}_0 \subset G$ ($T_0 = \lim T_\alpha$) implies $S_0 \subset G$. The continuity principle holds in a domain of holomorphy (**Hartogs's theorem of continuity**). This implies that if G is a bounded domain $\subset \mathbb{C}^n$ ($n \geq 2$) with connected boundary ∂G , then every function holomorphic in a neighborhood of ∂G extends to a holomorphic function in G (**Hartogs-Osgood theorem**). In particular, for $n \geq 2$, the set of singular points of a holomorphic function has no isolated point. A domain is pseudoconvex if the continuity principle holds there. Hence a domain of holomorphy is pseudoconvex.

I. The Levi Problem

Let G be a domain in \mathbb{C}^n and $z^0 \in \partial G$. If there exists an open neighborhood U of z^0 such that every connected component of $G \cap U$ is a domain of holomorphy, then G is called **Cartan pseudoconvex** at z^0 . On the other hand, if every 1-dimensional analytic set that has z^0 as an ordinary point contains points not belonging to $G \cup \{z^0\}$ in the neighborhoods of z^0 , then G is called **Levi pseudoconvex** at z^0 . Furthermore, G is called **locally Cartan (Levi) pseudoconvex** if G is Cartan (Levi) pseudoconvex at every point of ∂G . Every domain of

holomorphy is locally Cartan pseudoconvex. If G is pseudoconvex and there exists a neighborhood U of z^0 such that $G \cap U = \{z \mid \varphi(z) < 0\}$, where $\varphi \in C^1(U)$, then G is Levi pseudoconvex at z^0 .

The (proper) **Levi problem** of whether every pseudoconvex domain is a domain of holomorphy was proposed by E. E. Levi (1911). After unsuccessful efforts by various mathematicians to solve the problem, it was affirmatively solved by Oka (1942 for $n = 2$ and 1953 for manifolds spread over \mathbb{C}^n for $n \geq 2$), H. Bremermann, and F. Norguet. The problem was solved also by H. Grauert [14] (1958) in a more general form (- Section L) using results on linear topological spaces and by L. Hörmander [18] (1965) using methods of the theory of partial differential equations. A fundamental step in Oka's solution is his **gluing theorem**: Let G be a bounded domain $\subset \mathbb{C}^n$. If every connected component of $G_1 = \{z \mid x_1 > a\} \cap G$ and $G_2 = \{z \mid x_1 < b\} \cap G$ ($a < b$) is a domain of holomorphy, then G is a domain of holomorphy. Indeed, by virtue of the Behnke-Stein theorem and the fact that every pseudoconvex domain is the union of an increasing sequence of bounded locally Cartan pseudoconvex domains, it suffices to solve the Levi problem in the case of a bounded locally Cartan pseudoconvex domain. The Levi problem in this case is solved by the gluing theorem. Various integral representations of holomorphic functions are known besides the Cauchy representation. The Bergmann-Weil integral representation in a Weil domain was used as an important means of solving the Levi problem.

J. Holomorphic Mappings

Holomorphic functions with values in a \dagger quasi-complete \dagger locally convex complex vector space E have also been investigated. The classical theory described above has been generalized, to some extent, to this case. In this way, many applications of the theory have been discovered. An E -valued function in a domain $G \subset \mathbb{C}^n$ is holomorphic if and only if the mapping $u \mapsto \langle u, f \rangle$ is holomorphic for every continuous linear form u on E . By this theorem, most problems concerning E -valued holomorphic functions can be reduced to those of ordinary holomorphic functions. Note that the vector space $H(G)$ of ordinary holomorphic functions in G is a \dagger Fréchet space. The spaces \mathbb{C}^p and complex \dagger Banach spaces belong to the above category of E . A \mathbb{C}^p -valued holomorphic function in a domain $G \subset \mathbb{C}^n$ is called a **holomorphic (or analytic) mapping** of G into \mathbb{C}^p . An isomorphism in the category of do-

mains $G \subset \mathbb{C}^n$ and holomorphic mappings is called an **analytic isomorphism** (or **biholomorphic mapping**). An automorphism in the category is called an **analytic** (or **holomorphic**) **automorphism**. With every domain $G \subset \mathbb{C}^n$ is associated the sheaf \mathcal{O}_G of germs of holomorphic functions over G . Thus we have the notion of a **ringed space** (G, \mathcal{O}_G) . A complex analytic manifold can be defined as a (Hausdorff) ringed space that is locally isomorphic to some (G, \mathcal{O}_G) .

A **meromorphic function** in G is a function that is locally the quotient of two holomorphic functions with denominator $\neq 0$. It may be defined more rigorously as a meromorphic mapping of G into $\mathbb{P}_n(\mathbb{C})$ (- 23 Analytic Spaces D).

K. The Cousin Problems

The Cousin problems are those of constructing meromorphic functions with given **zeros** or **poles**. In terms of sheaves the problems are stated as follows: Let \mathcal{K}_G be the sheaf of germs of meromorphic functions over a domain $G \subset \mathbb{C}^n$. The **first Cousin problem** asks whether the mapping $\Gamma(G, \mathcal{K}_G) \rightarrow \Gamma(G, \mathcal{P}_G)$ induced by the exact sequence $0 \rightarrow \mathcal{O}_G \rightarrow \mathcal{K}_G \rightarrow \mathcal{P}_G \rightarrow 0$ ($\mathcal{P}_G = \mathcal{K}_G / \mathcal{O}_G$) is surjective, where $\Gamma(G, \mathcal{F})$ is the module of **sections** of \mathcal{F} over G (- 383 Sheaves C). Let \mathcal{K}_G^* be the sheaf of multiplicative groups of germs of meromorphic functions not identically 0 and \mathcal{O}_G^* be the subsheaf of \mathcal{K}_G^* formed by germs of nonzero holomorphic functions. The **second Cousin problem** asks whether the mapping $\Gamma(G, \mathcal{K}_G^*) \rightarrow \Gamma(G, \mathcal{D}_G)$ ($\mathcal{D}_G = \mathcal{K}_G^* / \mathcal{O}_G^*$) is surjective. P. Cousin (1895) solved the first problem for $G = \mathbb{C}^n$ or $\prod_{j=1}^n G_j$ and the second problem for $G = \mathbb{C}^n$. Oka (1935) proved that the first problem is solvable in every domain of holomorphy. In solving the second problem in a domain of holomorphy, Oka established the notion of **fiber bundles** and proved that the problem for any domain is reduced to holomorphic triviality of a holomorphic principal fiber bundle over the domain and that holomorphic triviality is equivalent to topological triviality when the domain is of holomorphy (**Oka's principle**). Using the solutions of the Cousin problems, Oka proved his gluing theorem, described in Section 1.

L. Stein Manifolds

Abstracting certain important properties of a domain of holomorphy, Stein [33] introduced the following category of complex analytic manifolds (X, \mathcal{O}_X) : (1) X is paracompact (i.e.,

each connected component of X has a countable open base). (2) Functions in $\Gamma(X, \mathcal{O}_X)$ separate the points of X . (3) For every point $x \in X$ there exists a system of local coordinates around x that is formed by functions in $\Gamma(X, \mathcal{O}_X)$. (4) X is holomorphically convex. (X, \mathcal{O}_X) is then called a **Stein manifold**. It was later discovered by Grauert [12] that conditions (2) and (4) imply (1) and (3).

Applying the theory of cohomology with coefficients in sheaves, H. Cartan and J.-P. Serre obtained for an analytic coherent sheaf \mathcal{F} on a Stein manifold X , the following **fundamental theorems of Stein manifolds**. **Theorem A:** $H^0(X, \mathcal{F})$ generates the stalk \mathcal{F}_x (as an \mathcal{O}_x -module) at every point x of X . **Theorem B:** $H^q(X, \mathcal{F}) = 0$ for all $q > 0$ [7, 30]. Conversely, for a complex analytic manifold X , if for every analytic coherent sheaf \mathcal{F} of ideals defined by a 0-dimensional analytic set in X (i.e., a discrete subset of X), $H^1(X, \mathcal{F}) = 0$, then X is a Stein manifold. Furthermore, if $\Gamma(X, \mathcal{O}_X) = \Gamma(Y, \mathcal{O}_Y)$ for a Stein manifold Y (as in the case where $X \subset \mathbb{C}^n$), then the fundamental theorem A for every coherent sheaf of ideals implies that X is a Stein manifold (I. Wakabayashi).

Due to the fundamental theorems, most results on domains of holomorphy hold unchanged for Stein manifolds. For instance, the first Cousin problem is always solvable. The second Cousin problem is solvable if and only if $H^2(X, \mathbb{Z}) = 0$. An n -dimensional Stein manifold can be realized as a (ramified) covering domain of holomorphy over \mathbb{C}^n . Furthermore, some theorems on differentiable manifolds have analogs on Stein manifolds. For instance, the cohomology groups of the complex of holomorphic differential forms over a Stein manifold X are isomorphic to the cohomology groups $H^*(X, \mathbb{C})$ (analog of **de Rham's theorem**). Every n -dimensional Stein manifold X is realized as a closed complex analytic submanifold in \mathbb{C}^{2n+1} ; that is, there exists an injective **proper** holomorphic mapping $f: X \rightarrow \mathbb{C}^{2n+1}$ with $df \neq 0$. Consider all the holomorphic **principal fiber bundles** over a Stein manifold X whose fibers are isomorphic to a complex Lie group G . The analytic isomorphism classes of the bundles and the elements in $H^1(X, G^a)$ (where G^a is the sheaf of germs of holomorphic mappings of X into G) are in one-to-one correspondence. The same is true for the topological isomorphism classes of the bundles and the elements in $H^1(X, G^c)$ (where G^c is the sheaf of germs of continuous mappings of X into G). The mapping $H^1(X, G^a) \rightarrow H^1(X, G^c)$ induced by the canonical injection $G^a \rightarrow G^c$ is bijective (Grauert [13]). Every relatively compact domain in a complex analytic manifold is holomorphically convex if it is strongly pseudoconvex (Grauert [14]). Hence

such a domain is a Stein manifold. It follows from this that every real analytic manifold with countable base for open sets is realized as a closed real analytic submanifold of some \mathbf{R}^n .

The notion of Stein manifolds is generalized to that of weakly 1-complete manifolds: a complex manifold X is called a **weakly 1-complete manifold** if there exists a plurisubharmonic function u of class C^∞ on X , such that for any $c \in \mathbf{R}$, $X_c = \{x \in X \mid u(x) < c\}$ is relatively compact. The family of such manifolds includes compact complex manifolds too. For a weakly 1-complete manifold also, vanishing theorems of cohomology have been established by H. Hironaka, S. Nakano [26], and H. Kazama [2] (- 232 Kähler Manifolds D).

The theory of entire functions of two variables has been developed from a new viewpoint established by T. Nishino. An entire function f of two variables defines a family of Riemann surfaces $\{f=c \mid c \in \mathbf{C}\}$ on \mathbf{C}^2 , and investigations of the structure of such a family play an important role. For instance the following is proved in this way: If every irreducible component of $f=c$ ($c \in \mathbf{C}$) is biholomorphic to \mathbf{C}^1 , then there exists an entire function g such that $(f, y): \mathbf{C}^2 \rightarrow \mathbf{C}^2$ is a biholomorphic mapping (Nishino [28]). In this theorem, the analyticity of g is obtained from the fact that \mathbf{C}^2 is a Stein manifold.

M. Continuation of Analytic Sets

The application of the theory of cohomology with coefficients in sheaves is not restricted to problems concerning Stein manifolds. Given $G_0 = \{z \mid |z_j| < 1, 1 \leq j \leq n\}$ ($n \geq 3$), $G_1 = \{z \mid |z_1| < \varepsilon, |z_j| < 1, 2 \leq j \leq n\}$, and $G^{(m)} = G_1 \cup (G_0 - \{z \mid z_2 = \dots = z_m = 0\})$ ($3 \leq m \leq n$), we have $H^p(G^{(m)}, \mathcal{O}_{G^{(m)}}) = 0$ ($1 \leq p \leq m-2$) (Scheja's theorem [32]). Let \mathcal{F} be a coherent analytic sheaf over a domain $G \subset \mathbf{C}^n$. If, for every point z of an analytic set $A \subsetneq G$, $\mathcal{F}_z = \{0\}$ or $p \leq n - \dim A - 2$ hd, \mathcal{F} (where hd, \mathcal{F} is the homological dimension of the $\mathcal{O}_{G,z}$ -module \mathcal{F}_z), then it follows from Scheja's theorem that the mapping $H^p(G, \mathcal{F}) \rightarrow H^p(G - A, \mathcal{F})$ induced by the canonical injection $G - A \rightarrow G$ is bijective. This generalizes Hartogs's continuation theorem for holomorphic functions, which corresponds to the case $p=0$.

Besides the continuation of holomorphic functions, we can consider the continuation of analytic sets. Let A be an analytic set in a domain $G \subset \mathbf{C}^n$ and S an analytic set in $G - A$. A point $z \in G$ is said to be **regular (essentially singular)** with respect to S if the closure \bar{S} of S in G is (is not) analytic at z . If $\dim A < \dim S$ for every point $z \in S$, then \bar{S} is analytic in G . If S is purely d -dimensional and S is analytic at

a point of a d -dimensional irreducible component A' of A , then S is analytic at every point of A' that is not located in any other irreducible component of A . Furthermore, if $\dim A \leq \dim S$ and S is purely d -dimensional, then the following hold: (1) The set E of essential singularities of S is, if not empty, a purely d -dimensional analytic set in G , formed by irreducible components of A . (2) If every irreducible component of A contains points of E not located in any other irreducible component of A , then $A \subset E$, and A is, if not empty, purely d -dimensional. (3) If every d -dimensional irreducible component of A contains points that are regular with respect to S , then S is a purely d -dimensional analytic set in G (Thullen, Remmert, and Stein). By these results it is possible to give a proof for †Chow's theorem that every analytic set in $\mathbf{P}_n(\mathbf{C})$ is algebraic.

The continuation of holomorphic functions is related to the continuation of their graphs. W. Rothstein investigated the continuation of analytic sets to obtain the following analog to Hartogs's theorem of continuity: If $G = G_1 \cup G_2$, $G_1 = \{z \mid |z_1| < 1/2, \sum_{j=2}^n |z_j|^2 < 1\}$, $G_2 = \{z \mid |z_1| < 1, 1/2 < \sum_{j=2}^n |z_j|^2 < 1\}$, and $\tilde{G} = \{z \mid |z_1| < 1, \sum_{j=2}^n |z_j|^2 < 1\}$ (the envelope of holomorphy of G) with $n \geq 3$, then every purely $(n-1)$ -dimensional analytic set A in G extends to an analytic set in \tilde{G} ; that is, there exists a purely $(n-1)$ -dimensional analytic set \tilde{A} in \tilde{G} such that $A = \tilde{A} \cap G$. K. Kasahara and H. Fujimoto generalized this theorem to the case of analytic spaces.

N. Nevanlinna Theory for Several Complex Variables

The Nevanlinna theory investigates holomorphic mappings between complex manifolds. In function theory of one variable, for a holomorphic mapping $f: \mathbf{C} \rightarrow \mathbf{P}^1(\mathbf{C})$ from \mathbf{C} into the 1-dimensional †complex projective space, the famous †Picard theorem states that if f omits three values, then f must be constant. R. Nevanlinna developed the quantitative theory of value distributions off: L. Ahlfors [1], introduced the geometric approach, and enunciated the principle that the negative curvature of the image manifold restricts a holomorphic mapping. In higher-dimensional situations, this principle has been realized in many cases. The Nevanlinna theory for a holomorphic mapping $f: \mathbf{C} \rightarrow \mathbf{P}^n(\mathbf{C})$ with respect to †hyperplanes was established by Ahlfors and H. Weyl and J. Weyl [34]. Holomorphic mappings into projective spaces have been studied in detail by W. Stoll, H. Fujimoto, and M. Green. Following the work of S. S.

Chern [9] of around 1970, the equidimensional case was investigated (P. A. Griffiths, K. Kodaira, S. Kobayashi and T. Ochiai). J. A. Carlson and Griffiths [6] succeeded in obtaining a defect relation for equidimensional holomorphic mappings and hypersurfaces of the image manifold. This yields the following Picard-type theorem (after the formulation by F. Sakai, *Inventiones Math.*, 16 (1974)): Let X be a projective algebraic manifold of dimension n and $f: \mathbb{C}^n \rightarrow X$ a holomorphic mapping. Let D be a hypersurface of X . We take a desingularization $\pi: X^* \rightarrow X$ so that the inverse image $D^* = \pi^{-1}(D)$ has at most normal crossings as singularities. We denote by K^* a canonical divisor of X^* . We assume that

$$\limsup_{m \rightarrow \infty} \frac{\dim H^0(X^*, \mathcal{O}(m(K^* + D^*)))}{m^n} > 0.$$

If f omits D , then the Jacobian of f vanishes everywhere. As a corollary, it follows that the universal covering manifold of $X - D$ cannot be \mathbb{C}^n . When $X = \mathbb{P}^n(\mathbb{C})$ and D is a nonsingular hypersurface of degree d , the above assumption is satisfied if $d \geq n + 2$. In the nonequidimensional case, Ochiai [29] (with supplementary works by M. Green, Y. Kawamata, and P. Wong) verified the following assertion, which was first stated by A. Bloch with rough arguments: Let X be a projective algebraic manifold of dimension n , and suppose $\dim H^1(X, \mathcal{O}_X) > n$; then the image of a holomorphic mapping $f: \mathbb{C} \rightarrow X$ is contained in a proper subvariety of X (\rightarrow 124 Distributions of Values of Functions of a Complex Variable; 272 Meromorphic Functions).

0. Hyperbolic Manifolds

Every complex analytic space X has two invariant pseudodistances: the Carathéodory pseudodistance c_X and the Kobayashi pseudodistance d_X , both of which generalize the Poincaré distance ρ of the unit disk $D = \{ |z| < 1 \}$. These pseudodistances can be defined by the property that d_X is the largest pseudodistance among all pseudodistances δ_X on X for which all holomorphic mappings $(X, \delta_X) \rightarrow (D, \rho)$ are distance-decreasing, while c_X is the smallest among all pseudodistances δ_X for which all holomorphic mappings $(D, \rho) \rightarrow (X, \delta_X)$ are distance-decreasing. Then $c_X \leq d_X$. If Y is another complex analytic space, every holomorphic mapping $f: X \rightarrow Y$ is distance-decreasing with respect to either its Carathéodory or Kobayashi pseudodistance. This may be considered to be a generalization of the Schwarz-Pick lemma. (The Schwarz lemma is often

referred to by this name, since G. Pick also investigated the distance-decreasing property.) The Kobayashi pseudodistance d_X can also be obtained by integrating an infinitesimal differential pseudometric called the Kobayashi pseudometric in the same manner as the Riemannian distance is obtained from the Riemannian metric (H. L. Royden).

If d_X is a (complete) distance on X , then X is said to be (complete) hyperbolic. A Riemann surface is hyperbolic in this sense if and only if its universal covering is biholomorphic to the unit disk. If X is open in Y and if, for every pair of sequences of points $\{p_n\}$ and $\{q_n\}$ in X converging to distinct points of X , $\lim d_X(p_n, q_n)$ is positive, then X is said to be hyperbolically embedded in Y . The Riemann sphere $\mathbb{C}U \setminus \{\infty\}$ minus three points is not only complete hyperbolic but also hyperbolically embedded in the Riemann sphere. Every holomorphic mapping of \mathbb{C} into a hyperbolic complex analytic space is constant, while every holomorphic mapping of the punctured disk $D^* = \{0 < |z| < 1\}$ into a hyperbolically embedded space $X \subset Y$ extends to a holomorphic mapping of D into Y . Thus the classical little Picard theorem reduces to the statement that $\mathbb{C} \setminus \{0, 1\}$ is hyperbolic, while the great Picard theorem reduces to showing that $\mathbb{C} \setminus \{0, 1\}$ is hyperbolically embedded in the Riemann sphere. These classical theorems can be generalized in two ways. If M is a symmetric bounded domain and Γ is a discrete arithmetic group acting freely on M , then M/Γ is not only complete hyperbolic but also hyperbolically embedded in its Satake compactification (Kobayashi and Ochiai). If X is the complement of $2n + 1$ hyperplanes in general position in the complex projective space $\mathbb{P}^n(\mathbb{C})$, then X is complete hyperbolic and hyperbolically embedded in $\mathbb{P}^n(\mathbb{C})$ (a restatement of a result going back to E. Borel, A. Bloch, and H. Cartan).

Although there are some noncompact nonhyperbolic complex manifolds X for which every holomorphic mapping $f: \mathbb{C} \rightarrow X$ is constant, a compact complex manifold X is hyperbolic if and only if every holomorphic mapping $f: \mathbb{C} \rightarrow X$ is constant (R. Brody).

For the Teichmüller space $X = \mathbf{T}_g$ of compact Riemann surfaces of genus g , the Kobayashi distance d_X agrees with the Teichmüller distance which had been introduced before the complex structure of \mathbf{T}_g was defined (H. L. Royden).

In the study of pseudoconvex domains, the Bergman metric, the Carathéodory distance, and the Kobayashi distance serve as useful tools. Their behavior at the boundary has been studied extensively.

Given an n -dimensional complex manifold X , an invariant measure Ψ_X can be defined as the largest measure such that every holomorphic mapping f from the polydisk D^n with invariant measure into X is measure-decreasing. For an algebraic manifold of general type, this measure is everywhere positive.

P. Bounded Domains in \mathbb{C}^n

For any bounded domain in \mathbb{C}^n there is naturally assigned a †Kähler metric called the Bergman metric. Using the invariance of this metric, E. Cartan proved that all the Hermitian symmetric spaces of noncompact type are realized as bounded domains. In view of the fact that some important period matrix domains (e.g., the 19-dimensional bounded symmetric domain of type IV, the Siegel upper space, etc.) are of this type, it is obviously of great significance in algebraic geometry to study discontinuous subgroups of the automorphism groups of such domains (Pyatetskii-Shapiro).

On the other hand, it is almost impossible for general bounded domains to determine the explicit form of their Bergman metrics. But Cartan also investigated strongly pseudoconvex real hypersurfaces in \mathbb{C}^2 , and he solved completely the (local) equivalence problem for them, introducing a definite type of †Cartan connections over them in a functorial way. Thereafter N. Tanaka (and for hypersurfaces also Chern and J. Moser) generalized this result to all pseudoconvex real submanifolds in higher-dimensional complex manifolds. One can further apply this result to the equivalence problem of bounded domains with smooth strongly pseudoconvex boundaries, for C. Fefferman [10] proved by analyzing the boundary behavior of the Bergman metric that every biholomorphic mapping between two such domains is extended smoothly up to their boundaries (I. Naruki [27] gave an alternative proof).

Q. History

In connection with †Abelian functions, analytic functions of several complex variables have been studied sporadically since the time of Riemann and Weierstrass (H. Poincaré, Cousin). A series of investigations by Hartogs ([17] (1906), etc.) that revealed the distinctive properties of several complex variables initiated a new epoch in complex analysis. Levi (1910–1911) generalized Hartogs's results to the case of meromorphic functions, introduced the notion of pseudoconvexity, and proposed

the so-called Levi problem. After a lapse of time, many contributions to this new area of complex analysis have been made since 1920. The study by K. Reinhardt (1921) of analytic automorphisms was further developed by C. Carathéodory and Behnke. The †kernel function introduced by S. Bochner and S. Bergmann (1922) produced many remarkable results. In contrast with †Picard's theorem in one variable, P. Fatou found a holomorphic mapping $f: \mathbb{C}^2 \rightarrow \mathbb{C}^2$ with nonvanishing Jacobian such that the image $f(\mathbb{C}^2)$ has an exterior point.

The theory of analytic functions of several complex variables has flourished since 1926. Behnke and Thullen in Münster, together with G. Julia and H. Cartan in Paris, were the most active investigators. The results on †normal families of analytic functions of several complex variables (Julia [20], 1926), the uniqueness theorem of holomorphic mappings (H. Cartan, 1930), and a characterization of a domain of holomorphy by holomorphic convexity (Cartan and Thullen, 1932) are their most remarkable achievements. Behnke and Thullen [3] systematized the results obtained since the discovery of the theory by providing a complete bibliography of articles up to 1934.

The three major unsolved problems at that time—those of Cousin, Levi, and the approximation of holomorphic functions—were intensively studied by Oka from 1936, who has given complete solutions [30]. The investigation of ideals of holomorphic functions by H. Cartan (1944), together with that of ideals with undetermined domains by Oka, has developed into the theory of coherent analytic sheaves. The notion of analytic spaces, first introduced by Behnke and Stein (1951), extended the field of investigation in the theory of analytic functions of several complex variables. The theory of cohomology with coefficients in sheaves has been effectively applied by H. Cartan and Serre (1951–1952). The introduction of the notion of Stein manifolds (1951) came at the same time. Grauert's deep investigations since 1955, together with those of Stein and Remmert, have contributed greatly to the development of the theory of analytic spaces. In the 1960s, active investigations took place also in the United States [16]. The theory of automorphic functions of several complex variables has been developed by C. L. Siegel, I. Satake, and others in connection with the theory of numbers. Entire functions of two variables have been investigated from a new point of view by Nishino and others since 1968 (→ last paragraph of Section N). The notion of a hyperbolic manifold introduced by Kobayashi (1967) enables us to obtain many results on

complex manifolds by means of the methods of differential geometry. The theory of automorphisms of bounded pseudoconvex domains was developed extensively in the 1970s by Fefferman, Naruki, and others. The theory of an envelope of holomorphy has also been successfully applied to the theory of elementary particles in physics.

22 (1.12) Analytic Sets

A. General Remarks

The notion of analytic sets was first defined by N. N. Luzin and M. Ya. Suslin in 1916, and it was extended to that of projective sets by operations such as complementation and projection (Luzin, 1924). Most mathematicians, including Luzin and W. Sierpinski, who worked in this field, were in agreement with †French empiricism (or tsemi-intuitionism), which defended the standpoint of R. Baire, E. Borel, H. Lebesgue, and others. An object is said to be **effectively given** if it can be uniquely, individually, and unambiguously determined in finite terms so that anyone can reach the same object by following the defining procedure. Semi-intuitionists claim that only effectively given objects have mathematical existence, and they do not recognize as a mathematical object something that needs the axiom of choice for its definition. From this point of view, †Borel sets were “well-defined” sets to which classical analysis had to be restricted. Thus the question was raised whether it is possible to extend the class of Borel sets to a wider class of sets with the same certainty. Lebesgue (*J. Math. Pures Appl.*, 1 (1905)) defined a function not belonging to any class of Baire functions by using the totality of †ordinals of the second class. (Later, this method was systematically developed as the †theory of sieves by Luzin.) However, it did not satisfy Borel as being effective. Can we, then, extend the Borel sets without any use of ordinals of the second class? The discovery of analytic sets gave an affirmative answer.

In this article (except in Section 1), we treat a space (denoted by X, Y, \dots) that is †homeomorphic to a †complete †separable †metric space and its subspace. Denote by \mathfrak{R} the **space of irrational numbers** (a metric space consisting of the irrational numbers $\in \mathbf{R}$ with the metric $|x - y|$ of x and y). The following properties of a subset S of a space X are equivalent: (i) S is a continuous image of \mathfrak{R} ; (ii) S is a continuous image of a Borel set in X ; (iii) S is the projection of a closed set in a product space $X \times \mathfrak{R}$; (iv) S is the projection of a Borel set in $X \times Y$. We call a set satisfying one of these properties an **analytic set**, an **A set**, or a Σ_1^1 set (in X). The complement of an analytic set is

called a **complementary analytic set** (or simply **coanalytic set**), a **CA set**, or a Π_1^1 set.

B. The Operation A and Sieves

When to each (n_1, \dots, n_k) of finite sequences of natural numbers there corresponds a unique element $E(n_1, \dots, n_k)$ of a family F of sets, this correspondence $\{E(n_1, \dots, n_k)\}$ is called a **schema of Suslin** (or **system of Suslin**) consisting of sets in F . Denoting an infinite sequence of natural numbers by $\{n_i\}$, the set given by $\bigcup_{i \in \mathbf{N}} \bigcap_k E(n_1, \dots, n_k)$ is called the **kernel** of a system of Suslin, and the operation of taking the kernel is called the **operation A** (**analytic operation**).

Let Q be the set of all rational numbers between 0 and 1 and F be a family of sets. Take a family $\{C_r\}_{r \in Q}$ of sets belonging to F with the index set Q (or more geometrically, a subset $C = \bigcup_{r \in Q} C_r \times r$ of $X \times Q$ when F is a family of subsets of a space X), and call it a **sieve** consisting of sets in F . Denoting by $\{r_i\}$ a (strictly) monotone decreasing sequence of elements of Q , we call the set $\bigcup_{i \in \mathbf{N}} \bigcap_k C_{r_k}$ (namely, the set of all x such that $C^{(x)} = \{r \mid (x, r) \in C\}$ is not well-ordered by the order \leq of rational numbers) the set obtained by a sieve C or the **sieved set** obtained by C . If the family F is closed with respect to countable intersection, then the family of all sets obtained by sieves consisting of sets in F is identical to the family of all sets obtained by applying the operation A to F . When F consists of all the closed sets in a given space, this is the family of all analytic sets. In particular, it is sufficient to take the family of closed intervals as F when X is the space of real numbers. Note that we can define sieves and sieved sets more generally by using the space of real numbers \mathbf{R} instead of the set Q of rationals.

C. Properties of Analytic Sets

It is evident from the definition that every †Borel set is analytic. If a Borel set is uncountable, then it is the union of a countable set and a one-to-one continuous image of \mathfrak{R} . The analyticity of sets is invariant under countable unions, intersections, and Cartesian products and the operation A and †Borel-measurable transformations. An uncountable analytic set contains a †perfect subset (Suslin). Therefore the possible cardinality of an analytic set is at most countable or is that of the continuum. Every analytic set enjoys the †Baire property, and in Euclidean space every analytic set is †Lebesgue measurable (Luzin, Sierpinski). If a set E in the Euclidean plane is analytic (coana-

lytic), then $I(E)$ is also analytic (coanalytic), where $I(E)$ is the set of all x such that the section $E^{(x)}$ of E that is parallel to the y -axis has a positive measure (M. Kondô and T. Tugué). Concerning the Baire property, the similar result for a set E of $X \times Y$ is obtained by replacing "to have a positive measure" by "to be the †second category (nonmeager) set" (A. S. Kechris). The Lebesgue measure of an analytic set is effectively calculable (in the sense that the measure of a Σ_1^1 (or $\Sigma_1^1(x)$) set is a Σ_1^1 (resp. $\Sigma_1^1(x)$) real number (- Section G and 356 Recursive Functions) (H. Tanaka). Every analytic (coanalytic) set E can be decomposed into \aleph_1 Borel sets. This decomposition is called a decomposition of E into constituents. An analytic (coanalytic) set is a Borel set if and only if it is decomposable into a countable number of constituents (Luzin, Sierpinski). In a space with the cardinality of the continuum, there exist analytic sets that are not Borelian. For example, in the space $C([0, 1])$ of continuous functions on the interval $[0, 1]$ (\rightarrow 168 Function Spaces) the set of all differentiable functions is coanalytic but not Borelian (S. Mazurkiewicz).

The following theorems are especially important in analytic set theory. **Luzin's first principle** (the first separation theorem): For every pair of disjoint analytic sets A, A_1 , there exists a Borel set B such that $A_1 \subset B$ and $B \cap A = \emptyset$. An immediate corollary of Luzin's first principle is **Suslin's theorem**: If both A and $X - A$ are analytic, then A is a Borel set. **Luzin's second principle** (the second separation theorem): For every pair of analytic sets A and B , there exist complementary analytic sets C and D such that $A - B \subset C$, $B - A \subset D$, and $C \cap D = \emptyset$. A one-to-one continuous image of a Borel set is Borelian (Suslin). More generally, for a given B -measurable function f defined on a Borel set B , the set A ($\subset f(B)$) of all points y whose inverse images $f^{-1}(y)$ are singletons is a complementary analytic set (**Luzin's unicity theorem**). In this theorem, we can replace "a singleton" by "a † σ -compact set" (V. Ya. Arsenin, K. Kunugui). Therefore, if a set is the image of a Borel set by a continuous function such that the inverse image of each point is a σ -compact set, then it is a Borel set.

D. Generalization to Projective Sets

A **projective set of class n** is inductively defined as follows: (i) the Borel sets are the projective sets of class 0; (ii) the projective sets of class $2n + 1$ are the continuous images of the sets of class $2n$; (iii) the projective sets of class $2n$ are the complements of the sets of class $2n - 1$.

The projective sets of class 1 are exactly the analytic sets, and those of class 2 are the complementary analytic sets. The following are fundamental properties of projective sets.

Denote by L_n the family of the projective sets of class n . Then (1) $L_{2n} \subset L_{2n+k}$ and $L_{2n+1} \subset L_{2n+2+k}$ ($k = 1, 2, \dots$). (2) the property of being a set of class n is invariant under countable unions, intersections, and Cartesian products and homeomorphisms; (3) a continuous image of a projective set of class $2n + 1$ is of the same class; (4) the projection on X of a set of class $2n + 1$ in $X \times Y$ is a set of class $2n + 1$ in X ; (5) the family of the projective sets of class $2n + 1$ in a space X is the family of the projections of all sets of class $2n$ in $X \times X$ (or $X \times \mathfrak{N}$); (6) the kernel of a system of Suslin consisting of sets of class n is a projective set of the same class, where $n \neq 0, 2$.

We frequently call a projective set of class $2n - 1$ a P_n set or a Σ_n^1 set, and that of class $2n$ a C_n set or a Π_n^1 set. A B_n set or a Δ_n^1 set is a set that is both P_n and C_n . The respective families of these sets are also denoted by $P_n(\Sigma_n^1)$, $C_n(\Pi_n^1)$, and $B_n(\Delta_n^1)$, respectively. In general, for a family \mathfrak{F} of sets in a space X , we denote by $C\mathfrak{F}$ the family of the complements $X - E$ of all sets E in \mathfrak{F} . We write $\text{Sep}_I(\mathfrak{F})$ and $\text{Sep}_{II}(\mathfrak{F})$ for the propositions obtained by substituting "set in \mathfrak{F} ," "set in \mathfrak{F} and in $C\mathfrak{F}$," and "set of $C\mathfrak{F}$ " for "analytic set," "Borel set," and "coanalytic set," respectively, in Luzin's first principle and Luzin's second principle, respectively. Furthermore, we say that the reduction principle holds for \mathfrak{F} , and denote it by $\text{Red}(\mathfrak{F})$, when for any sets $A, B \in \mathfrak{F}$ there exist $A_1, B_1 \in \mathfrak{F}$ such that $A_1 \subset A$, $B_1 \subset B$, $A_1 \cup B_1 = A \cup B$, and $A_1 \cap B_1 = \emptyset$. C. Kuratowski introduced the latter principle $\text{Red}(\mathfrak{F})$ which implies $\text{Sep}_I(C\mathfrak{F})$ and $\text{Sep}_{II}(C\mathfrak{F})$, and proved $\text{Red}(\Pi_1^1)$. Classically, reduction or separation principles for the projective sets of higher classes were not settled except for $\text{Sep}_{II}(\Pi_2^1)$, $\text{Sep}_{II}(\Pi_2^1)$ (P. S. Novikov), and $\text{Red}(\Sigma_2^1)$ (Kuratowski). Nowadays, it is known that these principles for $\{\Sigma_n^1, \Pi_n^1\}_{n \geq 3}$ are undecidable from the axiomatic set theory ZFC. If we assume †the axiom of constructibility $V = L$, then $\text{Red}(\Sigma_n^1)$ holds for $n \geq 3$ (J. W. Addison). On the other hand, under the assumption of †projective determinacy PD (\rightarrow Section H), it follows that $\text{Red}(\Pi_n^1)$ ($\text{Red}(\Sigma_n^1)$) holds when n is odd (even) (A. Martin, Addison and Y. N. Moschovakis).

E. Universal Sets

A set U in $\mathfrak{N} \times X$ is called the **universal set** for the projective sets of class n in X if for any projective set P of class n in X , there exists $z_0 \in \mathfrak{N}$ such that $P = \{x \mid (z_0, x) \in U\}$. Concern-

ing universal sets, we have the following result: for every $n > 0$, there exists a universal set for the projective sets of class n in X that is of the same class in $\mathfrak{N} \times X$. Hence in a space with the cardinality of the continuum, there exists a projective set of class $n + 1$ which is not of class n . In general, if a class \mathfrak{F} of sets is closed under taking a universal set and continuous preimages, then \mathfrak{F} and $C\mathfrak{F}$ cannot both have the reduction property. Therefore $\text{Red}(\Pi_n^1)$ or $\text{Red}(\Sigma_n^1)$ fails for each $n \geq 1$.

Any two universal sets of analytic sets are ${}^t\text{Borel}$ isomorphic. On the other hand, an analytic set E is not Borel isomorphic to any universal analytic set if the complement of E is an uncountable set without a perfect subset (A. Maitra and C. Ryll-Nardzewski). Hence, there are at least two equivalence classes of uncountable analytic sets with respect to the Borel isomorphism \cong under the assumption of $V=L$, since the latter assumption implies the existence of such a set E (- Section H).

F. Uniformization Principle

The uniformization problem arose during investigations of implicit functions. For a set E in a space $X \times Y$, **uniformization** of E is the finding of a subset V of E such that

$$\forall x(\exists y((x, y) \in E) \Leftrightarrow \exists! y((x, y) \in V)),$$

where $\exists! y$ is the t quantifier which means “there exists exactly one y .” A Borel set can be uniformized by choosing a suitable coanalytic set (Luzin). **Kondô’s uniformization theorem** (*Japan. J. Math.*, 15(1938)) is the most important result in descriptive set theory: every coanalytic set is uniformizable by a coanalytic set. As a corollary to this, any Σ_2^1 set is uniformizable by a Σ_2^1 set, and every Σ_2^1 set is obtained as a one-to-one continuous image of a coanalytic set.

Kondô’s original proof was very difficult to understand. Since t effective descriptive set theory was introduced by Kleene and Addison, the proof has been simplified by Addison, and a more elegant one has been given by J. R. Shoenfield [7, p. 188]. Nowadays, the theorem is also called the Novikov-Kondô-Addison theorem, and is one of the most powerful and fundamental theorems not only in descriptive set theory, but also in the t foundations of mathematics.

The uniformization of an analytic set is, in general, not to be found among analytic or coanalytic sets. There was a conjecture that any analytic set is uniformizable by specifying an A , set (difference of two analytic sets). Recently, this conjecture was negatively settled (J. Steel, Martin). Assuming that $V=L$, the

uniformization of a Σ_n^1 ($n \geq 3$) set is determined by specifying a Σ_n^1 set, and that of a Π_n^1 ($n \geq 2$) set by specifying a $\Pi_{n,p}^1$ set. On the other hand, if an axiom system of set theory (e.g., ZF; \rightarrow 33 Axiomatic Set Theory) is consistent, then it is still consistent even if we add to it the following proposition: There exists a Π_2^1 set whose uniformization is impossible by any choice of a definable set in the system (P. J. Cohen, A. Lévy). However, if we assume the existence of a t measurable cardinal (MC), it is known that every Π_2^1 set is uniformizable by a Π_2^1 set (Martin and R. M. Solovay). On the other hand, PD implies “every $\Pi_n^1(\Sigma_n^1)$ set is uniformizable by a $\Pi_n^1(\Sigma_n^1)$ set for each odd (resp. even) n ” (Moschovakis).

There are sufficient conditions on sections $E^{(x)}$ of a Borel set E in the Cartesian product $X \times Y$ for E to be uniformizable by the Borel set as follows: all sections $E^{(x)}$ are (i) countable (Luzin, Novikov), (ii) a -compact (Arsenin, Kunugui); or, as “large section property,” (iii) in the second category (S. K. Thomason, P. G. Hinman), or (iv) of positive measure (Tanaka, G. E. Sacks). For applications of descriptive set theory to analysis, an important uniformization result is **von Neumann’s selection theorem**: for any A set $E \subset X \times Y$, there exists a ${}^t\text{Baire}$ measurable and t absolutely measurable function $f: X \rightarrow Y$ (- 270 Measure Theory L (vi)) such that

$$\forall x(\exists y((x, y) \in E) \Leftrightarrow (x, f(x)) \in E).$$

Concerning implicit functions, any Borel set $E \subset X \times Y$ such that all sections $E^{(x)}$ are at most countable is expressed by a union of intersections of E with graphs of some Baire functions $f_n: X \rightarrow Y$, $n \in \mathbb{N}$ (Luzin). Recently, it was shown known as a generalization of this that any Borel set $E \subset X \times Y$ such that all sections are a -compact is a union of countably many Borel sets E_n for each of which all sections $E_n^{(x)}$ are compact (J. Saint-Raymond).

G. Kleene’s Hierarchy and Effectiveness

First, projective set theory in any space is reducible to the theory in the space of irrational numbers. Second, if we introduce a t weak topology in the set $\mathbb{N}^{\mathbb{N}} = {}^{\omega}\omega$ of t number-theoretic functions α with one argument, the resulting topological space $\mathbb{N}^{\mathbb{N}}$ is homeomorphic to the ${}^t\text{Baire}$ zero-dimensional space of irrational numbers. Third, any subset B of $\mathbb{N}^{\mathbb{N}}$ is open and closed in this topology if and only if there exist a function $\xi \in \mathbb{N}^{\mathbb{N}}$ and a predicate $A^{\xi}(\alpha)$ that is t general recursive in ξ such that $\alpha \in B \Leftrightarrow A^{\xi}(\alpha)$. Fourth, logical operations such as \neg , \vee , \wedge , $\exists x$ (where x is a variable ranging over the natural numbers), and $\exists \alpha$

exactly correspond to the operations (on sets) complementation, union, intersection, countable union, and projection, respectively. On the basis of these facts, projective set theory is regarded as the theory of the $\mathbb{N}^{\mathbb{N}}$ analytic hierarchy of Kleene. Here, the following example is remarkable: We can construct a Σ_1^1 set which is universal for the analytic sets (namely, a $\Sigma_1^1[\mathbb{N}^{\mathbb{N}}]$ set) in the space of irrational numbers (\rightarrow 356 Recursive Functions H).

The connection between projective set theory and logic has been discussed by C. Kuratowski and A. Tarski. From their point of view, semi-intuitionists such as Borel regard the set of natural numbers to be precisely clear in itself and also the continuum to be immediately recognizable by our geometric intuition. In their argument rational numbers do not play such an important role. They take, a priori, the set of irrational numbers as the fundamental domain, and intervals with rational extremities as the simplest sets of points among the subsets of the fundamental domain as the starting point of their argument. Here, the fundamental domain or each interval is not conceived as a totality of its elements, but recognized as a "uniform extent." In contrast to this, singletons and individual irrational numbers are not so simple. For this reason Borel introduced the notion of calculable numbers to study definable real numbers. Following Luzin, we say that a **calculable number** is a constructible real number in the sense that we can give it by an arithmetical approximation as precisely as we want. Now, this notion is nearly identical to the notion of an effectively calculable real number given by A. Church or A. M. Turing.

In the mathematics of the semi-intuitionists, the word "effective" has played an especially important role. Although these mathematicians have always agreed not to accept the axiom of choice, the exact meaning of "effective" has differed slightly among different members of their group or in different stages of the development of the theory. Such differences mainly arose in connection with the question: How can we tell whether given entities are finitary or individual? One way to guess the original intention held by Borel and others when they used the term "effective" is to replace the term by "recursive." Nowadays, the concept of "effectiveness" is used in this sense (\rightarrow 356 Recursive Functions C), and all classical results in descriptive set theory essentially have effective versions (or refinements via relativization). For example, the Novikov-Kondô-Addison theorem is described as follows: Any $\Pi_1^1(\Pi_1^1(\alpha))$ for an $\alpha \in {}^\omega\omega$ set is uniformizable by a Π_1^1 (resp. $\Pi_1^1(\alpha)$) set. Similarly, Suslin's theorem is that every analytic and

coanalytic (i.e., $\Delta_1^1(\alpha)$) set A is a Borel set of class $v(x)$ which is effective relative to the "definability α " of given A , where $v(a)$ is the +Constructive ordinal relative to α (Kleene, Tugué and Tanaka, A. Louveau, etc.).

H. Further Results in Axiomatic Set Theory and Strong Axioms

The recent development of axiomatic set theory has yielded the following propositions. Under the assumption that $V=L$ (K. Gödel, Novikov, Addison): (1) there exists an uncountable Π_1^1 set that does not contain any perfect subset; (2) there exists a nonmeasurable Δ_2^1 set; (3) there exists a Δ_2^1 set that does not have the Baire property. On the other hand, if the axioms of set theory ZFC plus "there exists an inaccessible cardinal number" are consistent, then so is "every projective set is Lebesgue measurable, has the Baire property, and has a perfect subset when it is uncountable" with them (Solovay). Concerning these properties, Martin's axiom MA and " $2^{\aleph_0} > \aleph_1$ " ($\text{MA} + \neg \text{CH}$ is consistent with ZFC; \rightarrow 33 Axiomatic Set Theory E) implies that every Σ_2^1 is measurable, and has the Baire property (Martin and Solovay). The possible cardinality of a Σ_2^1 set is at most \aleph_1 or that of the continuum, which is implied from "every Σ_2^1 set is a union of \aleph_1 Borel sets" (Sierpinski). It is known that one cannot prove or refute from ZFC the converse of the latter statement. If one assumes MC (the existence of a measurable cardinal), then every Σ_3^1 set is a union of \aleph_2 Borel sets. Therefore MC implies that the possible cardinality of a Σ_3^1 set is at most \aleph_2 or that of the continuum.

With each set $A \subset {}^\omega\omega$ we associate the following infinite game of perfect information $G(A)$, played by two players I and II. First player I chooses $n_0 \in \omega$, then player II chooses $n_1 \in \omega$, then I chooses $n_2 \in \omega$, and so on. The game ends after ω steps. Let $r(k) = n_k$; if $x \in A$, then I wins $G(A)$; otherwise II wins. A strategy (for I or II) is a rule that tells the player what move to make, depending on the previous moves of both players. A winning strategy is one such that the player who follows it always wins. The game $G(A)$ is determined if one of the players has a winning strategy. The axiom of **projective determinacy** PD is the assertion that for every projective set $A (\subset {}^\omega\omega)$ the game $G(A)$ is determined. PD is widely used to solve problems on projective sets that are not decidable from ZFC, and is a plausible hypothesis that does not seem to contradict the axiom of choice at present; and it has pleasing consequences in descriptive set theory. For $n \geq 3$,

reductions and uniformization results of Σ_n^1 (Π_n^1) sets mentioned earlier are such examples. Furthermore, PD implies that every projective set is Lebesgue measurable, has the Baire property, and contains a perfect subset if it is uncountable.

Now, write Determinacy (Σ_n^1) (Determinacy (Δ_n^1)), or simply, $\text{Det}(\Sigma_n^1)$ ($\text{Det}(\Delta_n^1)$), when $G(A)$ is determined for every Σ_n^1 (Δ_n^1) set A . Using the fact that the open game is determined, namely $\text{Det}(\Sigma_1^0)$ (D. Gale and F. M. Stewart), D. Blackwell has given a short proof of $\text{Sep}_1(\Sigma_1^1)$. The extremely difficult problem was to show $\text{Det}(\Delta_1^1)$ in ZF (indeed, one cannot prove $\text{Det}(\Delta_1^1)$ only from the Zermelo axioms $z; \rightarrow 33$ Axiomatic Set Theory B). In 1975, Martin solved this problem. Concerning Σ_1^1 , $\text{Det}(\Sigma_1^1)$ cannot be proved from only the ZF axioms, but MC implies $\text{Det}(\Sigma_1^1)$ (Martin). However, it is known that $\text{Det}(\Sigma_2^1)$ cannot be proved even if we assume MC.

By a pre-well-ordering, we mean a relation \leq having all the properties of a well-ordering except for \dagger antisymmetry. Denote by δ_n^1 the least ordinal that cannot be the length of a prewell-ordering on ${}^\omega\omega$ belonging to Δ_n^1 . It is a classical result that $\delta_1^1 = \omega_1 (= K)$. The following results are mainly due to Martin: $\delta_2^1 \leq \aleph_2$, MC $\Rightarrow \delta_3^1 \leq \aleph_3$, and also, PD $\Rightarrow \delta_4^1 \leq \aleph_4$. Let κ be an infinite cardinal. A set $A \subset X$ is called κ -Suslin when there exists a closed set $C \subset X \times {}^\omega\kappa$ (${}^\omega\kappa = \{f \mid f: \omega \rightarrow \kappa\}$) such that

$$x \in A \Leftrightarrow \exists f [f \in {}^\omega\kappa \wedge (x, f) \in C].$$

A is \aleph_0 -Suslin iff $A \in \Sigma_1^1$. If A is a Σ_2^2 set, then A is \aleph_1 -Suslin (Shoenfield). Under the assumptions of MC, if A is a Σ_3^1 set, then it is \aleph_2 -Suslin (Martin). Furthermore, $\text{Det}(\Delta_{2n}^1)$ implies the following facts (Kechris, Moschovakis): every Σ_{2n+2}^1 set is κ -Suslin, where κ is the cardinal of δ_{2n+1}^1 ; every Σ_{2n+1}^1 set is κ -Suslin for some $\kappa < \delta_{2n+1}^1$.

The axiom of determinacy AD is the assertion that the game $G(A)$ is determined for every set A . AD implies that every set is measurable (J. Mycielski and S. Swierczkowski), has the Baire property, and has a perfect subset if it is uncountable (Morton Davis). Though AD contradicts the axiom of choice, some consequences of AD in the area of projective sets are more desirable than the consequences of the axiom of choice. The following are examples of consequences of AD. (1) A is a Σ_2^1 set iff A is a union of \aleph_1 Borel sets (Moschovakis). (2) For each n , δ_n^1 is a cardinal (Moschovakis). (3) Generalization of Suslin's theorem holds as follows: $\mathcal{A}_n^1 = \mathbb{B}_{\delta_n^1}$ (= the smallest \dagger Boolean algebra containing the open sets and closed under complementation and unions of length $< \delta_n^1$) (Martin, Moschovakis).

I. Polish Spaces, Luzin Spaces, and Suslin Spaces

A topological space homeomorphic to a complete separable metric space is called a **Polish space**. A subspace E of a Polish space X is Polish if and only if it is a G_δ -subset of X , i.e., a countable intersection of open subsets of X (Aleksandrov and Uryson). A Hausdorff topological space X is called a **Luzin space** (resp. **Suslin space**) if we can find a Polish space S and a continuous bijective (resp. surjective) mapping $f: S \rightarrow X$. Every Polish space is a Luzin space and every Luzin space is a Suslin space.

Let X be a Hausdorff topological space. A subset E of X is called a **standard set** (resp. **analytic set**) if the set E with the relative topology is a Luzin (resp. Suslin) space. The analytic subsets are closed under analytic operations. Every analytic set is obtained from closed sets by applying the analytic operation. Every analytic set is \dagger universally measurable. Every standard set is a Borel set. Every countable union or intersection of standard sets is standard.

A subset E of a Suslin space is a Borel set if and only if both E and E^c are analytic. A subset E of a Luzin space is a Borel set if and only if E is standard.

Let f be a Borel measurable mapping from a Suslin space X into another Suslin space Y . Then the image $f(X)$ is an analytic subset of Y . Furthermore, if f is injective, then f^* gives a \dagger Borel isomorphism between X and $f(X)$. If both X and Y are Luzin spaces and if f is injective, then $f(X)$ is a Borel subset of Y . Every Suslin space is \dagger Borel isomorphic to an analytic subset of \mathbf{R} , and every Luzin space is Borel isomorphic to one of the following spaces: (1) $\mathbf{N}_n = \{1, 2, \dots, n\}$, (2) $\mathbf{N} = \{1, 2, \dots\}$, (3) \mathbf{R} .

The selection theorem due to von Neumann (- Section F) holds when X and Y are Suslin spaces. This fact and its ramifications [15, 16] are useful in nonlinear functional analysis and control theory.

Practically all useful spaces appearing in functional analysis and probability theory are Polish or Luzin spaces. Examples: (i) Every locally compact Hausdorff space with a countable open base is Polish. (ii) Every separable Banach space is Polish. (iii) The set C of all continuous functions on $[0, 1]$ with the \dagger topology of uniform convergence is a Polish space. (iv) The set D of all right continuous functions on $[0, 1]$ with left limits is a Polish space when it is endowed with the Skorokhod topology (- 250 Limit Theorems in Probability Theory E). (v) The space \mathcal{D}' of distributions and the space \mathcal{S}' of tempered distri-

butions (- 125 Distributions and Hyperfunctions) are Luzin spaces.

23 (X1.21) Analytic Spaces

A. General Remarks

An \dagger analytic function of a complex variable has as its natural domain of definition a \dagger Rie-

mann surface, i.e., a 1-dimensional complex analytic manifold. In the case of several complex variables, the set of zeros of an analytic function, the quotient space of a domain by a \dagger properly discontinuous group of analytic automorphisms, the existence domain of an \dagger algebroidal function, etc., are, strictly speaking, not necessarily complex analytic manifolds. It is necessary to consider a more general category of complex analytic manifolds with singularities, and the notion of analytic spaces is drawn from these examples. Many of the properties of complex analytic manifolds are extended to analytic spaces; on the other hand, theories specific to analytic spaces have also been developed.

B. Analytic Sets

We say that a subset A of a complex analytic manifold G is an **analytic set** in G if it is a closed subset and each point of A has a neighborhood U such that $U \cap A$ is the set of common zeros of a finite number of holomorphic functions in U . Specifically, if A is locally the set of zeros of a single holomorphic function that does not vanish identically, then A is called **principal**. Two subsets S_1 and S_2 of G are called equivalent at $z^0 \in G$ if there exists a neighborhood U of z^0 such that $S_1 \cap U = S_2 \cap U$. By this equivalence relation, every subsets S of G defines its germ S_{z^0} at z^0 . A **germ of an analytic set** at z^0 is the germ at z^0 of an analytic set in a neighborhood of z^0 . Each germ A , of an analytic set at $z^0 = 0 \in G$ is associated with an ideal $I(A_0) = \{f \mid f \in H(0), f|_A = 0\}$ in the ring $H(0)$ of \dagger germs of holomorphic functions at 0 . We call A , **reducible** if A is the union of two germs of analytic sets A_1 and A_2 with $A_0' \neq A_0$, $A_0'' \neq A_0$; otherwise, A is called **irreducible**. An analytic set A is called **irreducible at 0** if the germ at 0 of A is irreducible. Properties of A , and $I(A_0)$ correspond to each other. Thus A is irreducible if and only if $I(A_0)$ is prime.

As the ring $H(0)$ is \dagger Noetherian, in a neighborhood of every point z^0 an analytic set A is represented as a union of a finite number of analytic sets A_i that are irreducible at z^0 . These A_i are essentially unique. If an analytic set A is irreducible at z^0 , then there exists a system of local coordinates (z_1, \dots, z_n) centered at z^0 and a pair of natural numbers $d \leq n$ and k such that, in a neighborhood of z^0 , A is a k -sheeted **ramified covering space** with covering mapping $\varphi: (z_1, \dots, z_n) \rightarrow (z_1, \dots, z_d)$; i.e., for an analytic set R in a neighborhood of $0 \in \mathbb{C}^d$, $\varphi: A - \varphi^{-1}(R) \rightarrow \mathbb{C}^d - R$ is, in a neighborhood of z^0 , a k -sheeted covering mapping, where $A - \varphi^{-1}(R)$ is a connected d -dimensional com-

plex analytic manifold in the neighborhood. The coordinates of the k points of $A - \varphi^{-1}(R)$ over each point (z_1, \dots, z_d) are holomorphic in these variables. The number d is the **(local) dimension** of A at z^0 and is denoted by $\dim_{z^0} A$. From this local representation, we obtain **Rückert's zero-point theorem**: Every prime ideal \mathfrak{P} in $H(0)$ is equal to $I(A_0)$, with A , an irreducible germ of an analytic set at 0. In this case the dimension at 0 of an analytic set A that defines A , is equal to the \dagger Krull dimension of the \dagger local ring $H(0)/\mathfrak{P}$. The theory of local rings is very important in the study of germs of analytic sets. The dimension of a general analytic set A at z^0 is defined by $\dim_{z^0} A = \sup_i \dim_{z^0} A_i$, where $A = \bigcup_i A_i$ in a neighborhood of z^0 , with the A_i irreducible at z^0 . If $\dim_{z^0} A_i$ is equal to d for all i , then A is called **purely d -dimensional** at z^0 . The **(global) dimension** of A is defined by $\dim A = \sup_{z \in A} \dim_{z^0} A$. A **purely d -dimensional analytic set** is defined to be an analytic set that is purely d -dimensional at every one of its points.

A point z^0 of an analytic set A is called **ordinary (regular or simple)** if A has the structure of a complex analytic submanifold in a neighborhood of z^0 . The set A^* of ordinary points of A is dense and open in A . The set $A^* = A - A^*$ of **singular** (not ordinary) points is an analytic set in G . If A is purely d -dimensional, then A^* is a d -dimensional complex analytic manifold and A^* is an analytic set of dimension $\leq d - 1$.

Let A be an analytic set of dimension d in G , and B a purely d' -dimensional analytic set in $G - A$ with $d' > d$. Then the closure \bar{B} of B in G is a purely d' -dimensional analytic set (**Remmert-Stein continuation theorem** [17]).

For every analytic set A in G , the \dagger analytic sheaf $\mathcal{S}(A)$ of germs of holomorphic functions over G that vanish on A is \dagger coherent (H. Cartan). We call $\mathcal{S}(A)$ the sheaf of ideals defined by an analytic set A . Let \mathcal{O}_G be the sheaf of germs of holomorphic functions over G . Then $\mathcal{O}_A = (\mathcal{O}_G / \mathcal{S}(A))|_A$ is a coherent sheaf of rings over A . \mathcal{O}_A is called the sheaf of germs of holomorphic functions on an analytic set A .

C. Analytic Spaces

A \dagger ringed space $(X, 0_*)$ with Hausdorff base space X is called an **analytic space** if for every point $x \in X$, there exists an open neighborhood U of x such that the ringed space $(U, \mathcal{O}_X|_U)$ is isomorphic to a ringed space (A, \mathcal{O}_A) , where A is an analytic set in an open set G of some \mathbb{C}^n . The structure sheaf \mathcal{O}_X is then called a **sheaf of germs of holomorphic functions**. The notion of \dagger holomorphic mapping from one open set in \mathbb{C}^n into another is generalized to the case of

mappings from one analytic set into another. An analytic set Y in an analytic space X and the sheaf \mathcal{O}_Y of germs of holomorphic functions on Y are defined as in the case where X is a complex manifold. The ringed space $(Y, 0_*)$ is an analytic space and is called an **analytic subspace** of X . For an analytic space X , the notions of $\dim X$, $\dim X$, irreducibility, and pure dimensionality are defined as for an analytic set $A \subset G \subset \mathbb{C}^n$. Every analytic space X is the union of a locally finite family of irreducible analytic subspaces X_i , called the **irreducible components** of X .

Let $\varphi: X \rightarrow Y$ be a holomorphic mapping of an analytic space X into another, Y . Its **rank** at $x \in X$ is defined by $r_\varphi(x) = \dim_x X - \dim_x \varphi^{-1}(\varphi(x))$. The number $r_\varphi = \sup_{x \in X} r_\varphi(x)$ is called the **rank** of φ . The **set of degeneracy** E_φ of φ is the set of points $x \in X$ such that $r_{\varphi|_{X'}}(x) < r_{\varphi|_{X'}}$ for an irreducible component X' of X through x . The mapping φ is **non-degenerate** if $E_\varphi = \emptyset$. For any $k \in \mathbb{N}$, $\{x \in X \mid r_\varphi(x) \leq k\}$ is an analytic set (R. Remmert [16]). In particular, E_φ is analytic. For a holomorphic mapping $\varphi: X \rightarrow Y$, the inverse image of an analytic set in Y is an analytic set in X . However, the image of an analytic set is not necessarily analytic. If φ is \dagger proper, then the image $\varphi(X')$ of an analytic set X' in X is an analytic set in Y of dimension $r_{\varphi|_{X'}}$ and is irreducible if X' is irreducible (**Remmert's theorem** [16]).

D. Modifications and Resolution of Singularities

Let M be a subset of an analytic space X . If, for every point $x \in X$, there exists an open neighborhood U of x and an analytic set M^* in U , containing $U \cap M$ such that $U - M^*$ is dense in U , then M is called **analytically thin**. Let $\varphi: X \rightarrow Y$ be a holomorphic mapping. Suppose that there exist two analytically thin sets $A \subset X$, $N \subset Y$ such that φ induces an isomorphism between $X - M$ and $Y - N$. Then X is called a **holomorphic modification** of Y . If furthermore φ is proper, then X is called a **proper modification** of Y . A **monoidal transformation** of an analytic space X with respect to a coherent sheaf of ideals \mathcal{I} is defined as in the case of a complex manifold or an algebraic variety (\rightarrow 16 Algebraic Varieties L; 72 Complex Manifolds H). It is a proper modification $f: X^* \rightarrow X$ such that the inverse image ideal sheaf $f^{-1}\mathcal{I} \cdot \mathcal{O}_{X^*}$ is invertible, and is universal among all proper holomorphic mappings $h: Z \rightarrow X$ with the property that $h^{-1}\mathcal{I} \cdot \mathcal{O}_{Z^*}$ is invertible, where $f^{-1}\mathcal{I}$ is the \dagger inverse image of \mathcal{I} . If \mathcal{I} is the sheaf of ideals defined by an analytic set Y in X , the mon-

oidal transformation of X with respect to \mathcal{J} is often called the **blowing-up** of X with center Y .

H. Hironaka [14] proved that, if X is an analytic space which is countable at infinity (i.e., a countable union of compact sets), then there is a proper modification $\pi: X' \rightarrow X$ with X' smooth (i.e., free from singular points). Such a modification is called a **desingularization** (or **resolution of singularities**) of X . Moreover, over any relatively compact open set U of X , π is the product of a finite sequence of blowing-ups $\pi_i: X'_i \rightarrow X'_{i-1}$ ($X'_0 = X$), with smooth centers Y'_{i-1} along which X'_{i-1} is \dagger normally flat. This deep result enables one to derive properties of analytic spaces from those of complex manifolds.

Let X and Y be two analytic spaces and G an analytic set in $X \times Y$. If the canonical projection $\pi: G \rightarrow X$ is a holomorphic (or proper) modification, then we say that a **meromorphic mapping** (a proper meromorphic mapping) μ of X into Y is defined. The set G is then called the **graph** of μ . A holomorphic mapping $\varphi: X \rightarrow Y$ can be viewed as a proper meromorphic mapping. Let $\mu: X \rightarrow Y$ be a proper meromorphic mapping. Then $\mu(x)$ (the projection of $\pi^{-1}(x)$ into Y) is a nonempty analytic set in Y for every point $x \in X$. Moreover, there exists an analytic set N , with $X \setminus N$ dense in X , such that μ maps $X \setminus N$ into Y holomorphically. The smallest set N with this property is called the **set of points of indeterminacy** or the **singularity set** of μ . A meromorphic mapping $f: X \rightarrow \mathbf{P}^1(\mathbf{C})$ is called a **meromorphic function** on X if none of the irreducible components of X is mapped to $\{\infty\}$ by f . The set $f^{-1}(0) = \pi((X \times \{0\}) \cap G)$ is called the set of zero points of X , and the set $f^{-1}(\infty)$ is called the set of poles. These are analytic sets in X . Let f_1, \dots, f_k be meromorphic functions on X . Then, by a suitable proper modification of X , one can eliminate the points of indeterminacy of the meromorphic mapping $f: X \rightarrow (\mathbf{P}^1(\mathbf{C}))^k$ defined by $x \mapsto (f_1(x), \dots, f_k(x))$, i.e., one can modify f to be holomorphic. The ring of meromorphic functions on X is invariant under proper modifications of X . If X is irreducible and compact, then the field of meromorphic functions on X is a simple algebraic extension of the \dagger field of rational functions of k ($\leq \dim X$) variables.

Let $(X, 0_*)$ be an analytic space. A point $x \in X$ is called **normal** for X if $\mathcal{O}_{X,x}$ is a \dagger normal local ring. The set of nonnormal points for X is an analytically thin analytic set in X (K. Oka). Every ordinary point of X is normal. We call X **normal** if every one of its points is normal. Every nondegenerate holomorphic mapping of an irreducible X into an irreducible and normal Y is an open mapping if its rank is equal to the dimension of Y (Remmert).

For every analytic space X , there exists a proper modification $v: \tilde{X} \rightarrow X$ with \tilde{X} normal such that v is nondegenerate and $v: \tilde{X} \rightarrow v^{-1}(S)$ is an isomorphism, where S is the set of non-normal points. Such a proper modification of X is unique up to isomorphisms. We call \tilde{X} a **normalization** of X with normalizing mapping v .

Let $\varphi: X \rightarrow Y$ be a holomorphic modification. Suppose that Y is normal at $\varphi(x^0)$ ($x^0 \in X$). If the set $\varphi^{-1}(\varphi(x^0))$ contains an isolated point, then $\varphi^{-1}(\varphi(x^0)) = x^0$, and φ is an isomorphism in a neighborhood of x^0 (an analog of \dagger Zariski's main theorem). In particular, if $\varphi: X \rightarrow Y$ is a holomorphic modification and Y is normal, then φ maps $X - E_\varphi$ isomorphically onto the dense open set $\varphi(X - E_\varphi)$. Furthermore, if a holomorphic mapping $\varphi: X \rightarrow Y$ is injective and X and Y are irreducible, normal, and n -dimensional, then $\varphi(X)$ is an open set in Y and $\varphi^{-1}: \varphi(X) \rightarrow X$ is holomorphic.

E. Analytic Spaces in the Sense of Behnke and Stein

Let $\varphi: \tilde{G} \rightarrow G$ be a proper continuous mapping of a connected \dagger locally compact space \tilde{G} onto a domain $G \subset \mathbf{C}^n$. The triple $\mathfrak{G} = (\tilde{G}, \varphi, G)$ is an **analytic covering space** over G if the following conditions are satisfied: (i) $\varphi^{-1}(z^0)$ is a finite set for every point $z^0 \in G$. (ii) There exists an analytic set $A \subset G$ of dimension $\leq n-1$ such that $\varphi: \tilde{G} - \varphi^{-1}(A) \rightarrow G - A$ is a local homeomorphism and every point of $\varphi^{-1}(A)$ has a fundamental system of neighborhoods U such that both U and $U - \varphi^{-1}(A) \neq \emptyset$ are connected. As \mathfrak{G} is unramified over $G - A$, the number of points in $\varphi^{-1}(z^0)$ is constant for $z^0 \in G - A$ and is called the **number of sheets** of \mathfrak{G} . A point $\tilde{z} \in \tilde{G}$ is called a **ramification point** of \mathfrak{G} if the restriction of φ to any neighborhood of \tilde{z} is not a homeomorphism. Denote by B the set of ramification points of \mathfrak{G} . Then $\varphi(B) \subset A$ is an analytic set of dimension $\leq n-1$. Let f be a continuous complex-valued function in an open set D in \tilde{G} . We call f **holomorphic** in D if for every point $\tilde{z}^0 \in D - B$ and for every open neighborhood V of $z^0 = \varphi(\tilde{z}^0)$ over which φ is a homeomorphism, $f \circ \varphi^{-1}$ is holomorphic in V . Denote by $\mathcal{O}_{\tilde{G}}$ the sheaf of germs of holomorphic functions over \tilde{G} . Then $(\tilde{G}, \mathcal{O}_{\tilde{G}})$ is a ringed space. An **analytic space in the sense of Behnke and Stein** is a Hausdorff ringed space $(X, 0_*)$ that is locally isomorphic to a ringed space of the form $(\tilde{G}, \mathcal{O}_{\tilde{G}})$ [3]. \dagger Riemann's theorem on removable singularities holds for such spaces. Every normal analytic space is an analytic space in the sense of Behnke and Stein. An analytic covering space $\mathfrak{G} = (\tilde{G}, \varphi, G)$

is a **C-covering space** (covering space in the sense of Cartan) if for every point $z^0 \in G$ there exist an open neighborhood V of z^0 and a holomorphic function g in $U = \varphi^{-1}(V)$ which can be defined by an irreducible polynomial of degree k such that its coefficients are holomorphic functions on V and the coefficient of its highest term is 1, where k is the number of sheets of \mathfrak{G} . A **C-analytic space** is an analytic space in the sense of Behnke and Stein that is locally isomorphic to a C-covering space. The category of C-analytic spaces coincides with that of normal analytic spaces. According to H. Grauert and Remmert [10], every analytic covering space is a C-analytic covering space. Therefore every analytic space in the sense of Behnke and Stein is a normal analytic space.

Let R be an equivalence relation in an analytic space X . Given a subset A of X , denote by $R[A]$ the set of points of X which are R -equivalent to points of A . We call R **proper** if $R[K]$ is compact for every compact set K in X . Let φ be a proper holomorphic mapping of an analytic space X into another Y . For $x, x' \in X$, let $x \equiv x'(R)$ be defined by $\varphi(x) = \varphi(x')$. The equivalence relation R is then proper. We consider the quotient space X/R and the canonical projection $p: X \rightarrow X/R$. With each open set U in the quotient space X/R we can associate the ring of holomorphic functions in $p^{-1}(U)$ that are constant on $p^{-1}(\bar{x})$ for every $\bar{x} \in U$. This leads to a ringed space $(X/R, \mathcal{O}_{X/R})$, which is proved to be an analytic space by **Grauert's theorem** [9]: All the \dagger direct images of a coherent analytic sheaf over X by a proper holomorphic mapping $\varphi: X \rightarrow Y$ are coherent. For every proper equivalence relation R in X , the ringed space $(X/R, \mathcal{O}_{X/R})$ is an analytic space if and only if for every point $\bar{x} \in X/R$ there exists an open neighborhood V of \bar{x} such that functions in $\Gamma(V, \mathcal{O}_{X/R})$ separate the points of V (H. Cartan).

F. Stein Spaces

For an analytic space (X, \mathcal{O}_X) let us consider the following conditions: (i) Functions in $I(X, \mathcal{O}_X)$ separate the points of X . (ii) X is **K-complete**; i.e., for every point $x \in X$ there exist a finite number of $f_i \in I(X, \mathcal{O}_X)$ ($i = 1, \dots, k$) such that the holomorphic mapping $f = (f_i): X \rightarrow \mathbb{C}^k$ is nondegenerate at x . (iii) Every compact analytic set in X is a finite set. Condition (i) implies (ii), and (ii) implies (iii). If an irreducible analytic space X is K-complete, then X is a countable union of compact sets (Grauert [S]). In fact, if $n = \dim X$, there exist functions $f_i \in \Gamma(X, \mathcal{O}_X)$ ($i = 1, \dots, n$) such that the holomorphic mapping $f = (f_i): X \rightarrow \mathbb{C}^n$ is nondegen-

erate. The notion of holomorphic convexity (\rightarrow 21 Analytic Functions of Several Complex Variables H) is carried over to analytic spaces. For a holomorphically convex analytic space, conditions (i), (ii), and (iii) are equivalent (Grauert [8]). A **Stein space** (or **holomorphically complete space**) is a holomorphically convex analytic space that satisfies one of the conditions (i), (ii), or (iii). In a holomorphically convex analytic space (X, \mathcal{O}_X) , let R be the equivalence relation defined by $I(X, \mathfrak{G})$; i.e., for $x, x' \in X$, $x \equiv x'(R)$ if and only if $f(x) = f(x')$ for every $f \in \Gamma(X, \mathcal{O}_X)$. Then R is proper. The analytic space $(X/R, \mathcal{O}_{X/R})$ is a Stein space. A Stein space is a generalization of the notion of a Stein manifold. Fundamental theorems A and B on Stein manifolds hold Verbatim for Stein spaces (\rightarrow 21 Analytic Functions of Several Complex Variables L). Therefore the main properties of Stein manifolds are inherited by Stein spaces. Let $\varphi: X \rightarrow Y$ be a holomorphic mapping of an analytic space X into another, Y . If for every $x \in X$ all the connected components of the fibers $\varphi^{-1}(\varphi(x))$ are compact, then the equivalence relation R' defined by those components (i.e., for x and x' in X , $x \equiv x'(R')$ if and only if x and x' belong to the same component of $\varphi^{-1}(\varphi(x))$) is proper, and the ringed space $(X/R', \mathcal{O}_{X/R'})$ is an analytic space. In particular, if X is a holomorphically convex irreducible analytic space and R is the equivalence relation defined by $\Gamma(X, \mathcal{O}_X)$, then all the fibers of the canonical projection $p: X \rightarrow X/R$ are connected.

G. Further Topics

The notion of analytic space can be generalized as follows (Grauert [9]). A ringed space (X, \mathcal{O}_X) is a **general analytic space** if it is locally isomorphic to a ringed space (A, \mathcal{H}_A) , where A is an analytic set in a domain $G \subseteq \mathbb{C}^n$, and $\mathcal{H}_A = (\mathcal{O}_G/\mathcal{I})|_A$ for some coherent analytic subsheaf \mathcal{I} of \mathcal{O}_G such that $\text{Supp}(\mathcal{O}_G/\mathcal{I}) (= \{z \in G \mid (\mathcal{O}_G/\mathcal{I})_z \neq 0\}) = A$. An **analytic subspace** of (X, \mathcal{O}_X) is a ringed space (Y, \mathcal{O}_Y) where $Y = \text{Supp}(\mathcal{O}_X/\mathcal{I})$ and $\mathcal{O}_Y = \mathcal{O}_X/\mathcal{I}$ for some coherent sheaf of ideals \mathcal{I} of \mathcal{O}_X . (Y, \mathcal{O}_Y) is also a general analytic space. A. Douady [6] showed that for any general analytic space (X, \mathcal{O}_X) there exists a natural structure of a general analytic space on the totality of all the compact analytic subspaces of (X, \mathcal{O}_X) . The resulting analytic space is called the **Douady space** of (X, \mathcal{O}_X) . For the proof, the notion of a **Banach analytic space** is used, which is obtained by first defining analytic subspaces in an open subset of a complex \dagger Banach space and then patching them. A Douady space can

be used, for example, to show that the identity component of the analytic automorphism group of a compact Kähler manifold is a \dagger complex Lie group which is naturally an extension of a \dagger complex torus by a \dagger linear algebraic group (A. Fujiki, D. Lieberman; \rightarrow 232 Kähler Manifolds C).

24 (Xx1.1) Ancient Mathematics

A. General Remarks

To determine the beginning of the history of mathematics, one must define the term "mathematics." Only speculation based on the observation of primitive peoples today can be made regarding the development of the number concept among prehistoric peoples. The prehistoric period ended in Egypt and Mesopotamia c. 3000 B.C., and a little later in the valleys of the large rivers in India and China.

Since the basis of the civilizations in the river valleys of the ancient world was agriculture, the administrators first had to control watering systems through irrigation, drainage, pumping, and canalization; second, they had to measure land and harvests for tax collection; and third, they had to establish a calendar by observation of the heavenly bodies. All these tasks demanded some knowledge of mathematics.

Additional knowledge of mathematics was certainly needed for construction of the palaces and tombs. We know something of the development of mathematical knowledge during these ages from some recovered artifacts, but there remains the possibility of new finds that will bring about a basic change in our knowledge of the history of mathematics during this period.

B. Mathematics in Egypt

The main sources for our understanding of the history of mathematics in Egypt are the Moscow papyrus and the more important Rhind papyrus, both discovered in the 19th Century. The Greeks place the origin of their mathematics in Egypt, but it seems that Egyptian mathematics was limited to practical mathematics. The Egyptians had a decimal numeration system, but the place value was not clear; they used fractions, which they always decomposed into the sums of unit fractions (i.e., fractions with 1 as numerator); they solved the problems of everyday arithmetic that were reducible to linear equations; they computed approximate areas and volumes of some figures for the purpose of measurement of farmland or granaries and for construction work; they had exact formulas for the computation of areas of triangles and of trapezoids; and they used $(16/9)^2 = 3.1605$ as the value of π ; but no trace has been found to prove the existence of demonstrative mathematics in ancient Egypt.

C. Mathematics in Mesopotamia

Sources abound for the study of Mesopotamian mathematics, and these sources may very well increase in the future. The Mesopotamians kept exact records of astronomical observations for long periods of time. Their more advanced mathematics was not limited to practical use, as was that of the Egyptians. They used a sexagesimal system of numeration with place value, and also used sexagesimal fractions; however, they lacked a cipher to denote zero until the 4th Century B.C., and they did not have a symbol corresponding to our decimal point, so that exact place value had to be determined from the context of each expression. They had a multiplication table and tables of inverses, squares, and cubes of numbers, and they used these tables to solve equations, even some simple equations of the third degree, as well as simultaneous equations of the second degree for two unknowns. They had accurate solutions for quadratic equations (expressed in words); they discarded negative roots, but they admitted both positive roots when two existed. They studied integral solutions of $a^2 + b^2 = c^2$ (the largest of their solutions were 12,709, 13,500, and 18,541) and approximate computation of quadratic roots, which suggests some relation to Greek mathematics. We have evidence that some of the geometric algebra in Euclid's *Elements* can be traced to Mesopotamian algebra. Some historians also affirm that the concept of demonstration in Greek mathematics originated with the Mesopotamians, but this theory lacks sufficient proof.

By the 7th Century, the Mayas in Central America also possessed a numeration system, with the base 20. As far as we know, the Mesopotamians and the Mayas were the earliest people to possess numeration systems with place value (- 57 Chinese Mathematics, 187 Greek Mathematics, 209 Indian Mathematics).

Approximation Methods in Physics

A. Introduction

It is often possible to solve a differential equation of mathematical physics analytically by expanding the solution in a series with respect to a small (or large) parameter involved in the equation. In general, such an approach is called a **perturbation method** (- Section B). For an equation which is difficult to treat analytically, it is possible to get a numerical solution either by replacing the derivatives by difference quotients ([†]difference method), or by expanding the solution in terms of suitable functions and determining the expansion coefficients numerically from the equation rewritten in a weak form ([†]variational method, [†]method of weighted residuals, [†]Galerkin's method, [†]finite-element method, etc.). For such numerical methods → 46 Calculus of Variations, 301 Numerical Solution of Algebraic Equations, 302 Numerical Solution of Linear Equations, 303 Numerical Solution of Ordinary Differential Equations, 304 Numerical Solution of Partial Differential Equations, 441 Variational Principles.

In Section C we describe a method for deriving an asymptotic expression for a function written as an integral in a complex plane.

B. Perturbation Method

(1) **Regular Perturbation.** (a) Initial-value problem. Consider an initial-value problem of an ordinary differential equation involving a small parameter ε :

$$\frac{du}{dt} = f(t, u; \varepsilon), \quad (1)$$

$$u = b(\varepsilon) \text{ at } t = 0. \quad (2)$$

We assume that f is sufficiently smooth as a function of t and is regular as a function of u and ε , and that b is a regular function of ε .

Substituting the power series in ε for f , u , and b ,

$$f(t, u; \varepsilon) = f^{(0)}(t, u) + \varepsilon f^{(1)}(t, u) + \dots$$

$$u(t; \varepsilon) = u^{(0)}(t) + \varepsilon u^{(1)}(t) + \dots$$

$$b(\varepsilon) = b^{(0)} + \varepsilon b^{(1)} + \dots$$

Approximation Methods in Physics

into equations (1) and (2) and equating terms of equal power, we get

$$\begin{aligned}\frac{du^{(0)}}{dt} &= f^{(0)}(t, u^{(0)}), \quad u^{(0)}(0) = b^{(0)}, \\ \frac{du^{(1)}}{dt} &= f_u^{(0)}(t, u^{(0)})u^{(1)} + f^{(1)}(t, u^{(0)}), \quad u^{(1)}(0) = b^{(1)}, \\ \frac{du^{(2)}}{dt} &= f_u^{(0)}(t, u^{(0)})u^{(2)} + \frac{1}{2}f_{uu}^{(0)}(t, u^{(0)})u^{(1)^2} \\ &\quad + f_u^{(1)}(t, u^{(0)})u^{(1)} + f^{(2)}(t, u^{(0)}), \\ &\quad u^{(2)}(0) = b^{(2)},\end{aligned}$$

the solutions of which determine the perturbation series for u . The equation for $u^{(0)}$ (the unperturbed equation) is nonlinear in general, but those for $u^{(1)}$, $u^{(2)}$, are inhomogeneous linear equations with identical principal parts.

The system of differential equations

$$\frac{du_i}{dt} = f_i(t, u_1, \dots, u_n; \varepsilon) \quad (i = 1, 2, \dots, n),$$

$$u_i = b_i(\varepsilon) \text{ at } t = 0,$$

or a differential equation of higher order,

$$\frac{d^n u}{dt^n} = f\left(t, u, \dots, \frac{d^{n-1} u}{dt^{n-1}}; \varepsilon\right),$$

$$u = b^{(0)}(\varepsilon), \dots, \frac{d^{n-1} u}{dt^{n-1}} = b^{(n-1)}(\varepsilon) \text{ at } t = 0,$$

can be treated in a similar way.

(b) Boundary-value problem. Given a linear differential operator $H = H_0 + \varepsilon V$ involving a small parameter ε linearly (H_0 is a linear differential operator and V is a function of (x_1, x_2, \dots, x_n)), consider the boundary-value problem

$$(H_0 + \varepsilon V)u = f(x_1, \dots, x_n) \quad (x_1, \dots, x_n) \in \Omega, \quad (3)$$

$$Bu = 0 \quad (x_1, \dots, x_n) \in \partial\Omega, \quad (4)$$

where B is a linear and homogeneous operator.

Substitution of the Taylor expansion

$$u = u_0 + \varepsilon u_1 + \dots$$

into equations (3) and (4) gives

$$H_0 u_0 = f, \quad Bu_0 = 0,$$

$$H_0 u_1 + V u_0 = 0, \quad Bu_1 = 0,$$

...

of which the solutions are

$$u_0 = Kf, \quad u_1 = -KVKf,$$

$$u_2 = KVKVKf, \dots$$

Here $K \equiv H_0^{-1}$ is an integral operator such that, for any function $v = v(x_1, x_2, \dots, x_n)$, we have

$$(Kv)(x_1, \dots, x_n) = \int_S \int_S G(x_1, \dots, x_n | \xi_1, \dots, \xi_n) \times v(\xi_1, \dots, \xi_n) d\xi_1 \dots d\xi_n,$$

where $G(x_1, \dots, x_n | \xi_1, \dots, \xi_n)$ is the Green's function for the unperturbed problem. The perturbation series

$$u = Kf - \varepsilon KVKf + \varepsilon^2 KVKVKf - \dots$$

converges if VK is bounded and $|\varepsilon| < 1/\|VK\|$.

(c) Eigenvalue problem. The solution of an eigenvalue problem

$$(H_0 + \varepsilon V)u = \lambda u \quad (5)$$

with the boundary condition $Bu = 0$ for the operators considered in (b) can be obtained in power series in ε :

$$\lambda = \lambda_0 + \varepsilon \lambda^{(1)} + \varepsilon^2 \lambda^{(2)} + \dots,$$

$$u = u_0 + \varepsilon u^{(1)} + \varepsilon^2 u^{(2)} + \dots,$$

where u_0 and λ_0 are the eigenfunction and nondegenerate eigenvalue, respectively, of the unperturbed operator H_0 , which is assumed to be self-adjoint. Substitution of the series into (5) gives

$$(H_0 - \lambda_0)u^{(1)} = -Vu_0 + \lambda^{(1)}u_0, \quad (6)$$

$$(H_0 - \lambda_0)u^{(2)} = -Vu^{(1)} + \lambda^{(2)}u_0 + \lambda^{(1)}u^{(1)}$$

$$(H_0 - \lambda_0)u^{(3)} = -Vu^{(2)} + \lambda^{(3)}u_0 + \lambda^{(2)}u^{(1)} + \lambda^{(1)}u^{(2)},$$

If we normalize u_0 and u by the conditions $(u_0, u_0) = 1$ and $(u, u_0) = 1$, we get from equation (6)

$$\lambda^{(1)} = (Vu_0, u_0) \equiv \alpha.$$

Let S be the inverse of $H_0 - \lambda_0 I$ in the subspace perpendicular to u_0 (we put $Su_0 = 0$), then each term of the perturbation series for u and λ is obtained in the following way from the system of the equations given above:

$$u^{(1)} = -SVu_0,$$

$$\lambda^{(2)} = -(VSvu_0, u_0),$$

$$u^{(2)} = S(V - \alpha)SVu_0,$$

$$\lambda^{(3)} = (VS(V - \alpha)SVu_0, u_0),$$

$$\begin{aligned}u^{(3)} &= -S(V - \alpha)S(V - \alpha)SVu_0 \\ &\quad + (VSvu_0, u_0)S^2Vu_0,\end{aligned}$$

(2) **Singular Perturbation.** Formal application of the procedure described in (1) often fails when the term including the highest-order derivative is multiplied by a small parameter (or a lower-order term is multiplied by a large parameter), i.e., when we deal with singular

perturbation problems. Typical methods for treating such cases are described below.

(a) **WKB method.** The method for getting an asymptotic solution of the second-order differential equation

$$\frac{d^2 u}{dx^2} + k^2 P(x)u = 0 \quad (7)$$

for large values of k was developed for problems arising in classical wave motion (Jeffreys, 1924 [1]) and for problems of quantum mechanics (Wentzel, Kramers, Brillouin, 1926), and is called the **Jeffreys method**, **WKB method**, or **WKB method**.

If the function P in (7) does not vary rapidly, the solution is expected to have the form

$$u \propto \exp\{ik\varphi(x)\},$$

with $\varphi(x)$ not very different from a linear function of x , since the exact solution for $P = P_0 = \text{const}$ is $\exp(\pm ik\sqrt{P_0}x)$.

Substitution of this expression for u in equation (7) gives

$$ik\varphi'' - k^2\varphi'^2 + k^2P = 0.$$

Neglecting the first term, we get

$$\varphi'^2 = P, \quad \text{i.e.,} \quad \varphi(x) = \int^x P^{1/2} dx.$$

This result suggests a transformation of the form

$$w = P^{1/4}u, \quad z = \int^x P^{1/2} dx,$$

which gives

$$\frac{d^2 w}{dz^2} + (k^2 - Q)w = 0, \quad (8)$$

where

$$Q = P^{-1/4} \frac{d^2}{dz^2} (P^{1/4}) = -P^{-3/4} \frac{d^2}{dx^2} (P^{-1/4}).$$

Equation (8) can be transformed further into a Volterra's integral equation of the second kind:

$$w(z; k) = Ae^{ikz} + Be^{-ikz} + \frac{1}{k} \int_{z_0}^z \sin\{k(z-\zeta)\} Q(\zeta) w(\zeta; k) d\zeta.$$

Therefore, if we expand w as

$$w(z; k) = w_0(z) + \frac{1}{k} w_1(z) + \dots, \quad (9)$$

we have

$$w_0(z) = Ae^{ikz} + Be^{-ikz},$$

$$w_n(z) = \int_{z_0}^z \sin\{k(z-\zeta)\} Q(\zeta) w_{n-1}(\zeta) d\zeta \quad (n=1, 2, \dots).$$

If P is positive for the interval $z_0 \leq z \leq z_1$ in question and has continuous derivatives up to second order, the foregoing series converges to the solution of (8).

On the other hand, when kz takes complex values, the series (9) does not converge in general. The series expansion appropriate for this case is

$$w(z; k) = \exp\{\psi(z; k)\}, \quad \psi = \pm ikz + \sum_{n=1}^{\infty} \frac{1}{(ik)^n} \psi_n(z),$$

and we get the asymptotic expansion for w :

$$w \sim \exp \left\{ \pm ikz \mp \frac{i}{2k} \int Q d\zeta + \frac{1}{4k^2} Q(z) \pm \frac{i}{8k^3} \left[Q'(z) - \int^z Q^2 d\zeta \right] + \frac{1}{16k^4} \{ Q''(z) - 2Q(z)^2 \} + \dots \right\}$$

Now, in many cases, P takes both positive and negative values within the interval in question, e.g., in the problem of transonic flow of a gas, in the problem of determining the reflectivity and transmissivity of a wave propagating in a nonuniform medium, or in the quantum-mechanical problem of a material wave passing through a potential wall. The point at which P vanishes is called a **turning point**. In this case there arises the problem of analytic continuation of the solution obtained in one side into the other through the turning point. For the special case when $P \propto x^n$ (the turning point is chosen as $x = 0$), it can be shown that the exact solution of equation (7) is explicitly given by

$$w \propto \sqrt{z} Z_v(kz),$$

where $v = 1/(n+2)$, and Z_v is a cylindrical function of order v . Based on this fact, the continuation formula for the case when P is approximated by x^n near $x = 0$ has been obtained.

(b) **Lighthill's method.** With nonlinear equations, formal application of a perturbation procedure sometimes leads to the difficulty that the solution of the unperturbed equation has a singularity not exhibited by the exact solution of the original equation and whose order increases in higher approximations, so that the perturbation series ceases to have any meaning near this point. Such a difficulty can often be overcome by so-called coordinate straining. This method has been applied to a number of fluid-dynamical problems, such as those arising in theories of aircraft wings, boundary layers, and shock waves.

Before describing the method, it is convenient to sketch **Poincaré's method** of getting the perturbation series for the period of a nonlinear oscillation. In order to solve the

nonlinear equation

$$\frac{du}{dt} = f(u; T_0, \varepsilon),$$

where T_0 is the period of oscillation when the small parameter ε is taken to be zero, Poincaré wrote series expansions for both u and the period T :

$$u = u_0(t) + \varepsilon u_1(t) + \dots, \quad T = T_0 + \varepsilon T_1 + \dots,$$

and determined T_1, T_2, \dots in such a manner as to avoid resonance at each step in the determination of $u_i(t)$, $u_i(t), \dots$

Based on this idea, Lighthill(1949) [2] developed coordinate straining in order to overcome the difficulty stated above. We illustrate the method here by means of the following simple example.

Consider a boundary-value problem of a nonlinear differential equation

$$(x + \varepsilon u) \frac{du}{dx} + u = 0 \quad (0 < x < 1): \quad (10)$$

$$u(1) = 1. \quad (11)$$

Application of the usual perturbation method would give the series solution

$$u = \frac{1}{x} + \frac{\varepsilon}{2} \left(\frac{1}{x} - \frac{1}{x^3} \right) - \frac{\varepsilon^2}{2} \left(\frac{1}{x^3} - \frac{1}{x^5} \right) + \dots$$

As is seen, however, the order of an apparent singularity occurring at $x = 0$ increases as we proceed to higher approximations so that it is not possible to see the true behavior of the solution near $x = 0$.

In Lighthill's method, we assume that series expansion is valid not only for u but also for the independent variable x , i.e.,

$$u = u_0(\xi) + \varepsilon u_1(\xi) + \dots, \quad x = \xi + \varepsilon x_1(\xi) + \dots$$

Substitution of these series into equations (10) and (11) gives

$$\xi u'_0 + u_0 = 0, \quad u_0(1) = 1,$$

$$\xi u'_1 + u_1 = -(u_0 x'_1 + u'_0 x_1 + u_0 u'_0),$$

$$u_1(1) = 0, \quad x_1(1) = 0,$$

From the first equation we have $u_0 = 1/\xi$. Before solving the second equation for u_1 , we determine $x_1(\xi)$ so as to avoid the increase of the order of singularity in $u_0(\xi)$ at $\xi = 0$. This requirement is satisfied by taking $x_1 = (1/2)(\xi - 1/\xi)$, and this gives $u_1 \equiv 0$; thus, at this stage of approximation, we have

$$u = u_0(\xi) + \varepsilon u_1(\xi) = \frac{1}{\xi},$$

$$x = \xi + \varepsilon x_1(\xi) = \xi + \frac{\varepsilon}{2} \left(\xi - \frac{1}{\xi} \right)$$

The guiding principle is the same for higher approximations. (The foregoing expression happens to be the exact solution, but this a fortuitous result of our choice of this particular example.)

The convergence of the series obtained by Lighthill's method has been proved by Wasow (1955) [3] for the more general problem

$$(x + \varepsilon u) \frac{du}{dx} + q(x)u = r(x),$$

$$u(a) = b,$$

where ε , a , and b are positive constants and $q(x)$ and $r(x)$ are functions regular in $|x| \leq a$.

Lighthill's method can also be applied to partial differential equations. Sometimes it is called the **PLK method (Poincaré-Lighthill-Kuo method)**, after its successful application to the problem of the boundary layer of a thin flat plate by Kuo.

(c) **Method of matched asymptotic expansions.** In some cases it is possible to get a uniformly valid series solution if we divide the domain into two or more subdomains, solve the equation by use of a suitable independent variable for each subdomain, and then determine the coefficients in each solution by the process of matching neighboring solutions on their common boundary. Such a perturbation technique was developed in treating the boundary-layer equation in fluid dynamics and has been systematized into the **method of matched asymptotic expansions**.

The idea of the method can be shown by the following simple example. Consider the boundary-value problem

$$\varepsilon \frac{d^2 u}{dx^2} + \frac{du}{dx} = a \quad (0 < x < 1),$$

$$u(0) = 0, \quad u(1) = 1, \quad (12)$$

where ε is a small positive parameter and a is a constant such that $0 < a < 1$. In order to solve this problem, we first take x itself to be an independent variable (the **outer variable**) in the domain $x \gg \varepsilon$ and expand the solution as

$$u = U_0(x) + \varepsilon U_1(x) +$$

Because the highest derivative is multiplied by a small parameter ε in equation (12), the perturbation equations to be solved are all of first order, of which the first one is

$$\frac{dU_0}{dx} = a, \quad U_0(1) = 1.$$

Solving this, we get an approximation for the **outer solution**:

$$U_0(x) = 1 - a(1 - x).$$

On the other hand, we introduce a new independent variable ξ (the **inner variable**) by

putting $x = \varepsilon \xi$ for $x \lesssim \varepsilon$. This transforms equation (12) into

$$\frac{d^2 v}{d\xi^2} + \frac{dv}{d\xi} = \varepsilon a, \quad v(\xi) \equiv u(x).$$

If we assume the expansion

$$v = V_0(\xi) + \varepsilon V_1(\xi) + \dots,$$

we have the equation for V_0 :

$$\frac{d^2 V_0}{d\xi^2} + \frac{dV_0}{d\xi} = 0, \quad V_0(0) = 0.$$

This gives an approximation for the **inner solution**:

$$V_0(\xi) = c(1 - e^{-\xi}).$$

Finally, in order to match the inner and the outer solutions, we equate their values at some point within the interval $\varepsilon \ll x \ll 1$ ($\xi \rightarrow \infty$ for the inner solution, $x \rightarrow 0$ for the outer solution):

$$V_0(\infty) = U_0(0) = 1 - a,$$

from which the coefficient in V_0 is determined to be $c = 1 - a$. Therefore we have an approximate solution valid in the whole interval $0 \leq x \leq 1$:

$$\begin{aligned} u &\cong U_0(x) + V_0(\xi) - (1 - a) \\ &= ax + (1 - a)(1 - e^{-x/\varepsilon}). \end{aligned}$$

C. Method of Steepest Descent

If an analytic function $f(z)$ of a complex variable z is expressed in terms of an analytic function $g(t)$ by an integral

$$f(z) = \int_C \exp\{zg(t)\} dt, \quad (13)$$

where C is a curve on the complex t -plane, then an asymptotic expression for $f(z)$ for large values of $|z|$ can be derived by the **method of steepest descent** (the **saddle-point method**). The idea of the method may be traced back to Riemann, and various asymptotic expressions for cylindrical functions were obtained by Debye (1909) [5].

The point at which the first derivative of $g(t)$ in the integral (13) vanishes is called a **saddle point**. The function $g(t)$ is expanded in a power series near this point as

$$g(t) = g(t_0) + \frac{1}{2}g''(t_0)(t - t_0)^2 + \dots$$

We have an inequality

$$zg''(t_0)(t - t_0)^2 \leq 0$$

along the line

$$L: \arg(t - t_0) = \frac{\pi}{2} - \frac{1}{2} \arg\{zg''(t_0)\}. \quad (14)$$

25 Ref.

Approximation Methods in Physics

Therefore the absolute value of the integrand $\exp\{zg(t)\}$ reaches a maximum at t_0 on the line L and decreases along it more rapidly than along any other direction. Hence if we deform the integration path in such a way that it passes through the saddle point t_0 in the direction of steepest descent, the value of the integrand is practically zero on the new path except very near to t_0 when $|z|$ is large, whereas the value of the integral remains the same. Therefore we can get an asymptotic expression of $f(z)$ for large $|z|$ by truncating the Taylor series for $g(t)$ up to the second term and taking the line L as the integration path:

$$\begin{aligned} f(z) &\approx \exp\{zg(t_0)\} \int_L \exp\left\{\frac{1}{2}zg''(t_0)(t - t_0)^2\right\} dt \\ &= \sqrt{\frac{2\pi}{-zg''(t_0)}} \exp\{zg(t_0)\}. \end{aligned}$$

As an example, **Stirling's formula**

$$n! \approx \sqrt{2\pi n} n^n e^{-n}$$

for a large positive integer is derived if we start with the formula

$$\begin{aligned} n! &= \int_0^\infty e^{-t} t^n dt = \int_0^\infty e^{-ns} (ns)^n d(ns) \\ &= n^{n+1} \int_0^\infty \exp\{n(\log s - s)\} ds \end{aligned}$$

and make use of the method of steepest descent.

26 (Xx1.4) Arab Mathematics

The role of the Arabs in cultural history has been partly that of cultural transmitter. Between the 7th and 13th centuries, they established a religious empire that extended from India to Spain; later it was divided into the eastern and western empires. The caliphs of these empires encouraged research in the sciences, so the capitals Baghdad and Cordova became centers of culture where scholars from different countries gathered.

Arabic scholarship is sometimes called the stepfather of European culture. During the 13th Century, Alphonso X (1252–1284) invited Islamic and Hebrew scholars to the Spanish court to translate their writings on algebra, medicine, and astronomy into Spanish. This accomplishment earned him the title of Alphonso the Wise.

The first contact between Greek and Indian mathematics took place in Baghdad under Caliph Al-Mansūr (754–775); Euclid's *Elements* was introduced by way of the Byzantine Empire, while Brahmagupta's *Brahmasphutasiddhānta* came directly from India. Many mathematical texts found in the Eastern Roman Empire and Syria, including some Greek works, were translated into Arabic. Though it is difficult to discern essential scientific advances in Arabian works, the diffusion of these translations was instrumental in the development of European mathematics.

The Arabs did not use written numerals until Mohammed's time (570–632). Signs representing numbers had been introduced into Arabia when its influence encompassed Egypt and Greece. Indian numerals were imported with Brahmagupta's book and became our present **Arabic numerals** after a series of modifications.

Among all the branches of Arab mathematics, algebra was the most advanced. It started with Alkwarizmi's (820) *Al Gebr W'al Muqabala*, the origin of the word "algebra." It was the first mathematical book written in Arabic. Its content was essentially a variety of methods of solving algebraic equations. *Al gebr* means "transposition of negative terms on one side of the equation to the other side and changing their signs," and *al muqabala* means "simplification of the equation by

gathering similar terms." For example, quadratic equations can be brought by these methods into one of the following three types: $x^2 = px + q$; $x^2 + q = px$; $x^2 + px = q$, where p, q are positive numbers. The Arabs expressed the rule of solving these equations verbally. They apparently knew that quadratic equations have two roots, but they adopted only positive roots; when the equation had two positive roots they adopted the smaller root. The proof was given geometrically. It is possible that they learned geometric proofs from the Greeks.

For the Arabs, geometry was secondary to algebra. They did not appreciate proof as seen in Euclid's *Elements*. The book on conic sections by Apollonius was also translated into Arabic, but no essential progress was made in this area. The only remarkable contribution was that of Omar Khayyám, author of *The Rubáiyát*, who applied conic sections to the solution of the cubic equation $x^3 + bx = a$.

In trigonometry, Al Battani (c. 858–929) left a notable contribution. He studied *The Almagest*, the Arabic translation of Ptolemy's astronomical work. He added nothing outstanding to plane trigonometry, but obtained such formulas as $\cos a = \cos b \cos c + \sin b \sin c \cos \alpha$ for spherical triangles, which were not mentioned in *The Almagest*.

27 (V.18) Arithmetic of Associative Algebras

A. General Theory

Let \mathfrak{g} be a \dagger Dedekind domain (i.e., an integral domain in which every ideal is uniquely decomposed into a product of prime ideals), let F be the field of quotients of \mathfrak{g} , and let A be a \dagger separable algebra of finite degree over F . A \mathfrak{g} -lattice \mathfrak{a} of A is a \mathfrak{g} -submodule of A that is finitely generated over \mathfrak{g} and satisfies $A = F\mathfrak{a}$. If a subring \mathfrak{o} of A is a \mathfrak{g} -lattice containing \mathfrak{g} , then \mathfrak{o} is called an **order**. A **maximal order** is an order that is not contained in any other order. A maximal order always exists although

it may not be unique; in particular, if A is commutative, it has only one maximal order. If we put $\mathfrak{o}_l = \{x \in A \mid xa \subset \mathfrak{a}\}$ ($\mathfrak{o}_r = \{x \in A \mid ax \subset \mathfrak{a}\}$) for a g -lattice \mathfrak{a} of A , then \mathfrak{o}_l (\mathfrak{o}_r) is an order of A and is called the **left (right) order** of \mathfrak{a} . If the left order of \mathfrak{a} is maximal, then so is the right order; the converse is also true. If \mathfrak{o}_l and \mathfrak{o}_r are maximal, we call \mathfrak{a} a **normal g -lattice**. To describe the same situation we say that \mathfrak{a} is a **left \mathfrak{o}_l -ideal** or a **right \mathfrak{o}_r -ideal**. If $\mathfrak{o}_l = \mathfrak{o}_r = \mathfrak{o}$, then we say that \mathfrak{a} is a **two-sided \mathfrak{o} -ideal**. A lattice \mathfrak{a} with $\mathfrak{a} \subset \mathfrak{o}_l$ (or equivalently with $\mathfrak{a} \subset \mathfrak{o}_r$) is called an **integral g -lattice** or **integral left (right) ideal**. The product ab of two normal g -lattices $\mathfrak{a}, \mathfrak{b}$ is called a **proper product** if the right order of \mathfrak{a} coincides with the left order of \mathfrak{b} . The proper product defines the structure of a g -groupoid on the set of all normal g -lattices of A . In particular, the inverse $^{-1}$ of a normal g -lattice \mathfrak{a} satisfying $\mathfrak{a}\mathfrak{a}^{-1} = \mathfrak{o}_l$, $\mathfrak{a}^{-1}\mathfrak{a} = \mathfrak{o}_r$ is given by $\mathfrak{a}^{-1} = \{x \in A \mid xa \subset \mathfrak{o}_r\} = \{x \in A \mid ax \subset \mathfrak{o}_l\}$. For a fixed maximal order \mathfrak{o} , a maximal **integral two-sided \mathfrak{o} -ideal** \mathfrak{p} different from \mathfrak{o} is called a **prime ideal** of \mathfrak{o} . If \mathfrak{p} is prime, then $\mathfrak{o}/\mathfrak{p}$ is the matrix algebra of degree κ over a division algebra, and κ is called the **capacity** of the prime ideal \mathfrak{p} . The set of all two-sided \mathfrak{o} -ideals forms a multiplicative group, of which prime ideals are independent generators.

B. Maximal Orders of a Simple Ring

In the rest of this article, A is a \dagger simple ring, F is the \dagger center of A , and \mathfrak{o} is a maximal order of A . The prime ideals \mathfrak{q} of \mathfrak{o} and the prime ideals \mathfrak{p} of g are in one-to-one correspondence by the relation $\mathfrak{q} \cap g = \mathfrak{p}$; $\mathfrak{o}/\mathfrak{q}$ is a simple algebra over g/\mathfrak{p} , and $\mathfrak{q}^e = \mathfrak{p}\mathfrak{o}$ for some natural number e . The **different** \mathfrak{d} of \mathfrak{o} is defined by $\mathfrak{d}^{-1} = \{x \in A \mid \text{Tr}(x\mathfrak{o}) \subset g\}$. (Tr is the reduced trace from A to F ; \mathfrak{d} is an integral two-sided \mathfrak{o} -ideal, and is divisible by \mathfrak{q}^{e-1} if $\mathfrak{q}^e = \mathfrak{p}\mathfrak{o}$.) For \mathfrak{q} to divide \mathfrak{d} , it is necessary and sufficient that either $e > 1$ or $\mathfrak{o}/\mathfrak{q}$ not be separable over g/\mathfrak{p} . In particular, if A is a \dagger total matrix algebra over F , then $\mathfrak{d} = \mathfrak{o}$, $\mathfrak{q} = \mathfrak{p}\mathfrak{o}$. The ideal of g generated by the \dagger reduced norms (to F) of the elements in a normal g -lattice \mathfrak{a} of A is denoted by $N_{A/F}(\mathfrak{a})$. If ab is a proper product, then we have $N_{A/F}(ab) = N_{A/F}(\mathfrak{a})N_{A/F}(\mathfrak{b})$, where $N_{A/F}(\mathfrak{d})$ does not depend on the choice of \mathfrak{o} ; this is called the **discriminant** of A . If $[A : F] = n^2$ and $\mathfrak{q}^e = \mathfrak{p}\mathfrak{o}$, then $N_{A/F}(\mathfrak{q}) = \mathfrak{p}^f$, $ef = n$.

C. Simple Rings over a Local Field

Let F be a field that is complete with respect to a \dagger discrete valuation whose field of residue classes is finite. Let g be the \dagger valuation ring of

F , \mathfrak{p} be the maximal ideal of g , and A be a simple algebra with F as its center. If A is a \dagger division algebra and $[A : F] = n^2$, then A has only one maximal order \mathfrak{o} , and \mathfrak{o} has only one prime ideal \mathfrak{q} such that $\mathfrak{q}^n = \mathfrak{p}\mathfrak{o}$; $\mathfrak{o}/\mathfrak{q}$ is an extension of degree n of g/\mathfrak{p} . If A is not necessarily a division algebra, the relation $\xi\mathfrak{o}\xi^{-1} = \mathfrak{o}'$ with an element ξ of A holds between two maximal orders \mathfrak{o} and \mathfrak{o}' of A . Furthermore, for any left (right) \mathfrak{o} -ideal \mathfrak{a} , there exists an element α such that $\mathfrak{a} = \mathfrak{o}\alpha$ ($\mathfrak{a} = \alpha\mathfrak{o}$). By using the notation of \dagger cyclic algebra, we can express A in the form (K_n, σ, π) . Here K_n is the unramified extension of degree n over F , σ is the \dagger Frobenius substitution of K_n/F , π is a prime element of F , and $0 \leq \gamma < n$. The element of \mathbf{Q}/\mathbf{Z} determined by $\gamma/n \pmod{\mathbf{Z}}$ is denoted by $\langle A \rangle$ and is called the \dagger Hasse invariant of the algebra class containing A . The mapping $A \mapsto \langle A \rangle$ gives an isomorphism of the \dagger Brauer group of F onto the additive group \mathbf{Q}/\mathbf{Z} . If M is an extension of F of finite degree, then $\langle A^M \rangle = [M : F] \langle A \rangle$ holds for the algebra A^M obtained from A by scalar extension (- 29 Associative Algebras).

D. Simple Rings over an Algebraic Number Field

Let F be an algebraic number field of finite degree, and let A be a simple algebra with center F . Then A is a cyclic algebra and is isomorphic to a total matrix algebra over a division algebra D . The order n of the algebra class of A over F is determined by $n^2 = [D : F]$ (H. Hasse, R. Brauer, and E. Noether).

Denote by $F_{\mathfrak{p}}$ the completion of F with respect to a \dagger prime divisor \mathfrak{p} of F , and let $A_{\mathfrak{p}}$ be the algebra obtained from A by the scalar extension $F_{\mathfrak{p}}$ over F . For a finite prime divisor \mathfrak{p} , the meaning of $\{A_{\mathfrak{p}}\}$ is as before; for an infinite prime divisor \mathfrak{p} , put $\{A_{\mathfrak{p}}\} = 0$ or $1/2 \pmod{\mathbf{Z}}$ according as $A_{\mathfrak{p}}$ is a total matrix algebra over $F_{\mathfrak{p}}$ or not. Furthermore, define the subgroup $J_{\mathfrak{p}}$ of \mathbf{Q}/\mathbf{Z} by

$$\begin{aligned} J_{\mathfrak{p}} &= \mathbf{Q}/\mathbf{Z}, & \mathfrak{p} \text{ a finite prime divisor,} \\ &= \{0, 1/2 \pmod{\mathbf{Z}}\} & \mathfrak{p} \text{ a real infinite prime divisor,} \\ &= \{0\}, & \mathfrak{p} \text{ a complex infinite prime divisor.} \end{aligned}$$

Now let J be the subgroup of the direct product $\prod_{\mathfrak{p}} J_{\mathfrak{p}}$ consisting of all elements of the form $(\alpha_{\mathfrak{p}})$ ($\alpha_{\mathfrak{p}} \in J_{\mathfrak{p}}$) such that $\alpha_{\mathfrak{p}} = 0$ except for a finite number of prime divisors and $\sum_{\mathfrak{p}} \alpha_{\mathfrak{p}} = 0$. Then $A + (\{A_{\mathfrak{p}}\})$ gives rise to an isomorphism of the Brauer group over F onto J (Hasse). Each $\langle A_{\mathfrak{p}} \rangle$ is called the \dagger \mathfrak{p} -invariant of A . In particular, A is a total matrix algebra over F if

and only if A , is a total matrix algebra over F_p for all p (- 29 Associative Algebras). These theorems are closely related to †class field theory.

If \mathfrak{o} is a maximal order of A and a, b are left \mathfrak{o} -ideals, then $a\xi = b$ with an element ξ of A defines an equivalence relation between a and b . The number of equivalence classes of left ideals with respect to this equivalence is called the **class number** of A ; it is independent of the choice of \mathfrak{o} and is equal to the class number defined by using right ideals. The product of all real infinite prime divisors p with $\{A_p\} = 1/2$ is denoted by P_∞ . If P_∞ is the product of all infinite prime divisors and $[A : F] = 4$, then A is called a **totally definite quaternion algebra**.

If \mathfrak{o} is a maximal order of A and A is not a totally definite quaternion algebra, then $\mathfrak{a} \rightarrow N_{\infty}(\mathfrak{a})$ gives a one-to-one correspondence between the classes of left \mathfrak{o} -ideals and the congruence classes of ideals of F modulo P_∞ (- 14 Algebraic Number Fields H) (Eichler's theorem).

In particular, if A is a total matrix algebra over F , then the class number of A is equal to the class number of F . The class number of a totally definite quaternion algebra was determined by M. Eichler by using the zeta function (- Section F) of A [4].

Let \mathfrak{o} be a maximal order of A , a be an integral two-sided \mathfrak{o} -ideal, b be an integer of F , and ξ be an element of \mathfrak{o} . Furthermore, assume $b \equiv 1 \pmod{P_\infty}$, $N_{A/F}(\xi) \equiv b \pmod{a \cap F}$ (†multiplicative congruence). Then there exists an element β of \mathfrak{o} such that $N_{A/F}(\beta) = b$, $\beta \equiv \xi \pmod{a}$ ($N_{A/F}$ is the reduced norm), provided that A is not a totally definite quaternion algebra [5]. This theorem, which is called **Eichler's approximation theorem**, is widely applicable; e.g., it yields the previous theorem on the class number and can be generalized to the case of semisimple †algebraic groups (- 13 Algebraic Groups).

E. Algebras over a Function Field

The Hasse-Brauer-Noether and Hasse theorems also hold for †normal simple algebras over a †field of algebraic functions of one variable over a finite field. On the other hand, a normal simple algebra over a field K of algebraic functions of one variable over an algebraically closed field is a total matrix algebra over K (Tsen's theorem).

F. Other Notions

Adeles and ideles for a simple algebra A over an algebraic number field of finite degree can

be introduced as in the case of number fields (\rightarrow 6 Adeles and Ideles). If $N(\mathfrak{a})$ stands for the number of elements in $\mathfrak{o}/\mathfrak{a}$, where \mathfrak{o} is a maximal order of A and \mathfrak{a} is an integral left \mathfrak{o} -ideal, then the **zeta function of the simple algebra A** , called the **Hey zeta function**, is defined by $\zeta_A(s) = \sum N(\mathfrak{a})^{-s}$ (the sum over all integral left \mathfrak{o} -ideals). This function has properties similar to those of Dedekind zeta functions (- 450 Zeta Functions L). Let p be an infinite prime divisor of the center F of A , and let G_p be the group of elements in A , with the reduced norm 1. Put $G = \prod_p G_p$ (the product over all infinite prime divisors of F). Then the group Γ of units with the reduced norm 1 in \mathfrak{o} is naturally regarded as a subgroup of G . To be more precise, Γ is a discrete subgroup of G , the volume of G/Γ is finite with respect to an invariant measure, and G/Γ is compact if and only if A is a division algebra (\rightarrow 122 Discontinuous Groups). This result can be viewed as a special case of more general facts about semisimple algebraic groups (- 13 Algebraic Groups). If K is a †maximal compact subgroup of G , then Γ gives rise to a †discontinuous group operating on the homogeneous space G/K , and we obtain †automorphic forms with respect to Γ . The case where A is a †quaternion algebra has been studied extensively (- 32 Automorphic Functions).

28 (XXI.1 3) Artin, Emil

Emil Artin (March 3, 1898–December 20, 1962) was born in Vienna. After he studied at the Universities of Vienna, Leipzig, and Göttingen, he taught at the University of Hamburg from 1923 to 1937. In 1937 he left Germany under the Nazi regime for America, where he taught at Notre Dame, Indiana, and Princeton universities. He returned to Germany in 1948 and taught again at the University of Hamburg until his fatal heart attack.

In his thesis (1923), he proved affirmatively the \dagger Riemann hypothesis in function fields over finite constant fields in the hyperelliptic case, and conjectured that this should be valid in general. This was eventually verified by A. Weil in 1941. Also in 1923, he introduced the \dagger L-function for Galois extension and was led to the \dagger general law of reciprocity, which he stated as a conjecture and proved four years later, thus bringing \dagger class field theory to completion. Around the same period, he established in collaboration with O. Schreier the theory of \dagger formally real fields and solved the 17th \dagger problem of Hilbert. He also initiated the theory of \dagger braids, which he later developed with F. Bohnenblust in the 1940s. In view of these and other ingenious works as well as his inspiring teaching in all areas of mathematics, Artin is considered to have been one of the most influential mathematicians of this Century.

29 (III.1 0) Associative Algebras

A. Fundamental Concepts

Let K be a commutative ring with unity element 1 (- 368 Rings A), and let A be a ring which is a \dagger unitary K -module (- 277 Modules). Such a ring A is called an **associative algebra over K** (or simply **algebra over K**) if it satisfies the condition $\lambda(ab) = (\lambda a)b = a(\lambda b)$ ($\lambda \in K$; $a, b \in A$). An (associative) algebra A over

K is often written A/K , and K is called the **coefficient ring** (or **ground ring**) of the algebra $A = A/K$. In particular, if K is a \dagger field, then it is called the **coefficient field** (or **ground field**) of A . Algebras over fields have been studied in detail. Notions such as **zero algebra**, **unitary algebra**, **commutative algebra**, **(semi) simple algebra**, and **division algebra** are replicas of the respective ones for rings (- 368 Rings). Considering both structures as rings and as K -modules, homomorphisms and isomorphisms are defined in a natural manner, and are called **algebra homomorphism** and **algebra isomorphism**, respectively. In this connection, **subalgebra**, **quotient algebra** (or **residue class algebra**), and **direct product** of algebras are also defined as in the case of rings.

An \dagger **ideal** of an algebra A is defined as an ideal of the ring A , which is at the same time a submodule of the module A over the coefficient ring. The \dagger radical of an algebra A considered as a ring is then an ideal of A in this sense. In fact, the existence of a unity in an algebra A implies that any ideal of A considered as a ring is necessarily an ideal of the algebra A .

In the rest of this article, we assume that all rings have a unity element and that all homomorphisms are unitary. Hence, when we consider subalgebras of an algebra A , we require that they share the unity element with A . If e is the unity element of an algebra A over K , then the mapping $\lambda \rightarrow \lambda e = \lambda'$ ($\lambda \in K$) is a homomorphism $K \rightarrow A$ whose image Ke is contained in the \dagger center of A , and the scalar multiplication λa is equal to the ring multiplication $\lambda' a$ ($\lambda \in K$, $a \in A$). Conversely, given a homomorphism of K into a ring A whose image is contained in the center of A , we can regard A as an algebra over K in an obvious way. Hence we are given an algebra A over K if and only if there exists a pair (A, ρ) of a ring A and a homomorphism $\rho: K \rightarrow A$ whose image is contained in the center of A . There exists a uniquely determined (unitary) homomorphism of the ring \mathbb{Z} of rational integers into any ring; hence any ring can be regarded as an algebra over \mathbb{Z} . If the coefficient ring K of a nonzero algebra A is a field, then K can be regarded as a subfield contained in the center of A , and the unity element 1 of K coincides with the unity element of A .

Let A and B be algebras over K . Then the \dagger tensor product $A \otimes_K B$ of K -modules is an algebra over K under the multiplication $(a \otimes b)(a' \otimes b') = aa' \otimes bb'$ ($a, a' \in A$, $b, b' \in B$). This algebra is called the **tensor product** of algebras A and B . Moreover, the mapping $a \rightarrow a \otimes 1$ (resp. $b \rightarrow 1 \otimes b$) ($a \in A$, $b \in B$) gives an algebra homomorphism $A \rightarrow A \otimes_K B$ (resp. $B \rightarrow$

$A \otimes_K B$, which is called the **canonical homomorphism**. In particular, if A is a commutative algebra, then $A \otimes_K B$ can be regarded as an algebra over A by this canonical homomorphism; and in this case $A \otimes_K B$ is called the algebra obtained by **extension of the coefficient ring** of B to A (or a **scalar extension** of B by A), and is often denoted by B^A . The algebra $K \otimes_K B$ is canonically isomorphic to B . Furthermore, $(A \otimes_K B) \otimes_K C$ and $A \otimes_K (B \otimes_K C)$ are canonically isomorphic and are written $A \otimes_K B \otimes_K C$. Let A and B be commutative algebras over K . Then, for any commutative algebra C and homomorphisms $\alpha: A \rightarrow C$, $\beta: B \rightarrow C$, there exists one and only one homomorphism $\gamma: A \otimes_K B \rightarrow C$ such that $\alpha(a) = \gamma(a \otimes 1)$, $\beta(b) = \gamma(1 \otimes b)$ ($a \in A$, $b \in B$). This property characterizes the tensor product $A \otimes_K B$ of commutative algebras A and B . In this sense, $A \otimes_K B$ is sometimes called the **coproduct** of A and B (- 52 Categories and Functors E).

B. Examples of Associative Algebras

As we mentioned, any ring can be regarded as an algebra over the ring \mathbb{Z} of rational integers. But it is often useful to deal with algebras over "large" or more "efficient" coefficient rings. For instance, we have many rings which are algebras over a commutative ring K , such as the ring of polynomials, the ring of formal power series in n variables with coefficients in K , the endomorphism ring of a K -module, and the full matrix ring of degree n over K (- 368 Rings C). There are other important classes of algebras, such as (semi) group algebras, Hecke algebras, and crossed-product algebras, which will be explained later. These algebras are defined by a canonical basis connected directly with a (semi) group structure. On the other hand, the tensor algebra and the exterior algebra of linear spaces and the Clifford algebra associated with a given quadratic form are also important (- 61 Clifford Algebras, 256 Linear Spaces).

The most frequently used example of a division algebra is the **quaternion field \mathbf{H}** (often called **Hamilton's quaternion algebra**, W. R. Hamilton, 1858). This is a 4-dimensional linear space over the real number field \mathbf{R} with basis $\{1, i, j, k\}$, with the following laws of multiplication: 1 is a unity element, $i^2 = j^2 = k^2 = -1$, $ij = -ji = k$, $jk = -kj = i$, and $ki = -ik = j$. An element of \mathbf{H} is called a **quaternion**. The only finite-dimensional division algebras over the real number field \mathbf{R} are the real number field \mathbf{R} , the complex number field \mathbf{C} , and the quaternion field \mathbf{H} .

C. Group Algebras and Hecke Algebras

Let K be a commutative ring and $K^{(G)}$ be the direct sum $\sum_{s \in G} K_s$ of modules K_s , where each K_s is isomorphic to K with a group G as the index set (- 277 Modules F). The elements of $K^{(G)}$ are the families $(\lambda_s)_{s \in G}$ of elements of K whose components are all zero except for a finite number of them. Let $\{u_s\}_{s \in G}$ be the canonical basis of $K^{(G)}$, namely, u_s is an element of $K^{(G)}$ of which the s th component is 1 and the others are 0. The module $K^{(G)}$ has the structure of an algebra over K , where the law of multiplication is determined by $u_s u_t = u_{st}$ ($s, t \in G$). This algebra is called the **group algebra** of G over K . The product $\lambda * \mu$ of elements $\lambda = (\lambda_s)$ and $\mu = (\mu_s)$ of $K^{(G)}$ is then given by

$$(\lambda * \mu)_s = \sum_{s=rt} \lambda_r \mu_t, \quad s \in G. \quad (1)$$

Each basis element u_s is often identified with the group element s , and in this manner, the group G is regarded as a basis of $K^{(G)}$, which is usually written KG or $K[G]$.

In this definition, the group G can be replaced by a semigroup G , and then the algebra $K^{(G)}$ is called a **semigroup algebra**. As an example, let \mathbf{N} be the additive semigroup of all nonnegative rational integers and \mathbf{N}^n be the direct product of n copies of \mathbf{N} . If we denote the elements (i_1, \dots, i_n) of \mathbf{N}^n by $X_1^{i_1} \dots X_n^{i_n}$ and use multiplication instead of addition, then the semigroup algebra of \mathbf{N}^n over K is exactly the ring of polynomials $K[X_1, \dots, X_n]$. On the other hand, if G is a semigroup, then even when it is infinite, it may occur that for any $s \in G$, there exists only a finite number of pairs (r, l) of elements of G such that $s = rl$. In this case, formula (1) also defines the law of multiplication on the Cartesian product K^G . This algebra is called a **large semigroup algebra** and contains $K^{(G)}$ as a subalgebra. In particular, the large semigroup algebra of \mathbf{N}^n is exactly the ring of formal power series $K[[X_1, \dots, X_n]]$.

Let H be a subgroup of a group G , and assume that the index of $H \cap sHs^{-1}$ in H is finite for any $s \in G$. This assumption is equivalent to the condition that any double coset of G by H is a union of a finite number of left as well as right cosets. Let $H \backslash G$, G/H , and $H \backslash G/H$ be the set of all right cosets, left cosets, and double cosets, respectively. Then each element of the direct sum $K^{(H \backslash G)}$, $K^{(G/H)}$, or $K^{(H \backslash G/H)}$ can be regarded as a function defined on G taking a constant value on each right, left, or double coset, respectively. Conversely, any function defined on G can be regarded as an element of $K^{(H \backslash G)}$, $K^{(G/H)}$, or

$K^{(H \setminus G/H)}$ if it takes a constant value on each left, right, or double coset, respectively, and if it vanishes everywhere except on a finite number of cosets of respective type. Under such identification, let $\lambda_s, \lambda_l, \lambda_r,$ and λ_t denote the values of a function $\lambda: G \rightarrow K$ on $s \in G, l \in H \setminus G, r \in G/H,$ and $t \in H \setminus G/H,$ respectively. For any $\lambda, \mu \in K^{(H \setminus G/H)}$ we define a function $\lambda * \mu$ by

$$(\lambda * \mu)_s = \sum_{s \in rl} \lambda_r \mu_l, \quad s \in G, \quad (2)$$

where the right-hand side is the sum taken over all pairs (r, l) such that $s \in rl, r \in G/H, l \in H \setminus G$. It can be shown that this sum is a finite sum and that $\lambda * \mu \in K^{(H \setminus G/H)}$. Hence the module $K^{(H \setminus G/H)}$ has the structure of an algebra over K , which is called the **Hecke algebra** of (G, H) over K and often denoted by $\mathcal{H}_K(G, H)$. If $H = \{e\}$, the $\mathcal{H}_K(G, H)$ is exactly the group algebra of G . In general, $\mathcal{H}_K(G, H)$ can be regarded as an algebra obtained by extending the coefficient ring of $\mathcal{H}_Z(G, H)$ to K . Furthermore, $K^{(H \setminus G)} (K^{(G/H)})$ can be regarded as a right (left) module over the group algebra $K^{(G)}$, and the endomorphism ring $\mathcal{E}_{K^{(G)}}(K^{(H \setminus G)})$ (resp. $\mathcal{E}_{K^{(G)}}(K^{(G/H)})$) is canonically isomorphic (anti-isomorphic) to the Hecke algebra $K^{(H \setminus G/H)}$.

D. General Crossed Product

Let G be a group that operates on a commutative ring L , and denote the operation by $(s, \lambda) \rightarrow s(\lambda)$ ($s \in G, \lambda \in L$); thus for any $s \in G$ the mapping $\lambda \rightarrow s(\lambda)$ ($\lambda \in L$) is an automorphism of L satisfying $s(t(\lambda)) = st(\lambda)$ ($s, t \in G$). For any $\lambda, \mu \in L^{(G)}$, we define the product $\lambda * \mu \in L^{(G)}$ by

$$(\lambda * \mu)_s = \sum_{s \in rl} \lambda_r \mu_l f(r, l), \quad s \in G, \quad (3)$$

where $\{f(r, l)\}_{r, l \in G}$ is a given family of elements of L . If this family satisfies the equations

$$f(s, r)f(sr, l) = s(f(r, l))f(s, rl), \quad s, r, l \in G,$$

then $L^{(G)}$ forms a ring. In terms of the canonical basis $\{u_s\}_{s \in G}$, this ring structure is defined by the formulas $u_r u_l = f(r, l) u_{rl}, u_s \lambda = s(\lambda) u_s$ ($\lambda \in L$). If K is the subring of L consisting of all $\lambda \in L$ such that $s(\lambda) = \lambda$ ($s \in G$), then the ring $L^{(G)}$ is an algebra over K , called the **crossed product** of L and G with respect to the given operation and the given **factor set** f of G . In a narrower sense of the term, we consider only the case when L is a field, G is a finite group, $f(r, l) \neq 0$, and G operates on L faithfully. In this case, G can be identified with the t Galois group of a finite t Galois extension L/K , and so the crossed product is written $(L/K, f)$. This is a t central simple algebra over K (- Sections E, F).

If the operation of G in the above-mentioned general crossed product is trivial,

namely, $L = K$, the crossed product of K and G is called an **algebra extension** of G over K with respect to f . Usually, we assume that K is a field and $f(r, l) \neq 0$. If $f(r, l) = 1$, the algebra extension is the group algebra. If G is a finite group whose order is prime to the t characteristic of K , then any algebra extension of G over K (in particular, the group algebra) is always t semisimple and t separable. If G is a finite Abelian group and f is a factor set of G , then a bihomomorphism $\varphi: G \times G \rightarrow K^*$ (a mapping which is a homomorphism in each variable) is defined by $\varphi(s, t) = f(s, t) \cdot f(t, s)^{-1}$. An algebra extension of G over K with respect to f is a central simple algebra if and only if φ is nondegenerate. In particular, if G is a direct product of n copies of a group of order 2, then by choosing n elements s_1, s_2, \dots, s_n of G suitably, any element of G can be uniquely expressed as $s_a s_b \dots s_z$, where $\{a, b, \dots, z\}$ is a subset of $\{1, \dots, n\}$ in the natural order. Hence, if we take $u_{a, \dots, z} = u_a u_b \dots u_z$ as a basis of an algebra extension, then any factor set f is determined by $f(s_i, s_j) = \lambda_{ij}$, where $\lambda_{ij} = 1$ ($i < j$), $\lambda_{ij} = \pm 1$ ($i > j$), and λ_{ii} are arbitrary. When $\lambda_{ij} = -1$ ($i > j$), the corresponding algebra extension is a t Clifford algebra. Furthermore, if $\lambda_{ii} = 0$, then it is a t Grassmann algebra. If $\lambda_{ii} \neq 0$ and n is even, then it is a central simple algebra whenever the characteristic of K is not 2 (- 61 Clifford Algebras).

Now let K be the real number field \mathbf{R} and A , be the Clifford algebra with $\lambda_{ii} = 1$. Then A , is the quaternion field. Elements of A , are called **sedentions**, and are important in t spinor theory and t Dirac's equation. In general, let K be an arbitrary field whose characteristic is not 2 and put $n = 2, \lambda_{12} = 1, \lambda_{21} = -1, \lambda_{11} = \lambda \neq 0$, and $\lambda_{22} = \mu \neq 0$, in the previous notation. Then the corresponding central simple algebra Q is called a (**generalized**) **quaternion algebra**. Thus Q has a basis $\{1, u, v, w\}$ satisfying the following laws: 1 is the unity element, $w = uv = -vu, u^2 = \lambda$, and $v^2 = \mu$ ($\lambda, \mu \in K$). Any central simple algebra of dimension 4 is isomorphic to a certain quaternion algebra. (In particular, if $K = \mathbf{R}$ and $\lambda = \mu = -1$, then Q coincides with the quaternion field \mathbf{H} .) For any element $x = \alpha + \beta u + \gamma v + \delta w$ of Q , the element $\bar{x} = \alpha - \beta u - \gamma v - \delta w$ is said to be **conjugate** to x , and $N(x) = x\bar{x} \in K$ is called the **norm** of x . An element x of Q is invertible in Q if and only if $N(x) \neq 0$.

E. Finite-Dimensional Associative Algebras over a Field

For the rest of this article, we assume that the algebras considered are unitary and finite

dimensional over a field K . Then by general properties of left (right) \dagger Artinian rings, any associative algebra A has the following structure: the \dagger radical N of A is the greatest \dagger nilpotent ideal, and the quotient algebra $A/N = \bar{A}$ is \dagger semisimple and decomposed into a direct sum of ideals which are simple algebras:

$$\bar{A} = \bar{A}_1 + \dots + \bar{A}_n.$$

Each simple component \bar{A}_i is a full matrix ring of degree r_i over a certain division algebra D_i , and \bar{A}_i is decomposed into a direct sum of r_i minimal left ideals which are mutually A -isomorphic:

$$\bar{A}_i = \bar{A}_i \bar{e}_i^{(1)} + \dots + \bar{A}_i \bar{e}_i^{(r_i)}, \quad 1 \leq i \leq n,$$

where $\bar{e}_i^{(1)}, \dots, \bar{e}_i^{(r_i)}$ are orthogonal \dagger idempotent elements of \bar{A}_i whose sum is equal to the unity element of \bar{A}_i . On the other hand,

$$\bar{A}_i = \bar{e}_i^{(1)} \bar{A} + \dots + \bar{e}_i^{(r_i)} \bar{A}$$

gives a decomposition of A_i into the direct sum of minimal right ideals that are mutually A -isomorphic. Moreover, we can choose an idempotent element $e_i^{(s)}$ of A from each residue class $\bar{e}_i^{(s)}$ such that $\{e_i^{(s)}\}$ forms a system of orthogonal idempotent elements, whose sum is equal to the unity element 1 of A , and

$$A = \sum_{i=1}^n \sum_{s=1}^{r_i} A e_i^{(s)} = \sum_{i=1}^n \sum_{s=1}^{r_i} e_i^{(s)} A$$

gives a decomposition of A into a direct sum of \dagger direct indecomposable left (right) ideals. Here, $A e_i^{(s)}$ and $A e_j^{(t)}$ ($e_i^{(s)} A$ and $e_j^{(t)} A$) are A -isomorphic if and only if $i = j$. Conversely, every decomposition of A into indecomposable ideals is obtained as above. The A -submodule $N e_i^{(s)}$ of $A e_i^{(s)}$ is the unique maximal proper submodule, and $A e_i^{(s)}/N e_i^{(s)}$ and $A e_j^{(t)}/N e_j^{(t)}$ are A -isomorphic if and only if $i = j$. Any simple A -module is A -isomorphic to a certain $A e_i^{(s)}/N e_i^{(s)}$ (- Sections H, I).

Any simple algebra A over K is isomorphic to a full matrix ring $M_n(D)$ over a certain division algebra D . This is called **Wedderburn's theorem**. Here n is determined uniquely by A , and D is also determined uniquely by A up to isomorphism. Moreover, the center of A is isomorphic to the center of D . If the center of A coincides with K , then A is called a **central simple algebra** (or **normal simple algebra**) over K . In this case, any isomorphism of two simple subalgebras of A can be extended to an \dagger inner automorphism of A . Let $V(B)$ denote the \dagger commutator of a simple subalgebra B of A . Then $V(B)$ is also a simple subalgebra and $V(V(B)) = B$, $\dim A = \dim B \cdot \dim V(B)$. In particular, if B is central over K , then there is a canonical isomorphism $A \cong B \otimes_K V(B)$. If D is a central division algebra, then any maximal commutative subalgebra L of D is a field and satisfies

$(\dim L)^2 = \dim D$. Moreover, there are \dagger separable extensions over K among such L . In general, the dimension of a central simple algebra A is a square number r^2 , where r is called the **degree** of A .

Two central simple algebras are said to be **similar** if they are isomorphic to full matrix rings over the same division algebra. This is an equivalence relation, and each equivalence class is called an **algebra class**. On the other hand, if A is a central simple algebra and B is a simple algebra, then $A \otimes_K B$ is a simple algebra. Moreover, if B is central, then $A \otimes_K B$ is also a central simple algebra. If A and B are similar to A' and B' , respectively, then $A \otimes_K B$ is similar to $A' \otimes_K B'$. Hence, the tensor product \otimes defines multiplication in the set $\mathcal{B}(K)$ of the algebra classes over K . If A is a central simple algebra and A° is an algebra anti-isomorphic to A , then A° is also central simple and $A \otimes_K A^\circ$ is isomorphic to a full matrix ring over K . This shows that $\mathcal{B}(K)$ forms a group, which is called the **Brauer group**, after R. Brauer, who introduced this concept, or the **algebra class group** over K . For a central simple algebra A , the degree of a division algebra similar to it is called the **Schur index** of A (or of the algebra class of A), and the order of the algebra class of A in the Brauer group is called the **exponent** of A . The Schur index is divisible by the exponent; and conversely, the exponent is divisible by every prime divisor of the Schur index.

F. Extensions of Coefficient Fields

Let L be an \dagger extension field over a field K . Then for any algebra A over K , $L \otimes_K A$ can be regarded as an algebra over L . This algebra is denoted by A^L and is called an **algebra obtained by extending the coefficient field** to L . Let us denote the radical of a ring A by $\mathfrak{R}(A)$. An algebra A over K is called a **separable algebra** if it satisfies $\mathfrak{R}(A^L) = \{0\}$ for any extension field L over K . In the special case when A is an \dagger algebraic extension field over K , A is a separable algebra if and only if every element of A (or every element of a subset which generates A) is \dagger separable over K (- 149 Fields). A (finite-dimensional) algebra A over K is separable if and only if A is semisimple and the center of every simple component of A is a separable extension over K . If the quotient algebra $A/\mathfrak{R}(A)$ of an algebra A is separable, then there exists a subalgebra S such that $A = S + \mathfrak{R}(A)$ and $S \cap \mathfrak{R}(A) = \{0\}$, and S is uniquely determined up to inner automorphisms (**Wedderburn-Mal'tsev theorem**).

In order that an algebra A over K be central simple, it is necessary and sufficient that A^L be

simple for any extension field L over K . This latter statement holds if and only if A^L is isomorphic to a full matrix algebra over L for a certain extension field L over K . Such an extension field is a splitting field of A (- 362 Representations F). For a central simple algebra A , a (finite) extension field L of degree r over K is a splitting field of A if and only if there exists a central simple algebra B of degree r which is similar to A having a subfield which is K -isomorphic to L . In this case, r is divisible by the Schur index of A . Furthermore, A has a separable splitting field whose extension degree is equal to the Schur index of A . This shows that A has a splitting field which is a finite Galois extension field over K .

Let L be a finite \dagger Galois extension over a field K and G be its \dagger Galois group. If f is a factor set with respect to the operation of G on L^* , then the crossed product $(L/K, f)$ is a central simple algebra over K (- Section D). The product fg of two factor sets f and g is also a factor set, and the set of all factor sets forms an \dagger Abelian group. Thus $(L/K, fg)$ is similar to $(L/K, f) \otimes_K (L/K, g)$. On the other hand, factor sets f and g are said to be **associated** with each other if there exists a family $\{\lambda_s\}_{s \in G}$ of elements of L such that

$$f(r, l) = g(r, l)r(\lambda_l)\lambda_{r^{-1}}^{-1}\lambda_r, \quad r, l \in G.$$

Hence, f and g are associated with each other if and only if $(L/K, f)$ and $(L/K, g)$ are similar. Therefore, the mapping $f \rightarrow (L/K, f)$ gives a monomorphism of the group $H^2(G, L^*)$ of all associated classes of factor sets (which can be identified with the 2-dimensional \dagger cohomology group of G with coefficients in L^*) into the Brauer group $\mathcal{B}(K)$ over K . Its image coincides with the subgroup of all algebra classes which have L as a splitting field. In particular, any algebra class is similar to the crossed product of a certain finite Galois extension L and its Galois group G (R. Brauer, E. Noether, A. Albert, K. Shoda, and others).

G. Cyclic Algebras

Let Z be a \dagger cyclic extension field of degree n over a field K . Then the crossed product of Z and its Galois group G is called a **cyclic algebra** over K . For a fixed generator s of G and any element $\alpha \neq 0$ of K , a factor set $f(s^i, s^j)$ ($0 \leq i, j < n$) can be defined by $f(s^i, s^j) = 1$ ($i+j < n$) and $f(s^i, s^j) = \alpha$ ($i+j \geq n$). Let (Z, s, α) denote the corresponding crossed product. Then (Z, s, α) and (Z, s, β) are similar if and only if α/β is a norm of a certain element of Z into K . On the other hand, any crossed product of Z and G is similar to a certain (Z, s, α) , and the correspondence $\alpha \rightarrow (Z, s, \alpha)$

gives an isomorphism of $K^*/N_{Z/K}(Z^*)$ (the norm class group of Z/K) to the group consisting of the algebra classes over K which have Z as a splitting field. If K is a $\dagger p$ -adic field or a finite \dagger algebraic number field, then any central simple algebra over K is isomorphic to a certain cyclic algebra. In this section, we describe this situation in detail.

Let K be a p -adic field and q the number of residue classes modulo p . If A is a central simple algebra over K , then its Schur index coincides with the exponent, which is called simply the **index**. A finite extension field L over K is a splitting field for A if and only if the degree of L is a multiple of the index of A . If n is the degree of A , then the field $W = K(w)$ obtained by adjoining to K a \dagger primitive (q -1)st root of unity ω is a cyclic (and \dagger unramified) extension of degree n over K , and its Galois group is generated by the automorphism σ of W determined by $\omega^\sigma = \omega^q$, $\sigma|_K = \text{identity}$. Moreover, we have $A \cong (W, \sigma, \alpha)$ for a certain $\alpha \in K^*$. Let v be the \dagger exponential p -adic valuation $v(\alpha)$ of α . Then $v/n \pmod{\mathbf{Z}}$ is uniquely determined by the algebra class of A , which is called the **Hasse invariant** of A (or of the algebra class of A). By assigning to each of the algebra classes its Hasse invariant, we get an isomorphism of the Brauer group $B(K)$ over K to the group \mathbf{Q}/\mathbf{Z} , the additive group of the rational numbers mod \mathbf{Z} (H. Hasse, 1931).

Let K be a finite algebraic number field and A be a central simple algebra over K . Let \mathfrak{p} be a (finite or infinite) \dagger prime divisor of K and $K_{\mathfrak{p}}$ the $\dagger p$ -adic extension field over K . The algebra A , which is obtained from A by extending the coefficient field to $K_{\mathfrak{p}}$ is a central simple algebra over K . Except for a finite number of \mathfrak{p} , A is isomorphic to a full matrix ring over $K_{\mathfrak{p}}$, and A itself is isomorphic to a full matrix ring over K if and only if A is isomorphic to a full matrix ring over $K_{\mathfrak{p}}$ for all \mathfrak{p} . The index $m_{\mathfrak{p}}$ of A is called the \mathfrak{p} -index of A , and the Hasse invariant of A is called the **\mathfrak{p} -invariant** of A , which is denoted by (A/\mathfrak{p}) . If \mathfrak{p} is an infinite prime divisor, then $m_{\mathfrak{p}}$ is equal to 1 or 2, and in each case, we define the \mathfrak{p} -invariant by setting $(A/\mathfrak{p}) = 0$ or $1/2 \pmod{\mathbf{Z}}$ correspondingly. The Schur index of A is the L.C.M. of the \mathfrak{p} -indices $m_{\mathfrak{p}}$ for all \mathfrak{p} and coincides with the exponent of A . This is called simply the **index** of A . On the other hand, the \mathfrak{p} -invariants satisfy $(A/\mathfrak{p}) \equiv 0 \pmod{\mathbf{Z}}$ except for a finite number of \mathfrak{p} , and

$$\sum_{\mathfrak{p}} (A/\mathfrak{p}) \equiv 0 \pmod{\mathbf{Z}}.$$

Conversely, given a rational number $\rho_{\mathfrak{p}}$ for each \mathfrak{p} such that (i) $\rho_{\mathfrak{p}} \equiv 0 \pmod{\mathbf{Z}}$ except for a finite number of \mathfrak{p} ; (ii) $\rho_{\mathfrak{p}} \equiv 0 \pmod{\mathbf{Z}}$ if \mathfrak{p} is infinite and imaginary, $\rho_{\mathfrak{p}} \equiv 0$ or $1/2 \pmod{\mathbf{Z}}$ if

p is infinite and real; (iii) $\sum_p \rho_p \equiv 0 \pmod{\mathbf{Z}}$, then there is a uniquely determined algebra class of central simple algebras A over K such that $(A/p) \equiv \rho_p \pmod{\mathbf{Z}}$ for each p . In this way the structure of the Brauer group over a finite algebraic number field is completely determined (Hasse, 1933).

H. Frobenius Algebras

Let A be an algebra over a field K . A is called a **Frobenius algebra** if its \dagger regular representation and \dagger coregular representation (\rightarrow 362 Representations E) are similar. Thus A is a Frobenius algebra if the left A -module A and the dual module A^* of the right A -module A are isomorphic as left A -modules. Let

$$A = \sum_{i=1}^n \sum_{s=1}^{r_i} Ae_i^{(s)} = \sum_{i=1}^n \sum_{s=1}^{r_i} e_i^{(s)} A$$

be direct decompositions of A into indecomposable left (right) ideals (\rightarrow Section E). We denote $e_i^{(1)}$ by e_i . Then A is a Frobenius algebra if and only if there exists a permutation π on $1, \dots, n$ such that (i) $Ae_i \cong (e_{\pi(i)}A)^*$; (ii) $r_i = r_{\pi(i)}$. When there exists a permutation satisfying only condition (i), A is called a **quasi-Frobenius algebra**.

For a subset S of A , the ideals $I(S) = \{a \in A \mid aS = 0\}$ and $r(S) = \{a \in A \mid Sa = 0\}$ are called the **left annihilator** and **right annihilator** of S , respectively. Then A is a quasi-Frobenius algebra if and only if (ii) $l(r(I)) = I$ and $r(l(r)) = r$ for any left ideal I and any right ideal r . In general, if we are given a left (right) A -module M , we denote the right (left) A -module $\text{Hom}_A(M, A)$ by f_i . Then if A is a quasi-Frobenius algebra, there is a canonical isomorphism $\hat{M} \cong M$, and the annihilator relation gives a one-to-one and dual correspondence between the set of the submodules of M and the set of submodules of \hat{M} (M. Hall). If a quasi-Frobenius algebra A satisfies (iv) $\dim r + \dim I(r) = \dim l + \dim r(l) = \dim A$ for any left ideal I and any right ideal r , then A is a Frobenius algebra; the converse is also true.

A criterion for an algebra A to be a Frobenius algebra is that there is a linear form $x \rightarrow \lambda(x)$ on A such that if $\lambda(xa) = 0$ for all $x \in A$, then $a = 0$. Moreover, if λ satisfies $\lambda(xy) = \lambda(yx)$ ($x, y \in A$), then A is called a **symmetric algebra**. For example, semisimple algebras and group algebras are symmetric algebras. If A is a symmetric algebra, then for any left (right) A -module M the right (left) A -modules $M^* = \text{Hom}_K(M, K)$ and $\hat{M} = \text{Hom}_A(M, A)$ are canonically A -isomorphic.

If A is a Frobenius algebra, the radical N of A satisfies $l(N) = r(N)$, and the annihilator of N is a principal left and principal right ideal;

the converse is also true. For a two-sided ideal z of a Frobenius algebra A , the quotient algebra A/z is a Frobenius algebra if and only if $l(z)$ and $r(z)$ are a principal left and a principal right ideal, respectively. If A is a symmetric algebra, then any two-sided ideal z satisfies $l(z) = r(z)$, and A/z is also a symmetric algebra if and only if $l(z) = r(z)$ is a principal ideal generated by an element in the center.

Furthermore, for any extension L of the coefficient field K , A^L is a quasi-Frobenius algebra (resp. Frobenius algebra, symmetric algebra) if and only if A is (T. Nakayama, 1939, 1941). The concept of Frobenius algebras has been extended to algebras B over a ring A (F. Kasch, 1954).

I. Uniserial Algebras

In the notation of the preceding section, if each indecomposable left ideal Ae_i (right ideal e_iA) of an algebra A over K has a unique composition series, then A is called a **generalized uniserial algebra**. If an algebra A is decomposed into a direct sum of ideals which are primary rings, then it is called a **uniserial algebra**. Any left module over a generalized uniserial algebra A is decomposed into a direct sum of submodules which are A -homomorphic images of Ae_i . An algebra whose radical N is a principal left and principal right ideal is a generalized uniserial algebra. For an algebra A to be uniserial, it is necessary and sufficient that every two-sided ideal of A be a principal left and principal right ideal. Hence A is uniserial if and only if every quotient algebra of A is a Frobenius algebra. If A^L is uniserial for an extension field L of K , then A itself is uniserial. The converse, however, is not always true. If A^L is uniserial for any extension field L of K , then A is called an **absolutely uniserial algebra**. For A to be absolutely uniserial it is necessary and sufficient that its radical N be a principal ideal generated by an element in the center Z and Z be decomposed into a direct sum of simple extensions of K (i.e., ideals of the form $K[a]$) (K. Asano, G. Köthe, Nakayama, G. Azumaya).

J. Algebraic Algebras

Here, we consider general (not necessarily finite-dimensional) algebras A over a field K . We say that A is an **algebraic algebra** if every element of A is algebraic over K , i.e., every element of A is a root of a certain polynomial with coefficients in K . We say that A satisfies a **polynomial identity** $p(X_1, \dots, X_n) = 0$ or that A is a **PI-algebra** with an identity $p(X_1, \dots, X_n) =$

0 if there exists a nonzero (noncommutative) polynomial $p(X_1, \dots, X_n)$ in X_1, \dots, X_n with coefficients in K such that $p(a_1, \dots, a_n) = 0$ for all $a_i \in A$. A PI-algebra satisfies an identity which is homogeneous linear in each variable, and also an identity of the form $[x_1, \dots, x_n]^m = 0$ (where $[\]$ is the sum $\sum \pm x_{i_1} \dots x_{i_n}$ taken over all permutations of $1, 2, \dots, n$ and \pm is the sign of the permutation). An algebra is said to be **locally finite** if any finite number of elements of A generate a finite-dimensional subalgebra. For PI-algebras, an affirmative answer was found for Kurosh's problem, which asks whether an algebraic algebra is locally finite if the degree of any element α of A (i.e., $\dim K[a]$) is bounded.

K. Brauer Group of a Ring

Let R be a commutative ring. An R -algebra is called a **separable algebra** if A is \dagger projective as a two-sided A -module (- 200 Homological Algebra F). When the base ring is a field, this agrees with the classical notion of separability; and A is separable over R if and only if $A/\mathfrak{m}A$ is separable over the residue field R/\mathfrak{m} for every maximal ideal \mathfrak{m} of R . A **central separable algebra** is also called an **Azumaya algebra**. If P is a finitely generated faithful projective R -module (briefly: **R-progenerator**), the endomorphism ring $\text{End}_R(P)$ is an Azumaya R -algebra. Azumaya algebras A , and A , are said to be in the same class (similar) if there exist R -progenerators P_1 and P_2 such that $A \otimes \text{End}_R(P_1) \cong A \otimes \text{End}_R(P_2)$. The set of similarity classes forms an Abelian group with respect to \otimes . This is called the **Brauer group** $B(R)$ of R (Auslander and Goldman [10]). Every element of $B(R)$ is of finite order [12, 13].

$B(R)$ is a covariant functor from commutative rings to Abelian groups. If R is a field, $B(R)$ coincides with the classically defined one (- Section E). If R is a \dagger Henselian local ring with the residue field k , the mapping $B(R) \rightarrow B(k)$ is an isomorphism [9]. If R is a \dagger regular ring with the quotient field K , $B(R) \rightarrow B(K)$ is injective. If further $\dim R \leq 2$, we have $B(R) = \bigcap_{\mathfrak{p}} B(R_{\mathfrak{p}})$, \mathfrak{p} running over all primes of height 1 of R , where $R_{\mathfrak{p}}$ is the localization of R at \mathfrak{p} and $B(R)$ and $B(R_{\mathfrak{p}})$ are considered as embedded in $B(K)$ [10]. As an example, putting these facts together with the structure of $B(K)$ of the algebraic number field K (\rightarrow Section G), we have the structure of $B(R)$ of the ring of integers of K : $B(R) = 0$ if K is totally imaginary, and $\cong (\mathbb{Z}/2\mathbb{Z})^{r-1}$ if K has $r(>0)$ real infinite places.

A commutative R -algebra S is called a **splitting ring** of A if the S -algebra $S \otimes A$ is isomor-

phic to $\text{End}_S(P)$ for some S -progenerator P . We denote by $B(S/R)$ the subgroup of $B(R)$ consisting of all algebra classes split by S . Since an Azumaya algebra over a ring need not have a Galois extension as splitting ring, the description of the Brauer groups by means of Galois cohomology ceases to have full generality. Instead we have the following exact sequence of \dagger Amitsur cohomology, assuming S is an R -progenerator (Chase and Rosenberg [11]): $0 \rightarrow H^1(S/R, U) \rightarrow \text{Pic}(R) \rightarrow H^0(S/R, \text{Pic}) \rightarrow H^2(S/R, U) \rightarrow B(S/R) \rightarrow H^1(S/R, \text{Pic}) \rightarrow H^3(S/R, U) \rightarrow$, where we denote by $U(\dagger')$ and $\text{Pic}(T)$ of a commutative ring T the unit group and the \dagger Picard group of rank 1 projective modules of T , respectively. The full Brauer group $B(R)$ is mapped monomorphically into $H^2(R, U) = \varinjlim H^2(S/R, U)$, the limit over the \dagger faithfully flat R -algebras S .

Grothendieck and others studied the Brauer groups in a more general geometrical context [12].

30 (X.19) Asymptotic Series

A. Asymptotic Series and Asymptotic Expansions

Let $\varphi_n(x)$, $n=0, 1, 2$, be functions defined in \mathbf{R}_+ . The sequence of functions $\{\varphi_n(x)\}_{n=0}^\infty$ is called an **asymptotic sequence** for $x \rightarrow \infty$ if

$$\varphi_{n+1}(x) = o(\varphi_n(x)) \text{ as } x \rightarrow \infty \quad (1)$$

for each n . When $\{\varphi_n(x)\}_{n=0}^\infty$ is an asymptotic sequence, the formal series $\sum a_n \varphi_n(x)$ is called an **asymptotic series**. In most cases, the functions $\varphi_n(x)$ have the form $\psi(x)\varphi(x)^n$. When $\varphi_n(x) = x^{-n}$ an asymptotic series is called an **asymptotic power series**. A function $f(x)$ defined on \mathbf{R}_+ is said to have the **asymptotic expansion** (or be **asymptotically developable** in the form)

$$f(x) \sim a_0 \varphi_0(x) + a_1 \varphi_1(x) + \dots + a_n \varphi_n(x) + \dots \quad (2)$$

as $x \rightarrow \infty$ if $f(x)$ satisfies

$$\begin{aligned} f(x) - a_0 \varphi_0(x) - a_1 \varphi_1(x) - \dots - a_n \varphi_n(x) \\ = O(\varphi_{n+1}(x)) \end{aligned} \quad (3)$$

for any integer $n \geq 0$ as $x \rightarrow \infty$. The coefficients a_n ($n = 0, 1, \dots$) appearing in (2) are uniquely determined. This fact immediately follows from the formulas

$$a_0 = \lim_{x \rightarrow \infty} f(x)/\varphi_0(x), \dots,$$

$$\begin{aligned} a_n = \lim_{x \rightarrow \infty} (f(x) - a_0 \varphi_0(x) - \dots \\ - a_{n-1} \varphi_{n-1}(x))/\varphi_n(x). \end{aligned}$$

For example, the † Hankel function of the first kind $H_v^{(1)}(x)$ has an asymptotic expansion

$$\begin{aligned} H_v^{(1)}(x) \\ \sim \frac{1}{\sqrt{\pi x}} \exp \left[i \left(x - \frac{\pi v}{2} - \frac{\pi}{4} \right) \right] \sum_{m=0}^{\infty} \frac{(v, m)}{(-2ix)^m}, \quad (4) \\ (v, m) = \frac{(4v^2 - 1)(4v^2 - 3^2) \dots [4v^2 - (2m - 1)^2]}{2^{2m} m!} \end{aligned}$$

If $v + \frac{1}{2}$ is not a positive integer, $\sum_{m=0}^{\infty} (v, m) (-2ix)^{-m}$ is not convergent, and (4) means that for each n ,

$$\begin{aligned} H_v^{(1)}(x) - \frac{1}{\sqrt{\pi x}} \exp \left[i \left(x - \frac{v\pi}{2} - \frac{\pi}{4} \right) \right] \sum_{m=0}^{n-1} \frac{(v, m)}{(-2ix)^m} \\ = O(x^{-n-1/2}) \end{aligned}$$

for $x \rightarrow \infty$.

Assume that $f(x)$ and $g(x)$ admit asymptotic expansions in power series for $x \rightarrow \infty$. Then all functions defined by $f(x) + g(x)$, $f(x) - g(x)$, $f(x)g(x)$, $f(x)/g(x)$ ($\lim_{x \rightarrow \infty} g(x) \neq 0$) admit

asymptotic expansions in power series for $x \rightarrow \infty$. Furthermore, if $f'(x)$ has an asymptotic expansion for $x \rightarrow \infty$, its expansion is obtained by termwise differentiation of the $f(x)$'s.

For any asymptotic power series $\sum_{n=0}^{\infty} a_n x^{-n}$ there always exists a smooth function $f(x)$ defined in \mathbf{R}_+ such that

$$f(x) \sim a_0 + a_1 x^{-1} + a_2 x^{-2} + \dots$$

for $x \rightarrow \infty$, and all the derivatives of $f(x)$ are asymptotically developable in power series. Indeed, a function defined by

$$f(x) = \sum_{n=0}^{\infty} a_n \theta(x/t_n) x^{-n}$$

satisfies the required properties if $\theta(t)$ is a smooth function satisfying

$$\theta(t) = \begin{cases} 0, & t \leq 1, \\ 1, & t \geq 2, \end{cases}$$

and the sequence $\{t_n\}_{n=0}^\infty$ satisfies $1 \leq t_0 \leq t_1 \leq \dots$ and

$$|n(n+1) \dots (2n-1) 2na_n t_n^{-1}| \leq 2^{-n}$$

for all n .

Until now only asymptotic series for $x \rightarrow \infty$ have been considered, but the notion of asymptotic series has been adapted in various forms to the spaces of functions under consideration.

(a) Asymptotic series in a complex domain. Let α be a boundary point of an open connected domain D in the complex z -plane. When the asymptotic behavior for $z \rightarrow \alpha$ of holomorphic functions in D is considered, we adopt as an asymptotic sequence $\{\varphi_n(z)\}_{n=0}^\infty$ of holomorphic functions in D satisfying for each n

$$\varphi_{n+1}(z) = o(\varphi_n(z))$$

as z tends to α through D . Let D be an angular domain with vertex at α . For any asymptotic power series $\sum_{n=0}^{\infty} a_n (z - \alpha)^n$ there always exists a function $f(z)$ that is holomorphic in D and that admits an asymptotic expansion

$$f(z) \sim a_0 + a_1 (z - \alpha) + \dots + a_n (z - \alpha)^n + \dots \quad (5)$$

for $z \rightarrow \alpha$. Concerning the uniform convergence of asymptotic expansions, **Carleman's theorem** is well known [2]: If the asymptotic expansion (5) is valid as z tends to α through an arbitrary angular domain in the Riemann surface of $\log(z - \alpha)$ having α as its vertex, then the asymptotic expansion (5) is uniformly convergent.

(b) Asymptotic expansions by a large parameter. In the theory of differential equations, functions with a large parameter are often considered. Let Ω be a domain in \mathbf{R}^n and k a parameter ≥ 1 , and let $\varphi_n(x, k)$, $n=0, 1, 2, \dots$, be functions defined for $(x, k) \in \Omega \times [1, \infty)$. If

they satisfy for each $x \in \Omega$ and n

$$\varphi_{n+1}(x, k) = o(\varphi_n(x, k)) \quad (6)$$

for $k \rightarrow \infty$, the sequence $\{\varphi_n(x, k)\}_{n=0}^{\infty}$ is called an asymptotic sequence, and the formal series $\sum_{n=0}^{\infty} a_n(x) \varphi_n(x, k)$ is called an asymptotic series. A function $f(x, k)$ is said to be asymptotically developable in the form

$$f(x, k) \sim a_0(x) \varphi_0(x, k) + a_1(x) \varphi_1(x, k) + \dots + a_n(x) \varphi_n(x, k) + \dots$$

for $k \rightarrow \infty$ if for every $x \in \Omega$ and every n

$$f(x, k) - a_0(x) \varphi_0(x, k) - \dots - a_{n-1}(x) \varphi_{n-1}(x, k) = O(\varphi_n(x, k)) \quad (7)$$

holds as $k \rightarrow \infty$. Especially, if the order relations (6) and (7) hold for each n uniformly in $x \in \Omega$, we say that $f(x, k)$ is uniformly asymptotically developable. In most cases, the $\varphi_n(x, k)$ are of the form $\psi(x, k) k^{-n}$.

B. Methods of Asymptotic Expansion

There are several general methods of obtaining asymptotic expansions of functions represented by integrals with a large parameter. These methods are useful in applications because most special functions are represented by integrals (- 39 Bessel Functions, 389 Special Functions).

(a) **Laplace's method.** Let $h(s)$ be a smooth real-valued function in $[a - \delta, a + \delta]$ ($\delta > 0$) satisfying

$$h(a) < h(s) \text{ for all } s \in [a - \delta, a + \delta] - \{a\}$$

and

$$h''(a) > 0,$$

and let $g(s) \in C^{\infty}([a - \delta, a + \delta])$. Then

$$I(x) = \int_{a-\delta}^{a+\delta} e^{-xh(s)} g(s) ds$$

has an asymptotic expansion

$$I(x) \sim e^{-xh(a)} \frac{\sqrt{2\pi}}{\sqrt{x}} \left\{ g(a) \frac{1}{\sqrt{h''(a)}} + c_1 x^{-1} + \dots + c_n x^{-n} + \dots \right\}$$

for $x \rightarrow \infty$, where the c_n are determined by derivatives of $h(s)$ at $s = a$ of order $\leq 2n + 2$ and those of $g(s)$ at $s = a$ of order $\leq 2n$.

As an application of this method, consider the Γ -function $\Gamma(x) = \int_0^{\infty} e^{-t} t^{x-1} dt$. By a change of variable $t = xs$, we have $\Gamma(x) = x^x \int_0^{\infty} e^{-x(s-\log s)} s^{-1} ds$. Since for any $\delta > 0$

$$\left| \int_0^{1-\delta} e^{-x(s-\log s)} s^{-1} ds \right| + \left| \int_{1+\delta}^{\infty} e^{-x(s-\log s)} s^{-1} ds \right| \leq C e^{-x(1+\alpha)} \quad (\alpha > 0),$$

the asymptotic expansion by the Laplace method

$$\int_{1-\delta}^{1+\delta} e^{-x(s-\log s)} s^{-1} ds \sim e^{-x} \sqrt{\frac{2\pi}{x}} (1 + c_1 x^{-1} + \dots)$$

implies †Stirling's formula

$$\Gamma(x) = \sqrt{2\pi} x^{x-1/2} e^{-x} (1 + O(x^{-1})).$$

(b) **Stationary phase method.** Let $h(s)$ be a real-valued smooth function defined in $[a - \delta, a + \delta]$ such that

$$h'(u) = 0, h''(u) \neq 0 \text{ and } h'(s) \neq 0 \text{ for } s \neq a,$$

and let $g(s)$ be a function in $C_0^{\infty}(a - \delta, a + \delta)$. Then

$$I(x) = \int_{a-\delta}^{a+\delta} e^{ixh(s)} g(s) ds$$

has an asymptotic expansion

$$I(x) \sim e^{ixh(a)} e^{i\sigma\pi/4} \frac{1}{\sqrt{x}} \left\{ \frac{g(a)}{\sqrt{|h''(a)|}} + c_1 x^{-1} + \dots + c_n x^{-n} + \dots \right\},$$

where $\sigma = h''(a)/|h''(a)|$ and the c_n are determined by derivatives of $h(s)$ at $s = a$ of order $\leq 2n + 2$ and those of $g(s)$ at $s = a$ of order $\leq 2n$.

Further, †integration by parts and the †method of steepest descent are often used to derive asymptotic expansions of integrals with a large parameter.

C. Application to Differential Equations

For a system of linear ordinary differential equations with an †irregular singular point at $z = 0$, even when there exists a formal power series solution, the power series is generally divergent. Taking the hint given by Stirling's formula for the Γ -function, Poincaré introduced the notion of asymptotic expansions and succeeded in giving an analytic meaning to formal solutions of divergent type. Actual solutions for †difference equations, †difference-differential equations, and †ordinary differential equations of canonical form (including second-order linear †differential equations of confluent type) always have asymptotic expansions.

In the study of certain ordinary differential equations containing a large parameter k , an asymptotic solution is often obtained in the form

$$u(x, k) \sim e^{ik\varphi(x)} (a_0(x) + a_1(x)k^{-1} + \dots + a_n(x)k^{-n} + \dots)$$

(†WKB method). Also, in the study of linear

partial differential equations, an asymptotic solution of the above form plays an important role. For example, consider the Schrodinger equation

$$L_\lambda[u] = \frac{1}{i\lambda} \frac{\partial u}{\partial t} - \frac{1}{(i\lambda)^2} \Delta u - v(x)u = 0.$$

An asymptotic series

$$u(x, t; \lambda) \sim e^{i\lambda\phi(x, t)} \left(a_0(x, t) + a_1(x, t) \frac{1}{i\lambda} + \dots + a_n(x, t) \left(\frac{1}{i\lambda} \right)^n + \dots \right) \quad (8)$$

satisfies $L_\lambda[u] \rightarrow 0$ for $\lambda \rightarrow \infty$ if

$$\frac{\partial \phi}{\partial t} (\nabla \phi)^2 - v(x) = 0 \quad (\text{eikonal equation}),$$

$$\frac{\partial a_n}{\partial t} - 2\nabla \phi \cdot \nabla a_n - \Delta \phi a_n = \Delta a_{n-1}, \quad n=0, 1, 2, \dots \quad (\text{transport equation}),$$

where we set $a_{-1} \equiv 0$. For each asymptotic solution of the form (8) there exists an actual solution of $L_\lambda[f(x, t; \lambda)] = 0$ which is asymptotically developable in the form

$$f(x, t; \lambda) \sim \sum_{n=0}^{\infty} e^{i\lambda\phi(x, t)} a_n(x, t) (i\lambda)^{-n}$$

Then asymptotic solutions of the form (8) can describe the fundamental properties of the phenomenon governed by the equation $L_\lambda[u] = 0$.

†Geometric optics can also be illustrated by asymptotic solutions of the form (8) (\rightarrow 325 Partial Differential Equations of Hyperbolic Type L). The ideas of asymptotic series, asymptotic expansions, and asymptotic solutions are essential to the theory of †pseudodifferential operators and †Fourier integral operators (\rightarrow 345 Pseudodifferential Operators).

31 (XVI.1) Automata

A. General Remarks

Automaton is a generic term for the mathematical models for automatic machines having memory devices and capable of performing definite acts within each unit of time. There are several types of automata, namely, Turing machines for the theory of computability [6], linear bounded automata, push-down automata, and finite automata for mathematical language theory [10–13]. These models are also used in the theory of †complexity of computation of algorithms [14].

B. Turing Machines

Since the arithmetization of metamathematics was used in the proof of †Gödel's incompleteness theorem, mathematical formulations of the notion of effectively computable functions have been attempted by many mathematicians, including S. C. Kleene, A. Church, and others, as well as by Gödel himself (\rightarrow 356 Recursive Functions). With this end in mind, A. M. Turing and E. L. Post independently introduced a sort of ideal computer [1, 2], called a **Turing machine**.

Such a machine is capable of being in one of a finite number of **internal states** (possible contents of a memory device) q_0, q_1, \dots, q_n fixed for the machine; and the machine is supplied with a tape divided into squares. The tape is infinite in both directions. Each square can be blank or can have printed on it any one of the previously specified symbols s_0, s_1, \dots, s_m , where s_0 stands for the blank. In any situation the number of nonblank squares is finite. Let $Q = \{q_0, q_1, \dots, q_n\}$, $M = \{s_0, s_1, \dots, s_m\}$, and consider the mapping $t: Q \times M \rightarrow Q \times M \times \{R, L, 0\}$. A Turing machine T is specified by (Q, M, t, q_0, F) , where F is a subset of Q called a set of final states and q_0 is the specified initial state. If $t(q, s) = (q', s', x)$, then the 5-tuple (q, s, q', s', x) is called an **instruction** for T . The

machine acts as follows: (1) At the start, the machine is in the state q_0 . Some sequence of symbols in M are written on the tape as an input, and the machine is on the square next to the leftmost nonblank symbol. (2) With respect to the present state q and the scanned symbol, the machine selects an instruction (q, s, q', x) ; then the next state becomes q' , s is replaced by s' , and the machine moves one square right or left or stands still according as x is R , L , or 0 . (3) The machine stops when the state becomes an element of F , and then the sequence of symbols on the tape is the result of the computation and considered to be the output. A Turing machine is called **deterministic** if there is always at most one instruction associated with a given pair (q, s) ; otherwise it is called **nondeterministic**.

We represent a natural number y on the tape by $y + 1$ squares, each of which has the symbol s_1 printed on it. A pair (y_1, y_2) is represented on the tape by the following sequence of symbols of length $y_1 + y_2 + 5$: one s_0 , the representation of y_1 ; one s_0 , the representation of y_2 ; and one s_0 . Similarly, in general we can represent a k -tuple (y_1, \dots, y_k) of natural numbers on the tape. Let Φ be a partial function of k variables, $k \geq 0$. We say that a Turing machine T **computes** Φ if T starts with the tape in which the representation of (x_1, \dots, x_k) is printed and stops with the tape having the representation of (x_1, \dots, x_k, x) when $\Phi(x_1, \dots, x_k)$ is defined and equal to x . A partial function is **computable** (in the sense of Turing) if there exists a Turing machine that computes the function. It is known that a partial function is computable if and only if it is partial recursive. The equivalence of computability (in the sense of Turing) and recursiveness for number-theoretic functions is strong evidence for the validity of Church's thesis (- 356 Recursive Functions).

We can apply a Turing machine not only to the computation of number-theoretic functions but also to the transformation of a finite sequence of letters in any language with a finite list of letters. A finite nonempty list of distinct symbols is called an **alphabet**, and a finite sequence of symbols in the alphabet is called a **word** in that alphabet. All the words in an alphabet constitute a 'free monoid if we add the empty sequence and think of the concatenation of two words as its multiplication. We call a finite nonempty list $(A_1, B_1), \dots, (A_n, B_n)$ of pairs of words a set of **production rules**. By an **application** of a rule (A_i, B_i) to a word W , we mean that an occurrence of A_i exists in W , and by the application, A_i is replaced by B_i . We say that two words R and S are **equivalent** if they are transformable into each other by a finite number of applications of the production

rules. The following problem is called **Thue's (general) problem**: Is there an algorithm for deciding, for any given alphabet and a set of production rules, whether or not any given two words are equivalent? E. L. Post and A. A. Markov proved by applying Turing machines that this decision problem is unsolvable [4, 3] (a negative solution for the so-called word problem for semigroups).

C. Universal Turing Machine and Generalizations

Turing showed that it is possible to construct a machine U with the following property [1]: If we supply U with a tape on which a suitably coded list of instructions of any given machine T is printed then U successively prints on it the behavior of T which results from the execution of the instructions of T . In other words, U simulates the operations performed by any machine. Such a machine U is called a **universal Turing machine**. We can construct a universal Turing machine with only two internal states and also one having only two symbols, including the blank s_0 (C. E. Shannon and J. McCarthy [7]).

Let ψ_1, \dots, ψ_k be given functions that are all defined everywhere on the domain considered. Then we can relativize (\rightarrow 356 Recursive Functions) the notion of computability of functions (in the sense of Turing) to ψ_1, \dots, ψ_k . Indeed, we can consider a machine acting as follows: When the machine is in a state q_{ij} ($j = 1, \dots, k$ and we assume that these states are specified correspondingly to ψ_1, \dots, ψ_k and are not in F), then the machine prints the representation of $\psi_j(y_1, \dots, y_n)$ to the right of (y_1, \dots, y_n) and scans the resulting $(n_j + 1)$ -tuple $(y_1, \dots, y_n, \psi_j(y_1, \dots, y_n))$. In this process, the symbol a that is written to the right of (y_1, \dots, y_n) is moved one step to the right so that a is preserved on the right of the resulting $(n + 1)$ -tuple. Extending the preceding, Kleene defined a machine that computes a functional of finite types [S]. A functional of variables of any finite types is computable by such a generalized Turing machine if and only if it is partial recursive.

D. Language and Automata

Let M and N be mutually disjoint alphabets and $V = MU^*N$. Then $G = (N, M, P, S)$ is called a **Chomsky grammar** if P is a set of production rules consisting of finite number of pairs of elements of V^* and S is specified element of N , where V^* means the free monoid generated by V . For a word $u \in V^*$, if the result of a finite

Automata

number of applications of rules in P is v , then we write $u \rightarrow v$, and v is said to be **derived** from u by G . The **language** generated by G is $L(G) = \{u \mid S \rightarrow u \text{ and } u \in M^*\}$. N. Chomsky classified the grammars into three families with respect to the form of production rules: (1) **Context-sensitive grammar**: For each $(u, v) \in P$, the length of u is less than or equal to the length of v . (2) **Context-free grammar**: For each $(u, v) \in P$, u is an element of N and v is not a empty word. (3) **Regular grammar**: For each $(u, v) \in P$, $u \in N$ and v is either an element of M or of the form ax , where $a \in M$ and $x \in N$. Let $F_1(M)$, $F_2(M)$, and $F_3(M)$ be the families of languages generated by the grammars in the corresponding families classified as above. Then $F_1(M) \supsetneq F_2(M) \supsetneq F_3(M)$ holds and this is called a **Chomsky hierarchy** [10]. Formal language theory studies various structures of these families of languages.

Corresponding to the three families of languages, we have the following families of automata: (1) A **deterministic (nondeterministic) linear bounded automaton** is a Turing machine with input tape, namely, $T = (Q, M \cup N, t, q_0, F)$, where Q is the set of states, M an input alphabet, N a tape alphabet, t is a mapping from $Q \times (M \cup \{e\}) \times (N \cup \{e\})$ into $Q \times N \times \{L, R\}$ (the power set of $Q \times N \times \{L, R\}$), $q_0 \in Q$ is the initial state, and F is a subset of Q . A word $w \in M^*$ is placed on the input tape, and T starts its computation from the initial state with blank tape and by reading one symbol from the input tape, and with respect to the mapping t , we decide the configuration of the next step. If at a certain stage, T reaches a state in F when T reads up w and if the length of the tape used is a constant multiple of the length of the input tape, then w is said to be **accepted** by T . (The special symbol e makes it possible to change the configuration without moving the input tape.) (2) A **push-down automaton** is a Turing machine with an input tape. The working tape is of infinite length and moves in only one direction, say to the right. The computation with input word $w \in M^*$ starts with the position at the left end of the work tape. It uses the tape according to a first-in-first-out principle; namely, the machine may write a symbol to the blank square, but if it is on the rightmost nonblank square, it may not go left without erasing the nonblank symbol. If it reaches a state in F , then w is said to be **accepted** by T . (3) A **finite automaton** is a machine without its infinite tape; a word w is **accepted** if T reaches a state in F (without using the symbol e).

Let $L(T)$ be the set of words over M accepted by T ; then $L(T)$ is called the **language accepted** by T . Corresponding to the three families of automata, $DF_i(M)$ and $NF_i(M)$, $i =$

1, 2, 3, denote the family of languages accepted by deterministic or nondeterministic automata. It is known that $DF_i(M) = NF_i(M) = F_i(M)$ for $i = 2$ and 3 , and $NF_1(M) = F_1(M)$; however, whether $DF_1(M) = NF_1(M)$ holds or not is still open, and this problem is called the **LBA problem**. These automata are used to study the closure properties under various operations within the families $F_i(M)$. In particular, the LBA problem is equivalent to the problem of whether $F_i(M)$ is closed under complementation.

E. Applications of Automata Theory

Finite automata are formulated as models for digital circuits with memory. Therefore there exist structural studies of finite automata; for example, methods to decompose a given finite automaton to smaller automata corresponding to a circuit and its subcircuits are studied using tsemigroup theory [14, 17].

Context-free grammars are useful in describing the syntax of programming languages. For a context-free grammar G , a **derivation tree** of $x \in L(G)$ is a tree whose terminal nodes are labeled by each symbol of x , its root is labeled by S , and other nodes are labeled by some elements of N in such a way that if for a node with $A \in N$ the nodes connected by an outgoing edge from the former have labels x_1, \dots, x_k , then (A, x_1, \dots, x_k) is a production rule of G . **Parsing** is an algorithm to construct a derivation tree of each $x \in L(G)$. Various parsing algorithms have been studied within subfamilies of context-free grammars [16] and they are used in the construction of compilers.

32 (X1.22) Automorphic Functions

A. General Remarks [1]

Let X be a (complex) \dagger analytic manifold and Γ a \dagger discontinuous group of (complex) analytic automorphisms of X . A set of \dagger holomorphic functions (without zero) on X , $\{j_\gamma(z)\}$ ($\gamma \in \Gamma$), is called a **factor of automorphy** if it satisfies the condition $j_{\gamma\gamma'}(z) = j_\gamma(\gamma'(z))j_{\gamma'}(z)$ for all $\gamma, \gamma' \in \Gamma$, $z \in X$. A \dagger meromorphic function f on X is called a (multiplicative) **automorphic function** with respect to the factor of automorphy $\{j_\gamma(z)\}$ if it satisfies the condition $f(\gamma(z)) = f(z)j_\gamma(z)$ for all $\gamma \in \Gamma$, $z \in X$. When all $j_\gamma(z)$ are identically equal to 1, i.e., when $f(z)$ is Γ -invariant, f is simply called an **automorphic function with respect to Γ** . When all j_γ are constant (and hence $\gamma \rightarrow j_\gamma$ is a "quasicharacter" of Γ), f is called a **multiplicative function**. If we denote by $J_\gamma(z)$ the functional determinant of the transformation γ , then for an integer m , an automorphic function f with respect to

Automorphic Functions

a factor of automorphy of the form $j_{\gamma}(z) = J_\gamma(z)^m$ is called an **automorphic form of weight m** . (In this case, it is customary to assume that f is holomorphic. Also, in this and most other cases, we add a suitable condition on the behavior off at the "points at infinity," when $\Gamma \backslash X$ is not compact (- 234 Kleinian Groups).)

B. The Case of One Variable [2-6]

Except for the cases where Γ is a finite group or its extension by a free Abelian group of rank ≤ 2 (\rightarrow 134 Elliptic Functions E), it is essentially enough to consider the case where X is the upper half-plane $\mathfrak{H} = \{z \in \mathbb{C} \mid \text{Im } z > 0\}$. In this case, Γ may be obtained as a \dagger discrete subgroup of the \dagger special linear group $G = SL(2, \mathbb{R})$. In the following, we restrict ourselves to the case where Γ is a \dagger Fuchsian group of the first kind (i.e., the case where the \dagger Haar measure $\mu(\Gamma \backslash \mathfrak{H})$ of the quotient space $\Gamma \backslash \mathfrak{H}$ is finite; \rightarrow 122 Discontinuous Groups). An **automorphic function** (or **Fuchsian function**) f with respect to Γ is, by definition, a meromorphic function f on \mathfrak{H} satisfying the following conditions: (i) f is Γ -invariant, i.e., $f(\gamma z) = f(z)$ for all $\gamma \in \Gamma$; (ii) f is also meromorphic around any \dagger cusp x_0 of Γ , i.e., if φ_0 is a real linear fractional transformation mapping x_0 to ∞ (e.g., $\varphi_0(z) = -1/(z - x_0)$) and if the transformation $z \rightarrow z + h$ ($h > 0$) is a generator of $\varphi_0 \Gamma_{x_0} \varphi_0^{-1}$ (where Γ_{x_0} is the \dagger stabilizer of x_0), then $f(\varphi_0^{-1}(z))$ can be expanded into a \dagger Laurent series of $q_h = \exp((2\pi i/h)z)$ (which has only finitely many terms with negative exponent) in a neighborhood $\text{Im } z > y$, of ∞ (q_h is called the **local parameter** around the cusp x_0). If we denote by \mathfrak{R}_Γ the compact \dagger Riemann surface obtained from the quotient space $\Gamma \backslash \mathfrak{H}$ by adjoining a certain (finite) number of "points at infinity" corresponding to the equivalence classes of cusps of Γ , then conditions (i) and (ii) amount to saying that f gives rise in a natural manner to a meromorphic function on \mathfrak{R}_Γ . Thus the field \mathfrak{A}_Γ of all automorphic functions with respect to Γ can be identified with the \dagger algebraic function field belonging to the Riemann surface \mathfrak{R}_Γ (\rightarrow 11 Algebraic Functions A). (While any (nonconstant) automorphic function with respect to a Fuchsian group of the first kind Γ has the real axis as its \dagger natural boundary, an automorphic function with respect to a Fuchsian group of the second kind can always be analytically extended to the lower half-plane through a neighborhood of any "ordinary point" on the real axis (\rightarrow 234 Kleinian Groups).)

Let k be an even integer. A (holomorphic) **automorphic form** (or **Fuchsian form**) f of

weight k or of dimension $-k$ with respect to Γ is, by definition, a holomorphic function f on \mathfrak{H} satisfying the following conditions: (i) For every $\sigma = \begin{pmatrix} a & b \\ c & d \end{pmatrix} \in \Gamma$, $f(\sigma z) = f(z) \cdot (cz + d)^k$. (In other words, $J_\sigma(z)^{-k/2} = (d\sigma(z)/dz)^{-k/2} = (cz + d)^k$ is the factor of automorphy.) (ii) f is also holomorphic around any cusp x_0 , i.e., in the above notation, we have an integral "Fourier expansion" $f(\varphi_0^{-1}(z))(d\varphi_0^{-1}(z)/dz)^{k/2} = \sum_{n=0}^{\infty} a_n q_h^n$. Note that this definition of weight is different from that given in Section A (- Sections F, G). If, moreover, the constant term a_0 in this Fourier expansion vanishes at all cusps of Γ , f is called a **cusp form**. In particular, f is a cusp form of weight 2 if and only if $f(z)dz$ gives rise in a natural manner to a \dagger differential form of the first kind on the Riemann surface \mathfrak{R}_Γ . (By a slight modification of condition (ii), we can also define an automorphic form of odd weight k . When $\begin{pmatrix} -1 & 0 \\ 0 & -1 \end{pmatrix} \in \Gamma$, condition (i) (for k odd) implies that f is identically equal to zero. So assume that $\begin{pmatrix} -1 & 0 \\ 0 & -1 \end{pmatrix} \notin \Gamma$. Then cusps x_0 are classified into two categories, according as $\begin{pmatrix} -1 & h \\ 0 & -1 \end{pmatrix} \in \varphi_0 \Gamma_{x_0} \varphi_0^{-1}$ or not, and in the first case we should replace the power series in q_h in condition (ii) by $q_h^{1/2} \times$ (power series in q_h).) (Note that the above definition of weight is slightly different from the general one given in Section A. See also the Siegel and Hilbert modular cases (- Sections F, G).)

We denote by $\mathfrak{M}_k(\Gamma)$ (resp. $\mathfrak{S}_k(\Gamma)$) the linear space of all automorphic forms (cusp forms) of weight k with respect to Γ . Since clearly the relations $\mathfrak{M}_k \mathfrak{M}_{k'} \subset \mathfrak{M}_{k+k'}$, $\mathfrak{M}_k \mathfrak{S}_{k'} \subset \mathfrak{S}_{k+k'}$ hold, the direct sum $\mathfrak{M}(\Gamma) = \sum_k \mathfrak{M}_k(\Gamma)$ is a (commutative) \dagger graded algebra, of which $\mathfrak{S}(\Gamma) = \sum_k \mathfrak{S}_k(\Gamma)$ is an ideal. It is known that $\mathfrak{M}_k(\Gamma)$ is of finite dimension, and $d_k = \dim \mathfrak{M}_k(\Gamma)$, $d_k^0 = \dim \mathfrak{S}_k(\Gamma)$ can be determined (from the \dagger Riemann-Roch theorem) as follows:

$$d_k = 0 \quad \text{for} \quad k < 0;$$

$$d_0 = 1, \quad d_0^0 = \begin{cases} 1 & \text{for } t = 0 \\ 0 & \text{for } t > 0 \end{cases}$$

$$d_2 = \begin{cases} g & \text{for } t = 0 \\ g + t - 1 & \text{for } t > 0, \end{cases} \quad d_2^0 = g;$$

$$d_k = (k-1)(g-1) + \sum_{i=1}^s \left(\frac{k}{2} \left(1 - \frac{1}{e_i} \right) \right) + \frac{k}{2} t,$$

$$d_k^0 = d_k - t \quad \text{for} \quad k \text{ even, } \geq 4,$$

where s is the number of the equivalence classes of \dagger elliptic fixed points of Γ , e_i ($1 \leq i \leq s$) is the order of the stabilizers of these elliptic points, t is the number of the equivalence

classes of cusps of Γ , and g is the \dagger genus of the Riemann surface \mathfrak{R}_Γ . (When $\begin{pmatrix} -1 & 0 \\ 0 & -1 \end{pmatrix} \notin \Gamma$, we can obtain a similar formula for k odd except for d_1 , d_1^0 , which, in general, cannot be determined from the Riemann-Roch theorem.)

One method of constructing automorphic forms is provided by Poincaré series as follows: Let σ_0 be a \dagger linear fractional transformation that maps the unit disk to the upper half-plane (e.g., the \dagger Cayley transformation), and put $\Gamma' = \sigma_0^{-1} \Gamma \sigma_0$; let φ be a function holomorphic on the unit disk including its boundary (e.g., a polynomial). Then for $k \geq 4$, the series

$$P_k(z) = \sum_{\sigma \in \Gamma'} \varphi(\sigma'(z)) (d\sigma'(z)/dz)^{k/2}$$

is \dagger uniformly convergent in the wide sense (i.e., uniformly convergent on every compact set) in the unit disk and expresses an automorphic cusp form of weight k with respect to Γ' , i.e., we have $P_k(\sigma_0^{-1}(z))(d\sigma_0^{-1}(z)/dz)^{k/2} \in \mathfrak{S}_k(\Gamma)$. Conversely, every element in $\mathfrak{S}_k(\Gamma)$ ($k \geq 4$) can be expressed in this form. A series of this type is called a **theta-Fuchsian series of Poincaré** (or simply **Poincaré series**).

For $k \geq 3$, we can define a (positive definite Hermitian) inner product on $\mathfrak{S}_k(\Gamma)$ as follows:

$$(f, g) = \int_F f(z) \overline{g(z)} y^{k-2} dx dy,$$

where $z = x + iy$ and F is a \dagger fundamental region of Γ in \mathfrak{H} . This is called the **Petersson metric**. Since this integral converges also for $f, g \in \mathfrak{M}_k(\Gamma)$ if one of them belongs to $\mathfrak{S}_k(\Gamma)$, we can define the orthogonal complement $\mathfrak{E}_k(\Gamma)$ of $\mathfrak{S}_k(\Gamma)$ in $\mathfrak{M}_k(\Gamma)$. As we shall see, $\mathfrak{E}_k(\Gamma)$ is generated by \dagger Eisenstein series.

Any automorphic function f with respect to Γ can be expressed as a quotient of two automorphic forms $f_1, f_2 \in \mathfrak{M}_k(\Gamma)$ for a sufficiently large k . If we put $w = f(z)$, the inverse function $z = f^{-1}(w)$ can be expressed as the quotient of two linearly independent solutions of a \dagger linear differential equation of the form $d^2 z/dw^2 = \varphi(w)z$, where $\varphi(w)$ is an \dagger algebraic function belonging to the Riemann surface \mathfrak{R}_Γ .

C. Modular Functions and Modular Forms [4, 7, 8]

The (elliptic) \dagger modular group

$$\Gamma = \Gamma(1)$$

$$= SL(2, \mathbb{Z})$$

$$= \left\{ \begin{pmatrix} a & b \\ c & d \end{pmatrix} \middle| a, b, c, d \in \mathbb{Z}, ad - bc = 1 \right\}$$

is a Fuchsian group of the first kind acting on

the upper half-plane \mathfrak{H} . The quotient space $\Gamma \backslash \mathfrak{H}$ can be compactified to get a compact Riemann surface $\mathfrak{R}_\Gamma = \Gamma \backslash \mathfrak{H} \cup \{\infty\}$ of genus zero by joining one point at infinity corresponding to the cusp ∞ , around which we take $q = e^{2\pi iz}$ as a local parameter. The dimension $d_k = \dim \mathfrak{M}_k(\Gamma)$ (k even, ≥ 2) is given as follows:

$$d_k = \begin{cases} [k/12] & \text{for } k \equiv 2 \pmod{12}, \\ [k/12] + 1 & \text{for } k \not\equiv 2 \pmod{12}, \end{cases}$$

where $[]$ is the Gauss symbol.

More generally, an automorphic function (automorphic form) with respect to the principal congruence subgroup

$$\Gamma(N) = \left\{ \begin{pmatrix} a & b \\ c & d \end{pmatrix} \equiv \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix} \pmod{N} \right\}$$

is called a **modular function (modular form)** of level N . (For the number of cusps of $\Gamma(N)$, denoted by $t(N)$, and the genus of $\mathfrak{R}_{\Gamma(N)} \rightarrow 122$ Discontinuous Groups.) At any cusp of $\Gamma(N)$, the local parameter q_h in (ii) is given by $q_N = \exp(2\pi iz/N)$. For N , $k \geq 3$, the dimensions d_k , d_k^0 are given by the general formula of the preceding paragraph (including odd k). For $k \geq 3$, we define the (extended) **Eisenstein series** by

$$G_k(z; c_1, c_2, N) = \sum_{m_i \equiv c_i \pmod{N}} \frac{1}{(m_1 + m_2 z)^k},$$

where c_1, c_2 are integers such that $(c_1, c_2, N) = 1$ and the symbol \sum' denotes the summation excepting the pair $(m_1, m_2) = (0, 0)$. Then $G_k(z; c_1, c_2, N)$ depends only on $c_1, c_2 \pmod{N}$, and if we take a set $\{(c_1, c_2)\}$ such that $\{(c_1, c_2), (-c_1, -c_2)\}$ forms a complete set of representatives of the (primitive) residue classes (\pmod{N}) , then the corresponding set of Eisenstein series forms a basis of the space $\mathfrak{E}_k(\Gamma(N))$ ($k \geq 3$), whence we obtain $\dim \mathfrak{E}_k = d_k - d_k^0 = t(N)$ ($k \geq 3$) (for details, including the case $k=1, 2$, see E. Hecke, *Abh. Math. Sem. Univ. Hamburg*, 5 (1927)).

The Fourier coefficient a , of the Eisenstein series can be calculated easily, and we get an estimate $a_k = O(n^{k-1+\varepsilon})$ for $k \geq 2$, where ε is an arbitrary positive number. On the other hand, for cusp forms, Hecke (*Abh. Math. Sem. Univ. Hamburg*, 5 (1927)) gave $a_n = O(n^{k/2})$. In an attempt to improve this estimate, H. D. Kloosterman was led to consider the sum

$$K(u, v, q) = \sum_{\substack{x \pmod{q} \\ (x, q) = 1}} \exp\left(\frac{2\pi i}{q} \left(ux + \frac{v}{x}\right)\right) \quad (u, v, q \in \mathbb{Z}),$$

called the **Kloosterman sum**, which is also related to the arithmetic of quadratic forms. Using A. Weil's estimate $|K(u, v, p)| \leq 2\sqrt{p}$

(where p is an odd prime, $(u, p) = (v, p) = 1$), based on the analog of the Riemann hypothesis, we obtain $a_k = O(n^{k/2-1/4+\varepsilon})$. The estimate $a_n = O(n^{k/2-1/2+\varepsilon})$ is a weak form of what is known as the Ramanujan-Petersson conjecture (\rightarrow Section D). In the case $N=1$, we obtain the classical Eisenstein series $G_k(z) = G_k(z; 0, 0, 1)$ (k even, ≥ 4), from which we define the modular forms $g_2(z) = 60G_4(z)$, $g_3(z) = 140G_6(z)$, and $A(z) = g_2^3 - 27g_3^2$ of weight 4, 6, and 12, respectively. If we denote by $\wp = \wp(u; 1, z)$ the Weierstrass \wp -function with the fundamental period $(1, z)$ we have the relation $\wp'^2 = 4\wp^3 - g_2\wp - g_3$, and $A(z)$ is the \dagger discriminant of the cubic polynomial appearing in this relation. It is known that every modular form can be expressed uniquely as a polynomial in g_2 and g_3 , or in other words, we have $\mathfrak{M}(\Gamma(1)) \cong \mathbb{C}[g_2, g_3]$. The polynomial in g_2, g_3 expressing a modular form is, moreover, **isobaric**, i.e., consists of terms of the form $cg_2^\mu g_3^\nu$, $c \in \mathbb{C}$, where $2\mu + 3\nu$ is a constant called the **weight** of the isobaric polynomial. Also, $A(z)$ is a cusp form of the smallest weight, and the ideal of all cusp forms, $\mathfrak{S}(\Gamma(1))$, is a principal ideal in $\mathfrak{M}(\Gamma(1))$ generated by $A(z)$. The Fourier expansion of the Eisenstein series $G_k(z)$ is given as follows:

$$G_k(z) = (2\pi)^k \frac{1}{k!} \left(B_k + (-1)^{k/2} 2k \sum_{v=1}^{\infty} v^{k-1} \frac{q^v}{1-q^v} \right),$$

where $q = e^{2\pi iz}$ and B_k is the \dagger Bernoulli number. The discriminant $A(z)$ is expressed as an infinite product as follows:

$$\Delta(z) = (2\pi)^{12} q \prod_{v=1}^{\infty} (1 - q^v)^{24}.$$

If we put $J(z) = g_2^3/\Delta$, the function $J(z)$ is a modular function and gives an \dagger analytic isomorphism of the Riemann surface $\mathfrak{R}_{\Gamma(1)} = \Gamma(1) \backslash \mathfrak{H} \cup \{\infty\}$ onto the Riemann sphere $\mathbb{C} \cup \{\infty\}$ (which maps ζ_3, ζ_4, ∞ to 0, 1, ∞ , respectively). Hence the field of modular functions $\mathfrak{R}_{\Gamma(1)}$ is a rational function field $\mathbb{C}(J)$ generated by the function J . The analytic isomorphism class of \dagger complex tori of dimension 1 (= \dagger elliptic curves) $E_{(\omega_1, \omega_2)} = \mathbb{C}/(\mathbb{Z}\omega_1 + \mathbb{Z}\omega_2)$ with the fundamental period (ω_1, ω_2) is uniquely determined by the $\Gamma(1)$ -equivalence class of the **modulus** $\tau = \omega_2/\omega_1$ ($\in \mathfrak{H}$), and hence by the value $J(\tau)$ of the function J . This is the historical origin of the name of modular function [4].

As an example of a modular function of level 2, we have the λ -function:

$$\lambda(z) = \frac{\wp((1+z)/2) - \wp(z/2)}{\wp(1/2) - \wp(z/2)},$$

which gives an analytic isomorphism of the Riemann surface $\mathfrak{R}_{\Gamma(2)} = \Gamma(2) \backslash \mathfrak{H} \cup$ (three

points) to the Riemann sphere $\mathbb{C}U \setminus \{\infty\}$ (mapping 0, 1, ∞ to 1, ∞ , 0, respectively; this property is used in a proof of the \dagger Picard theorem). Hence we again have $\mathfrak{R}_{\Gamma(2)} = \mathbb{C}(\lambda)$. The following relation holds between J and λ :

$$J(z) = \frac{4}{2} \frac{(1 - \lambda + \lambda^2)^3}{7 \lambda^2 (1 - \lambda)^2}$$

In general, the field $\mathfrak{R}_{\Gamma(N)}$ of modular functions of level N is generated by $(g_2/g_3) \cdot \wp((a_1 + a_2 z)/N; 1, z)$ ($a_1, a_2 \in \mathbb{Z}$).

D. The Hecke Ring and Its Representation [S-1 13]

In general, let $\tilde{\Gamma}$ be a group, Γ a subgroup of $\tilde{\Gamma}$, and suppose that, for every $\sigma \in \tilde{\Gamma}$, $\sigma\Gamma\sigma^{-1}$ and Γ are \dagger commensurable, which amounts to saying that every double coset $\Gamma\sigma\Gamma$ is a union of a finite number of left or right cosets of Γ . Then in the free module generated by all double cosets $\Gamma\sigma\Gamma$ ($\sigma \in \tilde{\Gamma}$), we can define a bilinear associative product as follows:

$$\Gamma\sigma\Gamma \cdot \Gamma\tau\Gamma = \sum_{\rho \in \Gamma} m(\sigma, \tau; \rho) \Gamma\rho\Gamma,$$

where, writing $\Gamma\sigma\Gamma = \bigcup_i \Gamma\sigma_i$, $\Gamma\tau\Gamma = \bigcup_j \Gamma\tau_j$, we denote by $m(\sigma, \tau; \rho)$ the number of pairs (i, j) such that $\Gamma\sigma_i\tau_j = \Gamma\rho$. The associative ring thus obtained is called the **Hecke ring** (or **Hecke algebra**) and is denoted by $\mathcal{H}(\tilde{\Gamma}, \Gamma)$. (If $\tilde{\Gamma}$ is a \dagger topological group and Γ is an open compact subgroup, the Hecke ring $\mathcal{H}(\tilde{\Gamma}, \Gamma)$ can also be interpreted as the ring of all \mathbb{Z} -valued continuous functions on $\tilde{\Gamma}$ with compact support provided with a \dagger convolution product; \rightarrow 29 Associative Algebras C.)

As an example, setting $\tilde{\Gamma} = GL^+(2, \mathbb{Q})$, $\Gamma = SL(2, \mathbb{Z})$, we obtain a Hecke ring $\mathcal{H}(\tilde{\Gamma}, \Gamma)$. In virtue of the theory of \dagger elementary divisors, a complete set of representatives of $\Gamma \backslash \tilde{\Gamma} / \Gamma$ is given by

$$\left\{ \begin{pmatrix} a_1 & 0 \\ 0 & a_2 \end{pmatrix} \mid a_1, a_2 \in \mathbb{Q}, a_1, a_2 > 0, a_1 \mid a_2 \right\}.$$

We write $T(a_1, a_2) = \Gamma \begin{pmatrix} a_1 & 0 \\ 0 & a_2 \end{pmatrix} \Gamma$. From the relation $T(a_1 a_2, a_1 a_2) T(a_1^{-1}, a_2^{-1}) = T(a_1, a_2)$ follows the commutativity of $\mathcal{H}(\tilde{\Gamma}, \Gamma)$. Furthermore, if we put, for a positive integer n ,

$$T_n = T(n) = \sum_{\substack{a_1, a_2 \in \mathbb{Z} \\ a_1 a_2 = n}} T(a_1, a_2),$$

then the following multiplication formula holds:

$$T(n) \cdot T(m) = \sum_{d \mid n, m} d T(d, d) \cdot T(nm/d^2).$$

We obtain a representation of $\mathcal{H}(\tilde{\Gamma}, \Gamma)$ in $\mathfrak{M}_k(\Gamma)$ as follows. For $T = \Gamma\sigma\Gamma = \bigcup \Gamma\sigma_i\Gamma$

$\mathcal{H}(\tilde{\Gamma}, \Gamma)$ and $f \in \mathfrak{M}_k(\Gamma)$ we put

$$(f|T)(z) = \sum_i f(\sigma_i(z)) (c_i z + d_i)^{-k} \det(\sigma_i)^l,$$

where $\sigma_i = \begin{pmatrix} a_i & b_i \\ c_i & d_i \end{pmatrix}$ and l is a fixed integer. This representation leaves $\mathfrak{S}_k(\Gamma)$ and $\mathfrak{E}_k(\Gamma)$ invariant. In particular, the representation of T_n (with $l = k - 1$), called the **Hecke operator** (Hecke, *Math. Ann.*, 114 (1937)), is \dagger Hermitian with respect to the Petersson metric.

Following Hecke, we associate with every modular form $f(z) = \sum_{n=0}^{\infty} a_n q^n$ ($q = e^{2\pi i z}$) a \dagger Dirichlet series $\varphi(s) = \sum_{n=1}^{\infty} a_n n^{-s}$. Since $a_n = O(n^{k-1+\epsilon})$ for $f \in \mathfrak{M}_k$ ($k \geq 2$), $\varphi(s)$ is absolutely convergent in the half-plane $\text{Re } s > k$. The conditions for f to be a modular form of weight k are equivalent to the following conditions for φ : (s-k) $\varphi(s)$ can be extended to an entire function of finite genus (actually, of genus 1) and, if we put $R(s) = (2\pi)^{-s} \Gamma(s) \varphi(s)$, $R(s)$ satisfies a functional equation of the form $R(k-s) = (-1)^{k/2} R(s)$. A correspondence between f and φ that satisfies these conditions is one-to-one; in fact we have $a_n = (-1)^{k/2} \text{Res}_{s=k} R(s)$, and the function $g(x) = f(ix) - a_0(x > 0)$ and $R(s)$ are related by the \dagger Mellin transform as follows:

$$R(s) = \int_0^{\infty} g(x) x^{s-1} dx,$$

$$g(x) = \frac{1}{2\pi i} \int_{\text{Res}=\sigma_0} R(s) x^{-s} ds.$$

This correspondence between Dirichlet series and automorphic forms can be generalized to the case of a certain discrete subgroup of $SL(2, \mathbb{R})$, which is not necessarily of the first kind (Hecke, *Math. Ann.*, 112 (1936); [10]). It is also known that if the functional equations for $\sum_{n=1}^{\infty} \chi(n) a_n n^{-s}$ hold for sufficiently many characters χ , then $f = \sum_{n=1}^{\infty} a_n q^n$ is a cusp form with a character for some congruence subgroup (Weil, *Math. Ann.*, 168 (1967); [12]).

Now, suppose that a linear subspace \mathfrak{M} of $\mathfrak{M}_k(\Gamma)$ is invariant under all T_n ($n = 1, 2, \dots$), and let (f_1, \dots, f_κ) ($\kappa = \dim \mathfrak{M}$) be a basis of \mathfrak{M} . If we denote by $\lambda(n)$ the $\kappa \times \kappa$ matrix representing T_n in this basis, it can be shown that there exist $\kappa \times \kappa$ (complex) matrices $B^{(i)}$ ($1 \leq i \leq \kappa$) and $\lambda(0)$ such that we have

$$F(z) = \sum_{n=0}^{\infty} q^n \lambda(n) = \sum_{i=1}^{\kappa} f_i(z) B^{(i)}.$$

Similarly we associate with $F(z)$ a matrix-valued Dirichlet series

$$\Phi(s) = \sum_{n=1}^{\infty} n^{-s} \lambda(n).$$

Then from the multiplicative property of the $\lambda(n)$, we obtain the following \dagger Euler product

expression of $\Phi(s)$:

$$\Phi(s) = \prod_p (I_\kappa - \lambda(p)p^{-s} + p^{\kappa-1-2s}I_\kappa)^{-1},$$

where I_κ denotes the unit matrix of degree κ . In particular, when $\dim \mathfrak{M} = 1$, i.e., when $\mathfrak{M} = C f$, where f is an eigenfunction of all Hecke operators T_n , the corresponding Dirichlet series $\varphi(s)$ has an Euler product of the following form:

$$\varphi(s) = \prod_p (1 - \lambda_p p^{-s} + p^{\kappa-1-2s})^{-1}.$$

For instance, the Dirichlet series corresponding to the Eisenstein series G_k is $(2(2\pi i)^k (k-1)!) \zeta(s) \zeta(s-k+1)$ (where ζ is the Riemann zeta function), which has a well-known Euler product. Since $\mathfrak{S}_{12} = CA$, the Dirichlet series corresponding to $\Delta(z)$ also has an Euler product. (This is part of the Ramanujan conjecture. Ramanujan also conjectured that the quadratic polynomial $1 - \lambda_p X + p^{11} X^2$ appearing in this Euler product has imaginary roots, i.e., $|\lambda_p| < 2p^{1/2}$.) Generalizing the Ramanujan conjecture, Petersson conjectured that all eigenvalues of the Hecke operator T_p in \mathfrak{S}_k have absolute value $\leq 2p^{(k-1)/2}$ (Ramanujan-Petersson conjecture). P. Deligne proved this conjecture for $k \geq 2$, and his method extends to the case when Γ is a congruence subgroup (*Publ. Math. Inst. HES*, 53 (1974)). For $k=1$, see Deligne and J.-P. Serre (*Ann. Sci. Ecole Norm. Sup.*, 7 (1974)). It may be noted that this conjecture was proved earlier for $k=2$ (and for almost all p) by M. Eichler (1954) and by G. Shimura (1958) (\rightarrow 450 Zeta Functions M).

E. The Case of Many Variables [1, 15, 161]

Let X be a bounded domain in C^N and Γ a discontinuous group of analytic automorphisms of X . The Poincaré series of weight $(\rightarrow$ Section A) $m \geq 2$, defined similarly to the case of the unit disk, converges normally in X and expresses an automorphic form of weight m . If $\Gamma \backslash X$ is compact, let (f_1, f_κ) be a basis of the space of Poincaré series of weight m . Then for a sufficiently large m (which is a multiple of the order of Γ_x for all $x \in X$), the map $X \ni z \rightarrow (f_1(z), f_\kappa(z))$ defines in a natural manner a projective embedding of the quotient space $\Gamma \backslash X$ into $P^{\kappa-1}(C)$, which actually gives an analytic isomorphism of $\Gamma \backslash X$ onto a normal projective algebraic variety. It follows that the field of automorphic functions with respect to Γ is an algebraic function field of dimension N , and that every automorphic function can be written as the quotient of two Poincaré series of the same weight. In the case where $\Gamma \backslash X$ is not compact, we first discuss some examples.

F. Siegel Modular Functions [15, 17, 18]

The Siegel upper half-space \mathfrak{H}_n of degree n (or Siegel space of degree n) is, by definition, the space of all $n \times n$ complex symmetric matrices $Z = X + iY$ with the imaginary part $Y > 0$ (positive definite). (\mathfrak{H}_n is analytically equivalent to a symmetric bounded domain.) The group of all (complex) analytic automorphisms of \mathfrak{H}_n is given by the real (projective) symplectic group $Sp(n, \mathbf{R}) / \{\pm I_{2n}\}$, which acts transitively on \mathfrak{H}_n by $Z \rightarrow \sigma(Z) = (AZ + B)/(CZ + D)$ for $\sigma = \begin{pmatrix} A & B \\ C & D \end{pmatrix} \in Sp(n, \mathbf{R})$. The subgroup $\Gamma_n = Sp(n, \mathbf{Z})$ consisting of integral matrices, or the corresponding group of linear fractional transformations, is called the Siegel modular group of degree n . Γ_n is a discontinuous group of the first kind acting on \mathfrak{H}_n .

A Siegel modular form f of weight k or of dimension $-k$ is, by definition, a holomorphic function on \mathfrak{H}_n satisfying the following conditions: (i) for $\sigma = \begin{pmatrix} A & B \\ C & D \end{pmatrix} \in \Gamma_n$, $f(\sigma(Z)) = f(Z) \det(CZ + D)^k$; (ii) f has an integral Fourier expansion of the form $f(Z) = \sum_{T \geq 0} a_T e^{2\pi i \text{tr}(TZ)}$, where T runs over all half-integral positive semidefinite symmetric matrices of degree n . (Note that the Jacobian determinant $J_\sigma(Z)$ of $\sigma = \begin{pmatrix} A & B \\ C & D \end{pmatrix}$ is given by $J_\sigma(Z) = \det(CZ + D)^{-k-1}$.) For $n \geq 2$, condition (ii) is superfluous (M. Koecher, *Math. Z.*, 59 (1954)). We denote by $\mathfrak{M}_k^{(n)} = \mathfrak{M}_k(\Gamma_n)$ the space of all Siegel modular forms of degree n and weight k . When we write $\mathfrak{H}_n \ni Z = \begin{pmatrix} Z_1 & 3 \\ 3 & z \end{pmatrix}$ with $Z_1 \in \mathfrak{H}_{n-1}$, $3 \in C^{n-1}$, $z \in \mathfrak{H}_1$, and

$$\mathfrak{M}_k^{(n)} \ni f(Z) = \sum_{n=0}^{\infty} a_n(Z_1, 3) e^{2\pi i n z},$$

it turns out that $a_0(Z_1, 3)$ depends only on Z_1 and, writing it as $f_1(Z_1)$, we have $f_1 \in \mathfrak{M}_k^{(n-1)}$. The mapping $\Phi: f \rightarrow f_1$ thus defined is a linear mapping from $\mathfrak{M}_k^{(n)}$ into $\mathfrak{M}_k^{(n-1)}$, which is surjective if k is even and $> 2n$ (H. Maass, *Math. Ann.*, 123 (1951)). We denote the kernel of Φ by $\mathfrak{S}_k^{(n)}$ and call $f \in \mathfrak{S}_k^{(n)}$ a cusp form (viewing \mathfrak{H}_{n-1} as a cusp of \mathfrak{H}_n). For $f \in \mathfrak{M}_k^{(n)}$, the following three conditions are equivalent: (a) $f \in \mathfrak{S}_k^{(n)}$; (b) $f(Z) = \sum_{T > 0} a_T e^{2\pi i \text{tr}(TZ)}$; (c) $|f(Z) \det(Y)^{k/2}|$ is bounded. We have $\mathfrak{M}_k^{(n)} = \{0\}$ if $k < 0$ or if both k and n are odd, and $\mathfrak{M}_0^{(n)} = C$. In general, $\dim \mathfrak{M}_k^{(n)}$ is finite and $= O(k^{n(n+1)/2})$ ($k \rightarrow \infty$). The graded algebra $\mathfrak{M}(\Gamma_n) = \sum_{k=0}^{\infty} \mathfrak{M}_k^{(n)}$ is finitely generated, and its Krull dimension is $n(n+1)/2 + 1$. In particular, for $n=2$ the structure of the graded algebra $\mathfrak{M}(\Gamma_2)$ is determined explicitly. (The even part of this algebra is isomorphic to the

polynomial ring of four variables.) Also, $\dim \mathfrak{M}_k^{(2)}$ and the singularities of the quotient variety $\Gamma_2 \backslash \mathfrak{H}_2$ are known explicitly (J. I. Igusa, *Amer. J. Math.*, 84 (1962), 86 (1964); U. Christian).

As an example of Siegel modular forms, we have the **Eisenstein-Poincaré series**, defined as follows:

$$E_{S,k}(Z) = \sum_{\sigma \in \Gamma_n(S) \backslash \Gamma_n} e^{2\pi i \operatorname{tr}(S\sigma(z))} \det(CZ + D)^{-k},$$

where S is an $n \times n$ rational symmetric matrix ≥ 0 , and we put

$$\Gamma_n(S) = \left\{ \begin{pmatrix} U & T^t U^{-1} \\ 0 & {}^t U^{-1} \end{pmatrix} \in \Gamma_n \mid {}^t U S U = S, \right. \\ \left. e^{2\pi i \operatorname{tr}(ST)} = \det(U)^k \right\}$$

This series is convergent for $k > n + \operatorname{rank} S + 1$ if $\operatorname{rank} S < n$ and for $k > 2n$ if $S > 0$, and the totality of $E_{S,k}$ (those series with $S > 0$) spans $\mathfrak{M}_k^{(n)}(\mathfrak{S}_k^{(n)})$ (Maass, *Math. Ann.*, 123 (1951)). †Theta series defined by integral quadratic forms are examples of Siegel modular forms (with a certain level) and are of great significance in the arithmetic of quadratic forms (C. L. Siegel, *Ann. Math.*, (2) 36 (1935)).

The quotient space $\Gamma_n \backslash \mathfrak{H}_n$ can be compactified as follows (I. Satake and W. Baily [15]): There exists a positive integer k_0 such that, for any multiple k of k_0 , any basis of $\mathfrak{M}_k^{(n)}$ defines in a natural manner a one-to-one biholomorphic projective embedding of $\Gamma_n \backslash \mathfrak{H}_n$, of which the image is a Zariski open set of a normal projective algebraic variety. Since the structure of this projective variety is independent of k , we denote it simply by $\Gamma_n \backslash \mathfrak{H}_n$. In other words, $\Gamma_n \backslash \mathfrak{H}_n$ is the projective variety $\operatorname{Proj} \mathfrak{M}(\Gamma_n)$ associated with the graded algebra $\mathfrak{M}(\Gamma_n)$. Then we have $\Gamma_n \backslash \mathfrak{H}_n = \bigcup_{r=0}^n \Gamma_r \backslash \mathfrak{H}_r$. When $n \geq 2$ for $r < n$, $\Gamma_r \backslash \mathfrak{H}_r$ is of codimension ≥ 2 in $\Gamma_n \backslash \mathfrak{H}_n$, so that (by virtue of †Hartogs's continuation theorem) the conditions at the points at infinity in the definitions of modular functions and forms become superfluous. In fact, for $n \geq 2$, if we define a **Siegel modular function of degree n** simply as a Γ_n -invariant meromorphic function on \mathfrak{H}_n , then it can automatically be extended to a meromorphic function on the compactification $\Gamma_n \backslash \mathfrak{H}_n$, and hence be expressed as the quotient of two modular forms of the same weight. It also follows that the field of all Siegel modular functions of degree n is an algebraic function field of dimension $n(n+1)/2$. (These results can also be obtained from the pseudoconcavity of $\Gamma_n \backslash \mathfrak{H}_n$ without using compactification (A. Andreotti and H. Grauert, *Nachr. Akad. Wiss. Göttingen*.) For $n = 2$, the field of Siegel modular

functions is a rational function field. On the other hand, for $\mathbb{F}_1 \equiv 1 \pmod{8}$, $n > 9$, the field of Siegel modular functions is not rational (E. Freitag, *Abh. Math. Sem. Univ. Hamburg* (1978)).

Let Γ be a subgroup of Γ_n of finite index. Then $\Gamma \backslash \mathfrak{H}_n$ can be compactified in the same way as above [23]. However the singularities of $\Gamma \backslash \mathfrak{H}_n$ are extraordinarily complicated (Igusa [24]). When Γ is the principal congruence subgroup $\Gamma_n(N)$ of level $N > 2$, the blowing-up of $\Gamma_n(N) \backslash \mathfrak{H}_n$ along the cusps is nonsingular for $n = 2, 3$ (Igusa, *Math. Ann.*, 168 (1967)). Following Igusa's idea, it is possible to construct an explicit nonsingular compactification of $\Gamma \backslash D$, in which D is a bounded symmetric domain and Γ is a suitable arithmetic subgroup of $\operatorname{Aut}(D)$ ([19]; see also Satake, *Bull. Amer. Math. Soc.*, 79 (1973)). For $D = \mathfrak{H} \times \mathfrak{H}$ and Γ the Hilbert modular group (\rightarrow Section G), F. Hirzebruch has given explicit nonsingular compactifications of $\Gamma \backslash D$ (*Enseignement Math.*, 19 (1973)).

The Hecke theory (\rightarrow Section D) can also be extended to the Siegel modular case. For any integer $m > 0$, let $S_m = S_m^{(n)}$ be the set of $2n \times 2n$ integral matrices M such that ${}^t M J M = m J$,

where $J = \begin{pmatrix} 0 & -I_n \\ I_n & 0 \end{pmatrix}$ and I_n is the identity

matrix of degree n . We define the Hecke operator $T(m)$ on $\mathfrak{M}_k^{(n)}$ by

$$T(m)f = m^{nk-n(n+1)/2} \sum_{\begin{pmatrix} A & B \\ C & D \end{pmatrix} = M \in V(m)} \det(CZ + D)^{-k} f(MZ),$$

where $f \in \mathfrak{M}_k^{(n)}$, $S_m = \bigcup_{M \in V(m)} \Gamma_n M$, and $V(m)$ is a complete system of representatives of $\Gamma_n \backslash S_m$. Then for any prime number p , the formal operator series $D_p(X) = \sum_{n=0}^{\infty} T(p^n) X^n$ is formally equal to a rational function in X :

$$D_p(X) = \frac{P_p(X)}{Q_p(X)},$$

in which $P_p(X)$ and $Q_p(X)$ are polynomials in X of degree $2^{n-2} - 2$ and 2^n , respectively, with coefficients in the ring of Hecke operators (Satake, *Publ. Math. Inst. HES*, 18 (1964)). For $n = 2$ we have (Shimura, *Proc. Nat. Acad. Sci. US*, 49 (1963))

$$D_p(X) = (1 - p^{2k-4} X^2) \{ 1 - T(p)X + (T(p)^2 - T(p^2) - p^{2k-4} X^2 - p^{2k-3} T(p)X^3 + p^{4k-6} X^4) \}^{-1}.$$

Let $f(Z) \in \mathfrak{M}_k^{(2)}$ be a Siegel modular form of degree 2 such that $T(m)f = \lambda(m)f$ for all $m \geq 1$. We define $L_f(s)$ by

$$L_f(s) = \zeta(2s - 2k + 4) \sum_{m=1}^{\infty} \frac{\lambda(m)}{m^s},$$

in which $\zeta(s)$ is the Riemann zeta function. It is known that $L_f(s)$ can be meromorphically continued to the entire plane and satisfies the functional equation

$$\Psi_f(2k-2-s) = \Psi_f(s),$$

where $Y(s) = (2\pi)^{-2s} \Gamma(s) \Gamma(s-k+2) L_f(s)$ and the function $(s-k)(s-k+2) \Psi_f(s)$ is entire (A. Andrianov, *Trudy Math. Inst. Steklov.*, 112 (1971)).

G. Hilbert Modular Functions

Following a suggestion of Hilbert, O. Blumenthal studied a generalization of modular functions of the following type: Let K be a totally real algebraic number field of finite degree, and let $K^{(1)}, \dots, K^{(n)}$ be the conjugates of K , where $n = [K : \mathbb{Q}]$. ("Totally real" means that all the $K^{(i)}$ are real.) For $\alpha \in K$, we denote by $\alpha^{(i)} \in K^{(i)}$ the i th conjugate of α . Let \mathfrak{D} be the +Principal order of K , and consider the group

$$\Gamma_{\mathfrak{D}} = SL(2, \mathfrak{D}) \\ = \left\{ \sigma = \begin{pmatrix} \alpha & \beta \\ \gamma & \delta \end{pmatrix} \mid \alpha, \beta, \gamma, \delta \in \mathfrak{D}, \alpha\delta - \beta\gamma = 1 \right\}.$$

We define the action of $\Gamma_{\mathfrak{D}}$ on the n -fold product of the upper half-plane $\mathfrak{H}^n = \{z = (z_1, \dots, z_n) \mid z_i \in \mathfrak{H}\}$ by

$$a(z) = \left(\frac{\alpha^{(1)} z_1 + \beta^{(1)}}{\gamma^{(1)} z_1 + \delta^{(1)}}, \dots, \frac{\alpha^{(n)} z_n + \beta^{(n)}}{\gamma^{(n)} z_n + \delta^{(n)}} \right)$$

for $\sigma = \begin{pmatrix} \alpha & \beta \\ \gamma & \delta \end{pmatrix}$; then $\Gamma_{\mathfrak{D}}$ becomes a discontinuous group of the first kind ($\Gamma_{\mathfrak{D}}$ can also be considered as an irreducible discrete subgroup of $SL(2, \mathbb{R})^n$). The group $\Gamma_{\mathfrak{D}}$ is called the **Hilbert modular group** of K (in the strict sense). (The definition is sometimes modified by replacing the condition $\alpha\delta - \beta\gamma = 1$ by, say, $\alpha\delta - \beta\gamma = (\text{totally positive unit})$.) If the class number of K is h , the quotient space $\Gamma_{\mathfrak{D}} \backslash \mathfrak{H}^n$ can be compactified by adjoining h points at infinity. Therefore, if $n \geq 2$, a **Hilbert modular function** can be defined as a meromorphic function on \mathfrak{H}^n invariant under $\Gamma_{\mathfrak{D}}$; and similarly a **Hilbert modular form** f of weight k or of dimension $-k$ as a holomorphic function f on \mathfrak{H}^n such that $(f|_{\sigma})(z) = f(\sigma(z)) \prod_{i=1}^n (\gamma^{(i)} z_i + \delta^{(i)})^{-k} = f(z)$ for all $\sigma \in \Gamma_{\mathfrak{D}}$. (In the latter case, f is holomorphic at all cusps, i.e., for every $\sigma \in SL(2, K)$, $f|_{\sigma}$ has an integral Fourier expansion.) For Hilbert modular functions and forms, results quite similar to those for the case $n = 1$ or the case of Siegel modular groups have been obtained (Kloosterman, Maass, K. B. Gundlach, H. Klingen).

H. Further Generalizations

As further generalizations of the notion of modular function, we have Hilbert-Siegel modular functions (I. I. Pyatetskii-Shapiro, Baily, Christian [20], where we can find some 150 references), Hermitian modular functions (H. Braun, Klingen), etc. For the most general case, i.e., for an arithmetically defined discontinuous group acting on a symmetric bounded domain, a unified theory of automorphic functions has been established in the works of Pyatetskii-Shapiro [21, 22] and Baily and A. Borel [23, 24].

On the other hand, exactly as in the classical theory, where the elliptic modular function gave an invariant of 1-dimensional complex tori, generalized modular functions can be viewed as giving an analytic invariant of a certain family of (polarized) Abelian varieties. From this point of view, a deep number-theoretic (and algebrogeometric) study of automorphic functions (initiated by Hecke and Eichler) has been substantially carried forward by the work of Shimura (see the series of his papers in *Ann. Math.* starting from vol. 70 (1959); see also [9, 24, 25]).

From the analytic point of view, the theory of automorphic functions is closely connected with the unitary representation of G in the space $L_2(\Gamma \backslash G)$ (or its adelic analog) [26, 27] (for adelic analogs \rightarrow [12, 131]). In this respect, the trace formula of A. Selberg [28], generalizing the +Poisson summation formula, is of fundamental importance; and actually it can be used effectively for calculations of the dimension of the space of automorphic forms and of the trace of Hecke operators (R. P. Langlands, *Amer. J. Math.*, 85 (1963); H. Shimizu, *Ann. Math.*, (2) 77 (1963), *J. Fac. Sci. Univ. Tokyo*, 10 (1963); also [24]). When $X = G/K$ is a symmetric domain, we can define, for any representation ρ of K , a (matrix-valued) canonical automorphy factor, by which we define (vector-valued) automorphic forms with respect to a discrete subgroup Γ of G , and under a further condition (say, Γ free, $\Gamma \backslash X$ compact, and the highest weight of ρ sufficiently large) we obtain a formula for the dimension of the space of such automorphic forms in terms of the arithmetic genus of $\Gamma \backslash X$ and certain numbers related to the "dual" $X_u = G_u/K$ and the representation ρ [15, 29, 30].

33 (1.5) Axiomatic Set Theory

A. General Remarks

Axiomatic set theory pursues the goal of reestablishing the essentials of G. Cantor's rather intuitive \dagger set theory by axiomatic constructions consistent with modern theories of the foundations of mathematics.

A system of axioms for set theory was first given by E. Zermelo [47], and was completed by A. Fraenkel [8]. J. von Neumann [30] expressed it in \dagger symbolic logic, gave a formal generalization, and eliminated ambiguous concepts. P. Bernays and K. Gödel [2, 11]

further refined and simplified von Neumann's formulation. The theories based on the systems before and after the formal generalization are called **Zermelo-Fraenkel set theory** (ZF) and **Bernays-Gödel set theory** (BG), respectively.

B. Zermelo-Fraenkel Set Theory

ZF is a formal system expressed in first-order predicate logic with the predicate symbol = (equality) and based on the following axioms 1-9 (- 411 Symbolic Logic). These axioms do not contain any predicate symbol other than \in , where $x \in y$ is read "x is an element of y." Any formula containing only \in as a predicate symbol is called a **set-theoretic formula**. Following the usual convention, we omit the outermost universal quantifier, and use **restricted quantifiers** such as $\exists x \in a$, $\forall x \in a$.

Axiom 1 (axiom of extensionality):

$$\forall x(x \in a \equiv x \in b) \rightarrow a = b.$$

This asserts that sets formed by the same elements are equal. The formula $x \in a(x \in b)$ is denoted by $a \subset b$. This means "a is a subset of b." Then Axiom 1 can be expressed by

$$a \subset b \wedge b \subset a \rightarrow a = b.$$

Axiom 2 (axiom of the unordered pair):

$$\exists x \forall y(y \in x \equiv y = a \vee y = b).$$

This asserts the existence, for any sets a and b, of a set x having a and b as its only elements. This x is called the **unordered pair** of a and b and is denoted by $\{a, b\}$. The notion of **ordered pair** is characterized by

$$(a, b) = (c, d) \equiv a = c \wedge b = d.$$

An example of such a set is $(a, b) = \{\{a, a\}, \{a, b\}\}$.

Axiom 3 (axiom of the sum set):

$$\exists x \forall y(y \in x \equiv \exists z \in a(y \in z)).$$

This asserts the existence for any set a of the sum (or union) x of all the sets that are elements of a. This x is denoted by Ua or $S(a)$. We write $a \cup b$ for $U\{a, b\}$ and a' for $a \cup \{a, a\}$.

Axiom 4 (axiom of the power set):

$$\forall x \exists y(y \in x \equiv \forall z \in y(z \in a)).$$

This asserts the existence for any set a of the power set x consisting of all the subsets of a. This x is denoted by $P(a)$. We have $S(P(a)) = a$, so S is a left inverse of P, and the products SP and PS are idempotent.

Axiom 5 (axiom of the empty set):

$$\exists x \forall y(\neg y \in x).$$

This asserts the existence of the empty set. The empty set is denoted by \emptyset or 0.

Axiom 6 (axiom of infinity):

$$\exists x(0 \in x \vee \forall y \in x(y' \in x)).$$

This asserts the existence of a set containing all the natural numbers, where $0, 1 = 0' = \{0\}$, $2 = 1' = \{0, 1\}$, $3 = 2' = \{0, 1, 2\}$. This definition of natural number is due to von Neumann.

Axiom 7 (axiom of separation):

$$\exists x \forall y(y \in x \equiv y \in a \wedge A(y)).$$

This asserts that the existence for any set a and a formula $A(y)$ of a set x consisting of all elements of a satisfying $A(y)$. This x is denoted by $\{y \in a \mid A(y)\}$. This is rather a schema for an infinite number of axioms, for there are an infinite number of $A(y)$. This axiom, also called the **axiom of comprehension** or **axiom of subsets**, was introduced by Zermelo.

For example, the set of all natural numbers is introduced by

$$\{x \in a \mid \forall y(0 \in y \wedge \forall z \in y(z' \in y) \rightarrow x \in y)\},$$

where a is a set satisfying Axiom 6. The set of all natural numbers is denoted by ω or N.

Axiom 8 (axiom of replacement):

$$\exists x \forall y \in a(\exists z A(y, z) \rightarrow \exists z \in x A(y, z)).$$

This asserts the existence for any set a of a set x such that for any y of a, if there exists a z satisfying $A(y, z)$ then such z exists in x. If the relation $A(y, z)$ determines a function, then the image of a set by the relation is included in a set, so by Axiom 7, the image is a set. This axiom was introduced by Fraenkel.

Axiom 9 (axiom of regularity):

$$\exists x A(x) \rightarrow \exists x(A(x) \wedge \forall y \in x(\neg A(y))).$$

This asserts that if there exists a set satisfying $A(x)$, then there is a set x satisfying $A(x)$ but every element y of x does not satisfy the property $A(y)$. This axiom is also called the **axiom of foundation**. Its dual expression, called \in -induction, is of course equivalent to Axiom 9.

Axiom 9' (axiom of E-induction):

$$\forall x(\forall y \in x A(y) \rightarrow A(x)) \rightarrow \forall x A(x).$$

Using this we can show that $\neg x \in x$, $\neg(x \in y \wedge y \in x)$, etc. If we assume the axiom of choice stated below, then this is equivalent to the nonexistence of an infinite descending sequence

$$x_n \in \dots \in x_2 \in x_1.$$

If a model of set theory satisfies the axiom of regularity and has an infinite descending sequence that is not in the model, then such a model is called a nonstandard model.

Axiom 10 (axiom of choice):

$$\forall x \in a \exists y A(x, y) \rightarrow \exists y \forall x \in a A(x, y(x)).$$

This asserts that if for any element x of a there is a set y such that $A(x, y)$, then there is a **choice function** y for the formula, i.e., $A(x, y(x))$ for all x in a . Usually a function is represented by its graph. A set f is called a function defined on a if

$$\forall x \forall y ((x, y) \in f \rightarrow x \in a), \quad \forall x \in a \exists y ((x, y) \in f),$$

$$\forall x \in a \forall y \forall z ((x, y) \in f \wedge (x, z) \in f \rightarrow y = z).$$

This formula is denoted by $\text{Fnc}(f)$; then the formula $A(x, f(x))$ is an abbreviation of

$$\text{Fnc}(f) \wedge \exists y ((x, y) \in f \wedge A(x, y)).$$

The axiom of choice is equivalent to many properties, such as the well-ordering theorem, Zorn's lemma, and Tikhonov's theorem on the product of compact spaces, and it is used widely and essentially in mathematics.

The system of axioms 1 to 9 is called **Zermelo-Fraenkel set theory** and is denoted by **ZF**; the system ZF minus the axiom of replacement is called **Zermelo set theory**, denoted by **Z**; and the system ZF plus the axiom of choice is denoted by **ZFC**.

The system **Z** is weaker than **ZF**. Indeed, the existence of the set ω of all the natural numbers and of $P(\omega)$, $P(P(\omega))$, can be proved in **Z**, but the existence of the set $\{\omega, P(\omega), P(P(\omega)), \dots\}$ cannot be proved in **Z**. However, we can prove its existence in **ZF**.

The theory **ZF** minus the axiom of infinity is called **general set theory**. Its consistency can be reduced to the consistency of the theory of natural numbers as follows. Let n be any natural number and $n = 2^{n_1} + 2^{n_2} + \dots + 2^{n_k}$ ($n_1 < n_2 < \dots < n_k$) be its binary expansion. We can define a model of general set theory by identifying a set with the natural number n and defining $m \in n$ by "m appears as one of the n_i ." In general set theory we can show the existence of 0 , $P(0)$, $P(P(0))$, but the existence of the set $\{0, P(0), P(P(0)), \dots\}$ cannot be proved. However, we can prove its existence in **Z**. The set consisting of all **hereditary** finite sets is the smallest model of general set theory.

C. Bernays-Gödel Set Theory

The existence of $\{u \mid A(u)\}$ for an arbitrary set-theoretic formula $A(u)$ cannot be deduced from the axioms of **ZF**. We call this object a **class** to distinguish it from sets. We introduce a generalized logical system of first-order predicate logic by adding to the logical system used in **ZF** class variables, class constants, and

inference rules with respect to quantifiers for classes. For any set-theoretic formula $A(u)$ in which no ϵ -bound class variable occurs, we adopt

$$\exists X \forall u (u \in X \leftrightarrow A(u))$$

as an axiom, where capital letters X are class variables. The set theory thus obtained is equivalent to **Gödel set theory** [11]. Von Neumann axiomatized set theory by making use of the notion of functions instead of that of classes [30]. In refining this theory and introducing the notion of classes, Bernays and Gödel [2, 11] initiated **Bernays-Gödel set theory**, **BG**.

ZF and **BG** are related as follows: Any formula provable in **ZF** is provable in **BG**, and any set-theoretic formula provable in **BG** and having neither class variable nor class constant is provable in **ZF**. In this sense, the systems can be regarded as essentially equivalent, but as **BG** has class variables and class constants, it is more convenient for expressing set-theoretic notions.

Von Neumann defined the following function R by ϵ -transfinite induction:

$$R(0) = \emptyset, \quad R(\alpha) = \bigcup_{\beta < \alpha} \mathfrak{P}(R(\beta)),$$

where α and β are ordinal numbers and $\bigcup_{\beta < \alpha} \mathfrak{P}(R(\beta))$ denotes the set sum of $\mathfrak{P}(R(0))$, $\mathfrak{P}(R(1))$, \dots , $\mathfrak{P}(R(\beta))$, \dots ($\beta < \alpha$). The function R can be defined by a set-theoretic formula, so it exists as a class. Now consider the model $M = M(\alpha)$ for a fixed ordinal number α . We define sets of the model M as elements of $R(\alpha)$, and classes of the model as subsets of $R(\alpha)$. We denote the \in relation of the model by \in_M . For classes X and Y of the model, we write $X \in Y$, $Y \not\in X$ if $X \in Y$. Then a necessary and sufficient condition for $R(\alpha)$ to be a model of **BG** is that α is an ϵ -inaccessible ordinal number ($\rightarrow 3$ 12 Ordinal numbers). The existence of an ϵ -inaccessible ordinal number cannot be deduced from the axioms of **ZF**. There is a series of studies of axiomatization of set theory in which any number of inaccessible ordinal numbers is assumed to exist [23]. When $R(\alpha)$ is a model of **BG** (**ZF**), it is called a **natural model** of **BG** (**ZF**). Furthermore, if H is $\bigcup_{\alpha} R(\alpha)$ then H satisfies all the axioms of **BG** (**ZF**). As we do not need the axiom of regularity for defining the class H , we see that **BG** (**ZF**) is consistent as long as **BG** (**ZF**) without the axiom of regularity is consistent.

D. Independence of the Continuum Hypothesis and the Axiom of Choice

These axiomatizations of set theory motivated a series of studies from the standpoint of the

foundations of mathematics on problems that remained unsolved after the appearance of Cantor's primitive set theory. Among these, the problem of the relation between the continuum hypothesis and the axiom of choice was central.

Consistency of the Axiom of Choice and the Continuum Hypothesis. Gödel [11] proved that if ZF without the axiom of choice is consistent, then the system obtained by adding to ZF the axiom of choice and the continuum hypothesis is also consistent. To show this, he constructed a model of ZF satisfying the axiom of choice and the generalized continuum hypothesis as follows. Assume first that M is an arbitrary domain of objects among which the \in relation is defined. By a formula on M , we understand a formula having constants of M as its only constants, having \in as its sole predicate symbol, and further having exclusively variables whose ranges are restricted to M . Let us denote by M' the totality of subsets of M defined by a formula $A(x)$ on M . Now we put $M_0 = \{\emptyset\}$, $M_{\alpha+1} = M'_\alpha$, $M_\beta = \bigcup_{\alpha < \beta} M_\alpha$, if β is a limit ordinal number. We call x **constructible** if $x \in M_\alpha$ for some ordinal number α , assumed to be less than the first inaccessible ordinal number, if any. We denote the totality of constructible sets by L , and the totality of sets of ZF by V . We call the assertion $V = L$, that is, every set is constructible, the **axiom of constructibility**. If we add this axiom to ZF, the axiom of choice and the generalized continuum hypothesis become provable. On the other hand, if we regard elements of L as sets of the model and the original \in relation as the \in relation of the model, we have a model of ZF in which the axiom of constructibility holds.

Independence of the Axiom of Choice and the Continuum Hypothesis. Since the result of Gödel, attempts have been made to prove that the axiom of choice is independent of the other axioms. Fraenkel constructed a model of set theory without satisfying the axiom of choice, starting from a countable number of objects that are not sets. A. Mostowski constructed in ZF a model of set theory having objects that are not sets, and he proved that the model satisfies the axiom: Every set can be linearly ordered, but does not satisfy the axiom of choice [27]. E. Mendelson constructed a model of set theory that does not satisfy the axiom of choice by making use of an infinite descending chain $a, \ni a_2 \ni a_3 \ni \dots$ [25]. These models, however, do not satisfy all the axioms of ZF or of Zermelo set theory minus the axiom of choice, even though they satisfy most

of the axioms. Consequently, they are not sufficient for proving independence.

P. J. Cohen [3, 4] proved the following results in connection with the independence of the axiom of choice, the continuum hypothesis, and $V = L$: If ZF is consistent, each of the following conditions has a model. (1) The axiom of choice as well as the generalized continuum hypothesis holds, but there exists an ω satisfying $\omega \notin L$ and $\omega \subset \omega$. (2) $\mathfrak{P}(\omega)$ is not well-ordered. (3) The axiom of choice holds, but the continuum hypothesis does not hold. (4) $\mathfrak{P}(\mathfrak{P}(\omega))$ cannot be linearly ordered.

By (1), we see that $V = L$ is independent of the axiom of choice and the generalized continuum hypothesis: (2) shows the independence of the axiom of choice; and (3) shows that the continuum hypothesis is independent of the axiom of choice. In (4), $\mathfrak{P}(\mathfrak{P}(\omega))$ corresponds to the set F of all real-valued functions defined on the interval $[0, 1]$, and (4) shows that the proposition " F can be linearly ordered" is not deducible in ZF without the axiom of choice.

E. Some Recent Results

Boolean-Valued Set Theory. D. Scott and R. M. Solovay defined models of set theory in which the set-theoretic formula has values in a complete Boolean algebra. This viewpoint is motivated by P. J. Cohen's original notions of the forcing relation and the generic filter.

According to the relation between sets and their representing functions, a function $f: A \rightarrow B$ corresponds to a subset of A when B is a complete Boolean algebra. So by transfinite induction we put

$$V_\alpha^{(B)} = \bigcup_{\beta < \alpha} P^{(B)}(V_\beta^{(B)}),$$

where $P^{(B)}(A)$ is the Boolean-valued power set of A defined by

$$u \in P^{(B)}(A) \equiv u: A \rightarrow B.$$

Let $V^{(B)}$ be the union of all $V_\alpha^{(B)}$'s; then the truth values of the formulas $\llbracket u \in v \rrbracket$ and $\llbracket u = v \rrbracket$ are defined by transfinite induction as

$$\llbracket u \in v \rrbracket = \sum_{x \in \text{dom}(v)} v(x) \cdot \llbracket x = u \rrbracket,$$

$$\llbracket u = v \rrbracket$$

$$= \prod_{x \in \text{dom}(u)} u(x) \Rightarrow \llbracket x \in v \rrbracket \cdot \prod_{x \in \text{dom}(v)} v(x) \Rightarrow \llbracket x \in u \rrbracket,$$

where $a \Rightarrow b$ is an abbreviation for the element $-a + b$ in B .

In $V^{(B)}$ the following properties are satisfied:

- (i) The truth value of any formula provable from ZFC is 1, the largest element of B .
- (ii) Any complete homomorphism $h: B \rightarrow B_2$

can be extended to

$$h: V^{(B_1)} \rightarrow V^{(B_2)},$$

so that the commutative relation

$$h(\llbracket A(u_1, \dots, u_n) \rrbracket) = \llbracket A(h(u_1), \dots, h(u_n)) \rrbracket$$

is satisfied for every restricted formula; further, if h is an epimorphism then it is satisfied for every formula.

(iii) (maximum principle) For any formula $A(x)$ there is an element u of $V^{(B)}$ such that

$$\llbracket \exists x A(x) \rrbracket = \llbracket A(u) \rrbracket.$$

Moreover, if $\llbracket \exists x R(x) \rrbracket = 1$ then there an element u of $V^{(B)}$ such that $\llbracket R(u) \rrbracket = 1$ and

$$\llbracket \exists x (R(x) \wedge A(x)) \rrbracket = \llbracket A(u) \rrbracket.$$

Property (i) means that if $[A] < 1$, then A is not provable from ZFC. Many consistency results in set theory are obtained in this way by constructing special partial order structures, topological spaces, or complete Boolean algebras.

Axiom of Strong Infinity. The axiom of infinity, Axiom 6, of ZF asserts that there exists a set including the set ω of all natural numbers. The set ω is the smallest infinite cardinal number. In general, the axiom of strong infinity is stated in a form such that certain special properties of ω are satisfied for an uncountable cardinal number.

Though such an axiom asserts the existence of large cardinal numbers, their properties sometimes reflect, for example, those of the real numbers, or of the set of real numbers, etc.

We state here some typical examples:

(i) **Weakly inaccessible cardinal number.** This is a regular limit cardinal number, that is,

$$\text{cf}(\omega_\alpha) = \omega_\alpha, \quad \forall \beta < \alpha (\omega_{\beta+1} < \omega_\alpha).$$

(ii) **Strongly inaccessible cardinal number.**

$$\text{cf}(\omega_\alpha) = \omega_\alpha, \quad \forall \beta < \alpha (2^{\omega_\beta} < \omega_\alpha).$$

(iii) **Weakly compact cardinal number.** ω_α is uncountable and the space $X = 2^{\omega_\alpha}$ with $<_{\omega_\alpha}$ -topology is ω_α -compact.

(iv) **Measurable cardinal number.** ω_α is uncountable and there is a nonprincipal $<_{\omega_\alpha}$ -additive 2-valued measure $\mu: P(\omega_\alpha) \rightarrow \{0, 1\}$.

(v) **Strongly compact cardinal number.** ω_α is uncountable and any product of $2 = \{0, 1\}$ with $<_{\omega_\alpha}$ -topology is ω_α -compact.

The strength of these properties increases in the order presented here. Properties (i) to (iii) are compatible with the axiom of constructibility $V=L$. And (iv) implies $V \neq L$ while it is compatible with $V=L(\mu)$. But (v) implies $V \neq L(a)$ for any set a .

There are many other stronger axioms of

infinity, and the consistency proofs of these "axioms" within ZF or ZFC would involve essential difficulties. Inconsistency proofs of these properties, if they exist, would be very interesting.

F. Examples of Results

(1) Cardinality and Cofinality (\rightarrow 3 12 Ordinal Numbers). (i) (W. B. Easton [6]) Let \mathfrak{M} be a model of ZFC (the Zermelo-Frankel axioms plus the axiom of choice) in which the GCH (generalized continuum hypothesis) is valid, i.e., $\forall \alpha (2^{\omega_\alpha} = \omega_{\alpha+1})$, and let g be a function from ordinals to ordinals in \mathfrak{M} such that $\forall \alpha, \beta (\alpha < \beta \Rightarrow \omega_{g(\alpha)} \leq \omega_{g(\beta)})$ and $\forall \alpha (\omega_\alpha < \text{cf}(\omega_{g(\alpha)}))$. Then there is a Boolean model \mathfrak{N} of ZFC, $\mathfrak{N} \supset \mathfrak{M}$, having the same cofinality and satisfying $2^{\omega_\alpha} = \omega_{g(\alpha)}$ for every regular cardinal. (This means that König's condition $\text{cf}(2^{\omega_\alpha}) > \omega_\alpha$ is the only restriction on the cardinality of powers of regular ω_α .)

(ii) (J. H. Silver [39]) Suppose

$$\omega < \text{cf}(\alpha) = \text{cf}(\omega_\alpha) < \omega_\alpha.$$

Then for any $\lambda < \text{cf}(\alpha)$

$$\forall \nu < \alpha (2^{\omega_\nu} \leq \omega_{\nu+\lambda}) \rightarrow 2^{\omega_\alpha} \leq \omega_{\alpha+\lambda}.$$

However, the validity of the implication

$$\forall n < \omega (2^{\omega_n} = \omega_{n+1}) \rightarrow 2^{\omega_\omega} = \omega_{\omega+1}$$

still remains an open question. And it is known that if there is a model for

$$\forall n < \omega (2^{\omega_n} = \omega_{n+1}), \quad 2^{\omega_\omega} > \omega_{\omega+1},$$

then there is a model in which there are many measurable cardinal numbers.

(iii) (K. Prikry [31]) Let ω_α be a measurable cardinal number in a model M of ZFC. Then there is a Boolean extension N of M in which the notion of cardinality is not changed but the notion of cofinality is changed, that is $\text{cf}(\omega_\alpha) = \omega_\alpha$ in M but $\text{cf}(\omega_\alpha) = \omega$ in N .

(iv) (Solovay) Let ω_α be a strongly compact cardinal number. Then for any strong-limit singular cardinal $\omega_\beta > \omega_\alpha$ the continuum hypothesis holds at ω_β ; that is, the implication

$$\text{cf}(\omega_\beta) < \omega_\beta, \quad \forall \gamma < \beta (2^{\omega_\gamma} < \omega_\beta) \rightarrow 2^{\omega_\beta} = \omega_{\beta+1}$$

is provable.

(2) Lebesgue Measurability and the Baire Property. As is well known, every Δ_1^1 (Borel) set (and consequently every Σ_1^1 (analytic) set) of real numbers is Lebesgue measurable and has the Baire property.

(i) (Gödel) $V=L$ implies the existence of a Δ_2^1 set of real numbers that is neither Lebesgue measurable nor has the Baire property.

Let DC denote the **principle of depending choice**:

$$\forall x \in a \exists y \in aP(x, y) \\ \rightarrow \exists f: \omega \rightarrow a \forall n \in \omega P(f(n), f(n+1)).$$

DC is adequate for the development of the classical notions of measure theory, such as Jordan decomposition, the Radon-Nikodym derivate, etc. Let I denote the hypothesis $\exists \alpha (\text{cf}(\omega_\alpha) = \omega_\alpha \wedge \forall \beta < \alpha (2^{\omega_\beta} < \omega_\alpha))$ (strongly inaccessible).

(i) (Solovay [40]) The consistency of ZFC and I implies that of ZF and either of the following two axioms:

(a) DC plus the hypothesis that every set of real numbers is Lebesgue measurable and has the Baire property.

(b) The axiom of choice plus the hypothesis that every set of real numbers definable by an ω sequence of ordinals is Lebesgue measurable and has the Baire property.

Axiom (a) means that DC is not strong enough to construct a (Lebesgue) nonmeasurable set, while Axiom (b) implies that every projective set is Lebesgue measurable and has the Baire property, and hence implies that the set of all constructible real numbers, as a Σ_2^1 set, has Lebesgue measure 0, and is of the first category.

(3) Martin's Axiom. Let B be a Boolean algebra. We say that B satisfies ω_α c.c. (chain condition) if the cardinality of every disjoint family of positive elements of B is at most ω_α . Let B^* denote the topological space consisting of all homomorphisms $h: B \rightarrow 2 = \{0, 1\}$ with the open base $U(a) = \{h \mid h(a) = 1\}$ ($a \in B$); then B^* is a * Baire space. Then **Martin's axiom** (MA) is: Let B be an ω c.c. Boolean algebra and $\alpha < 2''$. Then the intersection of a dense open sets is dense in B^* . Since $\{h \mid \sum_\nu h(a_\nu) = h(b)\}$ is dense and open in B^* if $\sum_\nu a_\nu = b$, MA means the existence of an $h \in B^*$ preserving any given set of α ($< 2''$) equations in B . If $2'' = \omega_1$, MA merely reduces to the Baire property of B^* . However, if $2'' > \omega_1$, then the ω c.c. hypothesis is essential, for there exists a B satisfying ω_1 c.c. such that B^* contains ω_1 dense open sets with empty intersection.

(i) (Solovay and S. Tennenbaum [43]) The consistency of ZF implies that of ZFC, MA, and $2^\omega > \omega_1$.

(ii) (D. A. Martin and Solovay [24]) ZFC, MA, and $2'' > \omega_1$ imply the propositions:

- (a) $\forall \omega_\alpha < 2^\omega (2^{\omega_\alpha} = 2^\omega)$, hence $2'' = 2^\omega$;
- (b) the totality of the first category sets of Lebesgue measure zero sets is α -additive for any $\alpha < 2''$;
- (c) every Σ_1^1 set of real numbers is Lebesgue measurable and has the Baire property.

(4) Suslin's Hypothesis (SH) is: Every dense, linear, order complete set without end points, having at most ω disjoint intervals, is order isomorphic to the continuum of real numbers.

(i) (T. J. Jech, Tennenbaum) The consistency of ZF implies that of (a) ZFC, \neg SH, and GCH, as well as (b) ZFC, \neg SH, and $2'' > \omega_1$

(ii) (R. Jensen [15]) The consistency of ZF implies that of ZFC, SH, and $2'' = \omega_1$.

(iii) (Solovay and Tennenbaum [43]) ZFC, MA, and $2'' > \omega_1$ imply SH.

(iv) (Jensen [15]) $V = L$ implies \neg SH.

(5) Measurable and Real-Valued Measurable Cardinals. A cardinal $\kappa > \omega$ is said to be **measurable** if there is a measure $\mu: \mathfrak{P}(\kappa) \rightarrow \{0, 1\}$ with (a) $\mu(\kappa) = 1$, (b) $\forall v < \kappa (\mu(\{v\}) = 0)$ and (c) $\mu(\sum_{v < \alpha} A_v) = \sum_{v < \alpha} \mu(A_v)$; and κ is said to be **real-valued measurable** if there exists a $\mu: \mathfrak{P}(\kappa) \rightarrow [0, 1]$ that satisfies (a), (b) and (c), and is not measurable.

Let MC (RMC) denote the existence of a measurable cardinal (real-valued measurable cardinal).

(i) (S. Ulam [45]) The existence of an ω -additive measure $\mu: \mathfrak{P}(A) \rightarrow [0, 1]$, with $\mu(A) = 1$ and $\forall x \in A (\mu(\{x\}) = 0)$, implies RMC or MC; RMC implies the existence of an extension of Lebesgue measure defined on $\mathfrak{P}([0, 1])$; every real-valued measurable cardinal is $\leq 2''$ and weakly inaccessible.

(ii) Every measurable cardinal is strongly (hyper) inaccessible, and (a) $\exists \alpha F(\alpha) \rightarrow \exists \alpha < \omega_1 F(\alpha)$ for any Σ_1^1 formula $F(\alpha)$ on the ordinal numbers, (b) $\exists \alpha F(\alpha) \rightarrow \exists \alpha < \mu_1 F(\alpha)$ for any Π_1^1 formula $F(\alpha)$ and the smallest measurable μ_1 . (Many results have been obtained concerning the ordinal magnitude of ω_1 and the measurable cardinals.)

(iii) (Solovay [41]) The consistency of ZFC and MC is equivalent to that of ZFC and RMC.

(iv) (Martin and Solovay [24]) ZFC, RMC, and MA are not consistent.

(v) (Lévy and Solovay [21]) The consistency of ZFC and MC implies that of ZFC, MC, MA, and $2^\omega > \omega_2$.

(vi) (Solovay) ZFC and MC imply that every Σ_2^1 set of real numbers is Lebesgue measurable.

(vii) (Martin, Solovay) ZFC, MC, MA, and $2'' > \omega_2$ imply that every Σ_3^1 set of real numbers is Lebesgue measurable and has the Baire property.

(viii) (Silver [38]) The consistency of ZFC and MC implies that of ZFC and MC as well as the existence of (Lebesgue) non-measurable Λ_3^1 sets of real numbers.

(6) Axiom of Determinateness. We consider the following infinite game. Let A be a set consist-

ing of functions ω to ω . The players I and II choose alternatively natural numbers n_i and m_i , and, for the resulting infinite sequence, if $(n_1, m_1, n_2, \dots, n_k, m_k, \dots) \in A$,

then I wins, otherwise II wins.

A function $\sigma: \bigcup_{n \in \omega} \omega^n \rightarrow \omega$ is called a **strategy**. If II plays according to the sequence $\underline{m} = (m_1, m_2, \dots, m_k, \dots)$ and I plays according to the strategy σ , then the resulting sequence is

$$\sigma^* \underline{m} = (\sigma(\emptyset), m_1, \sigma(m_1), \dots, m_k, \sigma(m_1, \dots, m_k), \dots).$$

The strategy σ is called a **winning strategy** for I of the game defined above, if for any play \underline{m} of II, the resulting play $\sigma^* \underline{m}$ is in the set A , and similarly for the winning strategy of II.

The axiom of determinateness AD is the assertion that for any $A \subset \omega^\omega$, the player I or II has a winning strategy.

(i) (J. Mycielski [28]) Assume ZF and AD; then we have:

- (a) axiom of choice for countable sequence of sets of real numbers;
- (b) every set of real numbers is Lebesgue measurable and has the Baire property, so the axiom of choice does not hold;
- (c) every uncountable set of real numbers contains a perfect set.

(ii) (Solovay) Assume ZF and AD; then we have:

- (a) cardinalities of ω_1 and 2^ω are not comparable;
- (b) ω_1 and ω_2 are measurable cardinals, but ω_3 is a singular cardinal such that $\text{cf}(\omega_3) = \omega_2$.

(iii) (Martin) In ZFC, every Borel, namely Δ_1^1 , game is determined.

(iv) (Martin, Solovay) In ZFC:

- (a) if there exists a measurable cardinal, then every analytic, namely Π_1^1 , game is determined;
- (b) if every Δ_2^1 -game is determined, then there is a model of ZFC with many measurable cardinal numbers.

Since the axiom of determinateness AD is very strong, there is some suspicion that it might contradict ZF. But at present there is no such evidence.

34 (11.5) Axiom of Choice and Equivalents

A. The Axiom of Choice

In set theory, the following axiom is known as the **axiom of choice**: For any nonempty family \mathfrak{A} of nonempty subsets of a set X , there exists a single-valued function f , called the **choice function**, whose domain is \mathfrak{A} , such that for every element A of \mathfrak{A} the value $f(A)$ is a member of A . This axiom is equivalent to each of the following three propositions: (1) If $\{A_\lambda\}_{\lambda \in \Lambda}$ is a family of sets not containing the empty set and with an index set Λ , then the Cartesian product $\prod_{\lambda \in \Lambda} A_\lambda$ is not the empty set. (2) If a set A is a disjoint union $\bigcup_{\lambda \in \Lambda} A_\lambda$ of a family of subsets $\{A_\lambda\}_{\lambda \in \Lambda}$, which does not contain the empty set, there exists a subset B , called the **choice set**, of A such that every intersection of B and A_λ ($\lambda \in \Lambda$) contains one and only one element. (3) For every mapping f from a set A onto a set B , there is a mapping from B to A such that $f \circ g = 1$, (identity mapping). Also equivalent to the axiom of choice are the well-ordering theorem and Zorn's lemma, which are discussed in the following sections.

B. The Well-Ordering Theorem

In 1904, E. Zermelo [2] first stated the axiom of choice and used it for his proof of the **well-ordering theorem**, which says that every set can be well-ordered by an appropriate ordering. Conversely, the well-ordering theorem implies the axiom of choice. Many important results in set theory can be obtained by using the axiom of choice, for example, that \aleph_1 cardinal numbers are comparable, or that various definitions of the finiteness or infiniteness of sets are equivalent. Various important theorems outside of set theory, e.g., the existence of bases in a \aleph_1 linear space, compactness of the direct product of compact \aleph_1 topological spaces (\aleph_1 -Tikhonov's theorem), the existence of a subset which is not \aleph_1 -Lebesgue measurable in Euclidean space, etc., are proved using the axiom of choice. But for those proofs the well-ordering theorem or Zorn's lemma (stated

below) are used more often than the axiom of choice.

Using the well-ordering theorem, it can be proved in the following manner that for every field k , any linear space X over k has a basis. Let $\{x_v\}_{v \in A}$ be an enumeration of X . By \uparrow transfinite induction, we can define the function f from X to $B = \{0, 1\}$ such that (i) if $x_0 = 0$, $f(x_0) = 0$; if $x_0 \neq 0$, $f(x_0) = 1$; (ii) for $v > 0$, if x_v is expressed as a linear combination of elements of $\{x_\mu \mid \mu < v, f(x_\mu) = 1\}$, $f(x_v) = 0$; otherwise $f(x_v) = 1$. Then $U = \{x \in X \mid f(x) = 1\}$ is a basis of X .

C. Zorn's Lemma

An ordered set X is called an **inductively ordered set** if every \uparrow totally ordered subset of X has an \uparrow upper bound. A condition C for sets is called a **condition of finite character** if a set X satisfies C if and only if every finite subset of X satisfies C . A condition C for functions is called a **condition of finite character** if C is a condition of finite character for the graph of the function. **Zorn's lemma** [4] can be stated in any one of the following ways, which are all equivalent to the axiom of choice. It is often more convenient to use than the axiom of choice or the well-ordering theorem.

- (1) Every inductively ordered set has at least one maximal element.
- (2) If every well-ordered subset of an ordered set M has an upper bound, then there is at least one maximal element in M .
- (3) Every ordered set A has a well-ordered subset W such that every upper bound of M belongs to W .
- (4) For a condition C of finite character for sets, every set X has a maximal (for the relation of the inclusion) subset of X that satisfies C .
- (5) Let C be a condition of finite character for functions from X to Y . Then, in the set of functions that satisfy C , there is a function whose domain is maximal (for the relation of the inclusion).

Using Zorn's lemma (1), we can prove again in the following way any linear space X over a field k has a basis. Let \mathfrak{A} be the set of all non-empty subsets A of X such that arbitrary finite subsets of A are linearly independent over k . \mathfrak{A} is not empty. If we order \mathfrak{A} by the relation of inclusion, then \mathfrak{A} is an inductively ordered set. By Zorn's lemma (1), there is a maximal element U of \mathfrak{A} . Since U is maximal, U is a basis of X .

The same theorem is proved as follows using Zorn's lemma (4). Condition C for the subset A of X , that arbitrary finite subsets of A are linearly independent over k , is a condition

of finite character. Hence there is a maximal subset U that satisfies C and is a basis of X .

Concerning recent developments regarding the axiomatic basis for the axiom of choice \rightarrow 33 Axiomatic Set Theory D.

35 (1.2) Axiom Systems

A. History

A mathematical theory is based on a specific system of axioms, i.e., a system of hypotheses from which the whole theory is deduced without reliance on other assumptions.

One of the first deductive methods of mathematical reasoning was utilized by Thales, who returned to Greece from Egypt with the knowledge of surveying methods, and who deduced additional results from that empirical knowledge. His method gave impetus to the development of Greek geometry, which flowered with the Pythagorean school and research by members of Plato's Academy. In the course of this development, the deductive method led to the idea of constructing the whole theory upon a system of "absolutely obvious" statements from which the whole theory could be deduced. Euclid systematized Greek geometry in his *Elements* utilizing this idea. His work became the basis of geometry after the Renaissance, and Greek geometry came to be called \uparrow Euclidean geometry. In the *Elements*

Euclid called the basic obvious statements **common notions** when they were of general nature, and **postulates** when they were specifically geometric. Both were later called **axioms** (or **postulates**).

Among the axioms stated by Euclid, the “fifth postulate” concerning parallels was longer and more complicated than the other axioms. Many efforts were made to deduce this particular axiom from the other axioms. The failure of these attempts suggested the possibility of establishing a †non-Euclidean geometry, which was actually done by N. I. Lobachevskii and J. Bolyai, who replaced the fifth postulate by its negation and showed that the new system of “axioms” was as valid as the classical one. This development naturally led to a new evaluation of the idea of axioms, and eventually the traditional concept of recognizing the axioms as obvious truths was replaced by the understanding that they are hypotheses for a theory. D. Hilbert [1] established the latter idea as **axiomatization** and claimed that the whole science of mathematics should be built upon a system of axioms. His idea became the foundation of present-day mathematics. Hilbert reorganized classical geometry based upon his idea and published his result in *Foundations of Geometry* (1899).

B. Systems of Axioms

The **system of axioms** of a theory, i.e., the system of basic hypotheses from which we hope to deduce the whole theory, is written in **undefined terms** (or in terms of **undefined concepts**) by means of which all other terms are defined. On the other hand, a given theory is **axiomatized** by specifying such a system of axioms upon which the theory may be reorganized. It should also be noted that a system of axioms determines a †structure (→ 409 Structures).

A system of axioms is considered to be mathematically valid if and only if it is **consistent**. It is also desirable that the axioms in such a system be mutually **independent** (i.e., the negation of any one of the axioms is still consistent with the others). When such a system is not independent, it can be simplified by deleting redundant axioms from it.

When any two models of a system of axioms are isomorphic to each other, we call the system **complete** or **categorical** (→ 409 Structures). For example, the system of axioms (I)–(V) postulated by Hilbert as the foundation for Euclidean geometry is **complete** (→ 155 Foundations of Geometry), whereas the systems of axioms for the theories of †groups, †rings, or †fields are not complete since there

are nonisomorphic groups, etc. Although it is desirable that the systems of axioms postulated for a given theory (e.g., the †theory of real numbers, or Euclidean geometry) be **complete**, the study of partial systems that may not be complete is also important (→ 156 Foundations of Mathematics).

B

36 (XII.1 7) Banach Algebras

A. Definition [1-4]

A real or complex [†]Banach space R is called a **Banach algebra** (or **normed ring**) if a multiplication law between elements of R is introduced that makes R an [†]associative algebra and if $\|xy\| \leq \|x\| \cdot \|y\|$ is satisfied. The complex case is generally easier to handle, and a real Banach algebra can always be embedded in a complex one isomorphically and isometrically. When a Banach algebra contains a unity element e with respect to the multiplication, i.e., it is **unital**, we can suppose $\|e\| = 1$. If it is not unital, we can adjoin a unity element to it.

B. Examples

1. Let $C_0(\mathfrak{M})$ be the set of complex- (real-) valued continuous functions $x(\xi)$ on a locally compact space \mathfrak{M} that vanish at infinity. Endowed with the pointwise operations and the [†]supremum norm (- 168 Function Spaces), it forms a complex (real) Banach algebra. In the complex case, it has the involution $x^*(\xi) = \overline{x(\xi)}$.

2. Let X be a Banach space. The set $\mathcal{B}(X)$ of [†]bounded linear operators on X forms a Banach algebra if we define addition, multiplication by scalars, multiplication between elements, and the norm in the usual fashion.

3. Let G be a locally compact Hausdorff group (- 423 Topological Groups) and μ be its [†]left-invariant Haar measure. The Banach space $L_1(G)$ (with respect to μ) can be made into a Banach algebra by defining $xy(g) = \int x(h)y(h^{-1}g)d\mu(h)$ (- Section L).

4. Every subalgebra of a Banach algebra R , which is closed in the norm topology, is a Banach algebra with respect to the original algebraic operations and norm and is called a **closed subalgebra** of R .

Throughout this article, all Banach algebras are supposed to be complex Banach algebras unless otherwise specified.

C. Spectrum of an Element

We define a new operation $x \cdot y$ in R by setting $x \cdot y = x + y - xy$. If $x \cdot y = y \cdot x = 0$, y is called a **quasi-inverse** of x . When a unity element e exists, y is a quasi-inverse of x if and only if $e - y$ is an inverse of $e - x$. For a complex number λ such that $|\lambda| > \|x\|$, we see that

$\lambda^{-1}x$ possesses a quasi-inverse y given by the strongly convergent series $y = -\sum_{n=1}^{\infty} \lambda^{-n}x^n$. The set of all complex numbers λ such that $\lambda^{-1}x$ does not have a quasi-inverse is called the **spectrum** of x and is denoted by $\text{Sp}(x)$. (When x itself does not have an inverse, in particular, when R does not contain a unity element, we include 0 in this set.) $\text{Sp}(x)$ is a bounded closed set in the complex plane, and $\sup\{|\lambda| \mid \lambda \in \text{Sp}(x)\} = \lim_{n \rightarrow \infty} \|x^n\|^{1/n}$. In Example 2, this spectrum is the spectrum of the operator x , and the problem of determining the behavior of this spectrum constitutes one of the central problems in the theories of Banach and Hilbert spaces.

D. Representations of a General Banach Algebra [1, 2]

We understand by a **representation** of a Banach algebra R on a Banach space X any algebraic homomorphism π of R into the algebra $\mathcal{B}(X)$ (see Example 2) satisfying $\|\pi(x)\| \leq \|x\|$ for all $x \in R$. We call X the **representation space**. A Banach algebra always possesses an isomorphic and isometric representation. Especially important are the **irreducible representations**. A vector subspace (closed or not) Y of X is an invariant subspace if $\pi(x)Y \subset Y$ for any $x \in R$. A representation is called algebraically irreducible if the invariant subspaces are trivial, i.e., they are only $\{0\}$ or X . A representation is said to be topologically irreducible if closed invariant subspaces are trivial. The [†]kernel of an algebraically irreducible representation is called a **primitive ideal**, which can alternatively be defined in the following way: A left ideal $J (\neq \{0\}, R)$ is **regular**, by definition, if R contains an element u , a unity element modulo J , such that $x - xu \in J$ for any $x \in R$. Such an ideal is always contained in a maximal left ideal, which in turn is necessarily regular and closed. A two-sided ideal I is primitive if it is the set of elements a in R for which $aR \subset J$, where J is some fixed regular maximal left ideal. If R is commutative, a primitive ideal is a regular maximal ideal, and conversely. The intersection of all primitive ideals is called the **radical** of R , and when it is $\{0\}$, R is called **semisimple**.

The set of primitive ideals \mathfrak{J} is known as the **structure space** of R , in which the **hull-kernel topology** (or **Jacobson topology**) is introduced. The [†]closure of a set \mathfrak{A} in \mathfrak{J} is, under this topology, the set of primitive ideals containing the intersection of the ideals in \mathfrak{A} . This topology is rather intractable; even in commutative cases, it does not coincide with the Gel'fand topology (\rightarrow Section E), in general.

E. The Gel'fand Representation of a Commutative Banach Algebra

A complex Banach algebra is a field if and only if it coincides with the field \mathbb{C} of complex numbers (**Gel'fand-Mazur theorem**). This is the most fundamental fact in the study of commutative Banach algebras. Now let R be a commutative Banach algebra. Then every regular maximal ideal J of R is closed and the quotient algebra R/J is isomorphic to \mathbb{C} , so that the quotient mapping $R \rightarrow R/J$ is viewed as a complex-valued homomorphism of R . Conversely, if φ is a nonzero complex-valued homomorphism of R , it has norm ≤ 1 as a linear functional on R and its kernel, say R_φ , is a regular maximal ideal of R such that φ is exactly the quotient mapping $R \rightarrow R/R_\varphi$. The set $\Pi(R)$ of nonzero complex-valued homomorphisms (or regular maximal ideals) of R endowed with the weak* topology of the Banach space dual R' of R is called the **maximal ideal space** of R . $\mathfrak{M}(R)$ is a locally compact Hausdorff space, and its topology is called the **Gel'fand topology**. For each $x \in R$ we define a function \hat{x} on $\mathfrak{M}(R)$ by setting $\hat{x}(\varphi) = \varphi(x)$. Then the mapping $x \rightarrow \hat{x}$ is a homomorphism of R into the algebra $C_0(\mathfrak{M}(R))$ of all continuous complex-valued functions on $\mathfrak{M}(R)$ vanishing at infinity. This is the **Gel'fand representation** of R whose image, the **Gel'fand transform** of R , is denoted by \hat{R} . Concerning this, we have (1) $\mathfrak{M}(R)$ is compact if R has a unity element; (2) $\text{Sp}(x)$ equals the closure of the range $\hat{x}(\mathfrak{M}(R))$ of \hat{x} ; (3) the representation $x \rightarrow \hat{x}$ is norm-decreasing if $C_0(\mathfrak{M}(R))$ is endowed with the supremum norm; (4) $\|\hat{x}\|_\infty (= \sup\{|\hat{x}(\varphi)| \mid \varphi \in \mathfrak{M}(R)\})$ equals $\lim_{n \rightarrow \infty} \|x^n\|^{1/n}$. The kernel of the Gel'fand representation of R is the **radical** of R , which consists of **generalized nilpotent elements** of R .

F. Banach Star Algebras

An **involution** in a Banach algebra R is an operation $x \rightarrow x^*$ that satisfies (1) $(x + y)^* = x^* + y^*$; (2) $(\lambda x)^* = \bar{\lambda} x^*$; (3) $(xy)^* = y^* x^*$; (4) $(x^*)^* = x$. A Banach algebra with an involution is called a **Banach *-algebra**. A ***-homomorphism** Φ between two Banach *-algebras is an algebraic homomorphism which preserves involutions, i.e., $\Phi(x^*) = \Phi(x)^*$. To represent a Banach *-algebra we prefer a ***-representation**, i.e., a representation $x \rightarrow T_x$ on a Hilbert space such that T_{x^*} is equal to the adjoint T_x^* of T_x for any $x \in R$.

G. C*-Algebras [5–10]

A Banach *-algebra A satisfying $\|x^* x\| = \|x\|^2$ for all $x \in A$ is called a **C*-algebra**. Every C*-

algebra is *-isomorphic and -isometric to a Banach algebra of operators on a Hilbert space (see Example 2) that contains, along with an operator, its adjoint (the **Gel'fand-Vaĭmark theorem**). A C*-algebra is semi-simple, and a commutative C*-algebra A is *-isomorphic to $C_0(\mathfrak{M}(A))$ under the Gel'fand representation. A topologically irreducible *-representation of a C*-algebra is also algebraically irreducible (R. V. Kadison), and the set of unitary equivalence classes of these irreducible *-representations is called the **dual space**. It becomes a topological space if we introduce the hull-kernel topology inherited from the structure space, but other topologies are also introduced. Moreover, for the study of separable C*-algebras, Borel structure in the sense of G. W. Mackey is a very powerful tool. C*-algebras also have intimate connections with the theory of unitary representations of a topological group (see below) and with quantum physics. Many works have been published on *-representations, dual spaces, etc.

A linear functional ω on a C*-algebra A is said to be **positive** if $\omega(x^* x) \geq 0$ for any $x \in A$. For any nonzero positive linear functional ω of A , there exist a *-representation (π_ω, H_ω) of A on a Hilbert space H , and a vector $\xi_\omega \in H_\omega$ such that $\omega(a) = (\pi_\omega(a)\xi_\omega, \xi_\omega)$ for all $a \in A$ and that the subspace $\{\pi_\omega(a)\xi_\omega \mid a \in A\}$ is dense in H_ω . We call (π_ω, H_ω) a **cyclic representation** of A induced by ω . A *-representation (π, H) of A is called **universal** if for any *-representation (ρ, K) of A there exists a σ -weakly continuous *-homomorphism $\tilde{\rho}$ of $n(A)''$ onto $p(A)''$ such that $\rho(a) = (\tilde{\rho} \circ \pi)(a)$ for all $a \in A$, where $\pi(A)''$ is the double commutant of $\pi(A)$ and so is a von Neumann algebra (\rightarrow 308 Operator Algebras). Von Neumann algebras $\pi(A)''$ for universal representations π of A are mutually *-isomorphic, so that they determine the **enveloping von Neumann algebra** of A . Especially, the direct sum π of all cyclic representations π_ω is a universal representation and there is a unique isometric isomorphism of $n(A)''$ onto the second dual A^{**} of A that is bicontinuous in the σ -weak topology of $n(A)''$ and the $\sigma(A^{**}, A^*)$ -topology of A^{**} . So A^{**} is identified with the enveloping von Neumann algebra of A .

H. Some Classes of C*-Algebras

Let A be a C*-algebra. If A is a **CCR (liminal C*-) algebra** if it is mapped to the algebra of compact operators under any irreducible *-representation. It is a **GCR (postliminal C*-) algebra** if every nonzero quotient C*-algebra of A has a nonzero CCR closed two-sided ideal. These classes of C*-algebras have inter-

esting properties. For example, the dual space of a separable C^* -algebra is a ${}^{\dagger}T_0$ space (${}^{\dagger}T_1$ space) if and only if the algebra is GCR (CCR) (J. Glimm).

A is called an **AF (approximately finite) algebra** if it is the uniform closure of an increasing sequence of finite-dimensional C^* -algebras (0. Bratteli). AF algebras are classified by so-called dimension groups. To see this, we call an ordered Abelian group G (written additively) a **Riesz group** if (a) for any integer $n > 0$ and any $g \in G$, $ng \geq 0$ implies $g \geq 0$ and (b) for any g_i, h_j ($1 \leq i \leq m, 1 \leq j \leq n$) in G with $g_i \leq h_j$ for all i and j , there exists $k \in G$ with $g_i \leq k \leq h_j$ for all i, j . Then the isomorphism classes of AF algebras correspond bijectively to the isomorphism classes, as local semi-groups, of generating upward-directed hereditary subsets of the positive cones of countable Riesz groups, and a dimension group, defined otherwise, is exactly a countable Riesz group (G. Elliot, E. G. Effros, D. E. Handelman and C. L. Shen) (\rightarrow [II]).

Now consider two C^* -algebras A and B . The algebraic † tensor product $A \otimes B$ over C becomes a $*$ -algebra in the natural way. A norm β on $A \otimes B$ is a **C^* -crossnorm** if $\|xy\|_{\beta} \leq \|x\|_{\beta} \|y\|_{\beta}$ and $\|x^*x\|_{\beta} = \|x\|_{\beta}^2$ for $x, y \in A \otimes B$ and $\|a \otimes b\|_{\beta} \leq \|a\| \|b\|$ for $a \in A, b \in B$. The completion of $A \otimes B$ under such a norm β is a C^* -algebra, which is denoted by $A \otimes_{\beta} B$. There are two special C^* -crossnorms on $A \otimes B$: $\|\cdot\|_{\min}$ and $\|\cdot\|_{\max}$. The former is called the spatial (minimal, injective) C^* -crossnorm and is defined by $\|x\|_{\min} = \sup_{\varphi, \psi} \|(\varphi \otimes \psi)(x)\|$, where φ and ψ run over all $*$ -representations of A and B , respectively. The algebra $A \otimes_{\min} B$ is called the **spatial tensor product** of A and B . The latter is called the greatest C^* -crossnorm and is defined by $\|x\|_{\max} = \sup_T \|T(x)\|$, where T runs over all $*$ -representations of $A \otimes B$. And the algebra $A \otimes_{\max} B$ is called the **projective C^* -tensor product** of A and B . Any C^* -crossnorm β on $A \otimes B$ lies in between these two norms, i.e., $\|x\|_{\min} \leq \|x\|_{\beta} \leq \|x\|_{\max}$ for $x \in A \otimes B$. A C^* -algebra A is called **nuclear** if $A \otimes B$ has a unique C^* -crossnorm for any C^* -algebra B . It is known that any GCR algebra is nuclear and that an inductive limit of nuclear C^* -algebras (e.g., any AF algebra) is nuclear. Given a linear mapping φ between C^* -algebras A and B , we define for any integer $n \geq 1$ a linear mapping $\varphi_n: A \otimes M_n \rightarrow B \otimes M_n$ by setting $\varphi_n(x \otimes e_{ij}) = \varphi(x) \otimes e_{ij}$, where $\{e_{ij}\}$ are the matrix units for the C^* -algebra M_n of $n \times n$ complex matrices. φ is said to be **completely positive** if φ_n is positive for any $n \geq 1$. A C^* -algebra A is then called **injective** if, for any C^* -algebras B, C with $B \subseteq C$ and any completely positive contraction $\varphi: B \rightarrow A$, there

exists a completely positive contraction $\tilde{\varphi}: C \rightarrow A$ that extends φ . A C^* -algebra A is nuclear if and only if its enveloping von Neumann algebra A^{**} is injective. Every injective C^* -algebra B is not necessarily a von Neumann algebra but every **AW*-algebra**, i.e., every maximal commutative $*$ -subalgebra M of B , is monotone complete (i.e., every increasing net of self-adjoint elements has a least upper bound in M) and the lattice of projections in B is conditionally complete.

I. Crossed Product

Let A be a C^* -algebra, G a locally compact Hausdorff group with left-invariant measure μ , and α a continuous action of G on A as $*$ -automorphisms $\alpha_g, g \in G$. Let $K(G, A)$ be the linear space of continuous functions from G to A with compact support, which is a $*$ -algebra under the multiplication $y * z$ and the involution y^* given by $(y * z)(g) = \int_G y(h) \alpha_h(z(h^{-1}g)) d\mu(h)$ and $y^*(g) = \Delta(g^{-1}) \cdot \alpha_g(y(g^{-1})^*)$ for $y, z \in K(G, A)$, where Δ is the † modular function of G . By completing $K(G, A)$ under the norm $\|y\|_1 = \int_G \|y\| d\mu(g)$, we get a Banach $*$ -algebra $L_1(G, A)$. $L_1(G, A)$ is then made into a C^* -algebra by furnishing the norm $\|x\| = \sup_{\pi} \|\pi(x)\|$, where π runs over all $*$ -representations of $L_1(G, A)$. This C^* -algebra, denoted by $A \otimes_{\alpha} G$, is the **crossed product** of A by G relative to the action α . Crossed products are useful in the structure theory of C^* -algebras.

J. Extensions by C^* -Algebras (BDF Theory) [12]

Let H be a separable infinite-dimensional Hilbert space and $\mathcal{L}\mathcal{C}(H)$ the ideal of $\mathcal{B}(H)$ consisting of all compact operators. The quotient C^* -algebra $\mathcal{B}(H)/\mathcal{L}\mathcal{C}(H)$ is called the **Calkin algebra**. We denote it by $\mathcal{Q}(H)$ and the quotient mapping by $\pi: \mathcal{B}(H) \rightarrow \mathcal{Q}(H)$. By an **extension** of $\mathcal{L}\mathcal{C}(H)$ by a separable unital C^* -algebra A we mean a unital (preserving unity elements) $*$ -isomorphism τ of A into $\mathcal{Q}(H)$. We call two extensions $\tau_1, \tau_2: A \rightarrow \mathcal{Q}(H)$ **equivalent** if, for some unitary operator $u \in \mathcal{B}(H)$, $\pi(u)\tau_1(a)\pi(u)^* = \tau_2(a)$ for any $a \in A$, and denote by $\text{Ext}(A)$ the set of all equivalence classes $[t]$ of extensions τ by A . $\text{Ext}(A)$ forms a commutative semigroup with respect to the addition $[\tau] = [\tau_1] + [\tau_2]$, where $\tau(a) = \tau_1(a) \oplus \tau_2(a) \in \mathcal{Q}(H) \oplus \mathcal{Q}(H) \subset \mathcal{Q}(H \oplus H)$. Call an extension $\tau: A \rightarrow \mathcal{Q}(H)$ trivial if there is a unital $*$ -isomorphism σ of A into $\mathcal{B}(H)$ with $\tau = \pi\sigma$. Then (1) all trivial extensions are equivalent,

and we define the unity element of the semi-group $\text{Ext}(A)$ (D. Voiculescu); (2) $\text{Ext}(A)$ is a group if A is commutative (L. G. Brown, R. G. Douglas, and P. A. Fillmore) or, more generally, if A is nuclear (M. D. Choi and E. G. Effros); (3) $\text{Ext}(A)$ is not always a group (J. Anderson). For further information \rightarrow 390 Spectral Analysis of Operators J.

K. Derivations in C^* -Algebras

A linear operator δ in a C^* -algebra A is a **derivation** in A if its domain $D(\delta)$ is a dense subalgebra of A and $\delta(xy) = \delta(x)y + x\delta(y)$ for $x, y \in D(\delta)$. δ is a **$*$ -derivation** if, moreover, $x \in D(\delta)$ implies $x^* \in D(\delta)$ and $\delta(x^*) = \delta(x)^*$. δ is called bounded (unbounded, closed) if it is bounded (unbounded, closed) as a linear operator.

Every bounded derivation δ is expressed as $\delta(x) = \tilde{a}x - x\tilde{a}$ with some \tilde{a} in the enveloping von Neumann algebra A^{**} of A (R. V. Kadison and S. Sakai). The element \tilde{a} can be taken from the **multiplier algebra** $M(A) = \{b \in A^{**} \mid bA + Ab \subseteq A\}$ of A if A is simple (Sakai) or if A has continuous trace (C. A. Akemann, Elliott, G. K. Pedersen, and J. Tomiyama). If A is separable, we see that all bounded derivations in A are given by elements in $M(A)$ if and only if A is the C^* -direct sum of a family of simple C^* -algebras and a C^* -algebra with continuous trace (Elliott, Akemann, and Pedersen) [13] and that every bounded derivation in the quotient C^* -algebra A/I , I being any closed two-sided ideal, can be lifted to a derivation in A (Pedersen).

Next we consider unbounded derivation. By a **$*$ -automorphism group** on A we mean a \dagger one-parameter group $\rho_t, t \in \mathbf{R}$, of $*$ -automorphisms of A such that, for each $x \in A$, $\rho_t x$ is continuous in $t \in \mathbf{R}$. A **C^* -dynamical system** is a pair consisting of a C^* -algebra A and a $*$ -automorphism group ρ_t on A . The fact that the time evolution of a physical system is often represented by such a dynamical system has made the study of unbounded derivations quite active. We have to see if a given derivation δ is \dagger closable and if, in case of a closable δ , the closure $\bar{\delta}$ generates a $*$ -automorphism group. Sample results: (1) If a $*$ -derivation δ is **well-behaved** in the sense that for every self-adjoint x in $D(\delta)$ there exists a \dagger state φ with $|\varphi(x)| = \|x\|$ and $\varphi(\delta(x)) = 0$, then δ is closable and its closure is well-behaved (A. Kishimoto and Sakai); (2) if a $*$ -derivation δ is closable, its closure $\bar{\delta}$ generates a $*$ -automorphism group if and only if δ is well-behaved and $(1 \pm \delta)D(\delta)$ is dense in A (R. T. Powers and S. Sakai; O. Bratteli and D. W. Robinson). For further results \rightarrow [14].

L. Applications to the Theory of Topological Groups [2, 3, 6, 15]

Banach algebras have many applications in different branches of mathematics and quantum physics. Here we mention some that concern topological groups. Let G be a locally compact Hausdorff group and μ be its left-invariant measure. We make the complex algebra $L_1(G)$ of Example 3 into a Banach **$*$ -algebra** by defining $x^*(g) = \overline{x(g^{-1})}\Delta(g^{-1})$, where Δ is the \dagger modular function of G . This is called the **L_1 -algebra** (or **group algebra**). It is not C^* but is semisimple. Considering a unitary representation of G is equivalent to considering a $*$ -representation of the L_1 -algebra. Replace the norm of $x \in L_1(G)$ by $\sup \|\pi(x)\|$, where the supremum is taken over all the $*$ -representations. The new norm satisfies the C^* condition, and the completion of $L_1(G)$ with respect to this norm is a C^* -algebra, which we call the **C^* -group algebra** of G . The dual of the C^* -group algebra thus defined is called the dual of the group G , and this notion plays an important role in the study of topological groups. Unitary representations of a group G , $*$ -representations of the L_1 -algebra of G , and $*$ -representations of the C^* -group algebra of G are all characterized by positive definite functions on G . A function $p(g)$ is **positive definite**, by definition, if it is measurable on G and

$$\iint p(g^{-1}h)x(g)x(h)d\mu(g)d\mu(h) \geq 0$$

for any continuous function $x(g)$ with compact support.

The Abelian case. When G is an Abelian group (\rightarrow 422 Topological Abelian Groups), a regular maximal ideal M of the L_1 -algebra R of G and a character γ of G are in a one-to-one correspondence by the relation

$$\hat{x}(M) = \int x(g)\gamma(g)d\mu(g)$$

(the left-hand side is the value of x at M under the Gel'fand representation). Moreover, the set of regular maximal ideals of R provided with the Gel'fand topology and the set \hat{G} of characters of G provided with the Pontryagin topology (the \dagger character group of G) are homeomorphic by this correspondence. Therefore the Gel'fand transform of an element x of the L_1 -algebra R is seen to be a function $\hat{x}(\gamma)$ on \hat{G} defined by the integral on the right-hand side in the above expression, which is properly called the **Fourier transform** of x . Of course, the Fourier transform can be defined for other classes of functions (e.g., for the L_2 -space over G , the Fourier transform in the sense of Plan-

cherel), and classical theories of Fourier series, Fourier integrals, and harmonic analysis (- 192 Harmonic Analysis) are studied from a more extensive point of view. Thus the statement that the Fourier transform of an element x of the L_1 -algebra of G is a continuous function vanishing at infinity (\rightarrow Section E), for example, is a version of the classical \dagger Riemann-Lebesgue theorem. **Bochner's theorem** in classical \dagger Fourier analysis is restated thus: A continuous \dagger positive definite function on an Abelian group can be put in the form

$$p(g) = \int \gamma(g) d\rho(\gamma),$$

where ρ is a uniquely determined bounded positive \dagger Radon measure on the character group \hat{G} . Developing these theories further, we obtain an alternative proof of the \dagger Pontryagin duality theorem (H. Cartan and R. Godement). A closed ideal I in the L_1 -algebra R determines a set $Z(I)$ in \hat{G} as the set of common zeros of the Fourier transforms of elements of I . We ask whether, conversely, I is characterized by $Z(I)$. This question is the problem of **spectral synthesis**, and many important results have been obtained. The statement that I must coincide with R when $Z(I)$ is empty is a formulation of the **generalized Tauberian theorem** of N. Wiener. A considerable simplification of the proof was accomplished by using the theory of Banach algebras, which was the first application of the theory (I. M. Gel'fand).

M. Holomorphic Functional Calculus [16,171]

Let R be a unital commutative Banach algebra with maximal ideal space $\mathfrak{M} = \mathfrak{M}(R)$. We define the **joint spectrum** $\text{Sp}(X)$ of a finite n -tuple $X = \{x_1, \dots, x_n\}$ in R by $\{(\hat{x}_1(\varphi), \dots, \hat{x}_n(\varphi)) \mid \varphi \in \mathfrak{M}\}$, a nonempty compact subset of \mathbb{C}^n . Then the **holomorphic functional calculus** says the following: For each $X = \{x_1, \dots, x_n\} \subset R$ there exists a unique algebra homomorphism Φ_X of the algebra $H(\text{Sp}(X))$ of \dagger germs of holomorphic functions on $\text{Sp}(X)$ into R with the following properties: (1) $\Phi_X(1) = 1$, the unity element of R , and $\Phi_X(z_i) = x_i$, $1 \leq i \leq n$; (2) if $n < m$, $X' = \{x_1, \dots, x_n\}$ and $\tilde{F}(z_1, \dots, z_m) = F(z_1, \dots, z_n)$ with $F \in H(\text{Sp}(X))$, then $\Phi_{X'}(\tilde{F}) = \Phi_X(F)$; (3) if $\{F_k \mid k = 1, 2, \dots\}$ are holomorphic in a fixed neighborhood U of $\text{Sp}(X)$ and $F_k \rightarrow F$ uniformly on U , then $\Phi_X(F_k) \rightarrow \Phi_X(F)$ (L. Waelbroeck). From this follows the **implicit function theorem**: Let $x_1, \dots, x_n \in R$, $f \in C(\mathfrak{M})$, and let $F(w, z, \dots, z_n)$ be holomorphic in a neighborhood of the set $\text{Sp}(f, x_1, \dots, x_n) = \{(f(\varphi), \hat{x}_1(\varphi), \dots, \hat{x}_n(\varphi)) \mid \varphi \in \mathfrak{M}\}$. Suppose that

$F(f, \hat{x}_1, \dots, \hat{x}_n) = 0$ but $\partial F / \partial w \neq 0$ on $\text{Sp}(f, x_1, \dots, x_n)$. Then there exists a unique $y \in R$ such that $\hat{y} = f$ and $F(y, x_1, \dots, x_n) = 0$ (R. Arens and A. Calderon). As an application we obtain Shilov's **idempotent theorem**: If K is a closed-open subset of \mathfrak{M} , there exists $x \in R$ with $\hat{x} \equiv 1$ on K and $\hat{x} \equiv 0$ on $\mathfrak{M} - K$. Set $Q(R) = \{x \in R \mid e^{2\pi i x} = 1\}$. Then $Q(R)$ is an additive subgroup of R and Shilov's theorem says that the Gel'fand representation gives an isomorphism of $Q(R)$ onto $Q(C(W)) (\cong H^0(\mathfrak{M}, \mathbb{Z}))$. Another theorem of this sort is the **Arens-Royden theorem**: $R^{-1} / \exp(R) \cong C(\mathfrak{M})^{-1} / \exp(C(\mathfrak{M})) \cong H^1(\mathfrak{M}, \mathbb{Z})$, where R^{-1} is the set of invertible elements of R and $\exp(R) = \{e^x \mid x \in R\}$. Further extensions related to K-theory have been given by J. L. Taylor and others. (For functional calculus for one variable \rightarrow 25 1 Linear Operators)

37 (X11.3) Banach Spaces

A. General Remarks

The notion of **Banach space** was introduced in 1922 by S. Banach and N. Wiener, working independently. The idea was to apply topological and algebraic methods to fundamental problems of analysis, such as mapping problems in infinite-dimensional function spaces (- 168 Function Spaces, 197 Hilbert Spaces, 251 Linear Operators).

B. Definition of Banach Spaces

We associate to each element x of a \dagger linear space X over the real (or complex) number field a real number $\|x\|$ satisfying the following conditions: (i) $\|x\| \geq 0$ for all x , and $\|x\| = 0$ is equivalent to $x = 0$; (ii) $\|\alpha x\| = |\alpha| \cdot \|x\|$ for any real (complex) number α ; (iii) $\|x + y\| \leq \|x\| + \|y\|$. Then $\|x\|$ is called the **norm** of the vector x , and X is called a **normed linear space**. The norm is thus an extension of the notion of the length of a vector in a \dagger Euclidean space. A normed linear space X is a \dagger metric space under the distance $\rho(x, y) = \|x - y\|$. We write $\lim_{n \rightarrow \infty} x_n = x$ or simply $x_n \rightarrow x$ when $\lim_{n \rightarrow \infty} \|x_n - x\| = 0$ and say that x_n **converges strongly** to x . If this metric space X is \dagger complete, then X is called a **Banach space**. In normed linear spaces the addition and the multiplication by scalars are continuous. A closed linear subspace M of a Banach space X is again a Banach space, and the \dagger quotient space X/M becomes a Banach space if the norm of a \dagger coset is defined by $\|x + M\| = \inf_{m \in M} \|x + m\|$. The subset $\{x \mid \|x\| \leq 1\}$ of a normed linear space X is called the (closed) **unit ball** (or unit sphere) of X .

Examples. \dagger Function spaces C, L_p ($1 \leq p < \infty$), M, W_p^l, H_0^l , \dagger sequence spaces c, l, m and BV are all Banach spaces (- 168 Function Spaces).

C. Linear Operators and Linear Functionals

Suppose that a linear subspace $D(T)$ of a linear space X is the (definition) **domain** of a mapping T with values in a linear space X_1 . T is called a **linear operator** if $T(\alpha x + \beta y) = \alpha Tx + \beta Ty$ for any scalars α, β and $x, y \in D(T)$. $R(T) = \{Tx \in X_1 \mid x \in D(T)\}$ is called the **range** of T . In the special case where X_1 is the real or complex number field, T is called a **linear functional**. If X and X_1 are both normed linear spaces, then T is **continuous** if and only if $s\text{-}\lim_{n \rightarrow \infty} Tx_n = Tx$ whenever $s\text{-}\lim_{n \rightarrow \infty} x_n = x$. This is equivalent to the condition $\sup_{x \in D(T), \|x\| \leq 1} \|Tx\| < \infty$. In particular, if $D(T) = X$, the linear operator T is **continuous** if and only if the set $\{Tx \mid \|x\| \leq 1\}$ is bounded. In this case, T is called a **bounded linear operator**, and $\|T\| = \sup_{\|x\| \leq 1} \|Tx\|$ is called the **norm** of the operator T . In particular, a linear operator T satisfying $\|T\| \leq 1$ is called a **contraction**. (Sometimes T is called a contraction only when $\|T\| < 1$. In that case, an operator with $\|T\| \leq 1$ is called a **nonexpansive operator**.) The **scalar multiple**, **sum**, and **product** of linear operators are defined by $(\alpha T)x = \alpha(Tx)$, $(T + S)x = Tx + Sx$, and $(ST)x = S(Tx)$, respectively. The **identity operator** I in X is defined by $I \cdot x = x$ for all $x \in X$. If the inverse mapping T^{-1} of $x \rightarrow Tx$ exists, then it is called the **inverse operator** of T . A normed linear space X is said to be **isomorphic** to a normed linear space Y if there exists a bounded linear operator T from X onto Y with bounded inverse. If T can be chosen to be isometric (i.e., $\|Tx\| = \|x\|$ for all $x \in X$), then X is said to be **isometrically isomorphic** to Y .

D. The Dual Space and the Dual Operator

The totality of continuous linear functionals f defined on a normed linear space X is a Banach space X' under the previously defined linear operations and the norm $\|f\| = \sup_{\|x\| \leq 1} |f(x)|$. This X' is called the **dual** (or **conjugate**) space of X . In view of useful properties of the \dagger inner product in \dagger Hilbert spaces, it is sometimes convenient to write $\langle x, f \rangle$ for $f(x)$. Let X and Y be normed linear spaces, and let T be a linear operator with the dense domain $D(T)$ in X and the range $R(T)$ in Y . If (f, g) is a pair with $f \in Y'$ and $g \in X'$ satisfying the equation $(Tx, f) = \langle x, g \rangle$ for any $x \in D(T)$, then g is determined uniquely by f . The operator T' defined by $T'f = g$ is linear and is called the **dual operator** (or **conjugate** or **adjoint operator**) of T . This is an extension of the notion of the \dagger transpose of a matrix in matrix theory. If T is a bounded linear operator then

T' is also a bounded linear operator such that $\|T'\| = \|T\|$.

E. The Weak Topology and the Strong Topology

Let X be a normed linear space and X' its dual space. Take a finite number of elements x'_1, x'_2, \dots, x'_n from X' , and consider the subset of $X: \{x \in X \mid \sup_{1 \leq i \leq n} |\langle x, x'_i \rangle| \leq \varepsilon\}$, $\varepsilon > 0$. If we take the totality of such subsets of X as a fundamental system of neighborhoods of 0 of X , then X is a locally convex topological linear space, denoted sometimes by X_w . This topology is called the **weak topology** of X . If a sequence $\{x_n\} \subset X$ converges to $x \in X$ with respect to the weak topology of X , then it is said to **converge weakly**. This is equivalent to the convergence $(x_n, f) \rightarrow (x, f)$ for any $f \in X'$. The original topology of X determined by the norm is then called the **strong topology** of X , and to stress the strong topology we sometimes write X_s in place of the original X . Take a finite number of elements x_1, x_2, \dots, x_n from X , and consider the subset of $X': \{x' \in X' \mid \sup_{1 \leq i \leq n} |\langle x_i, x' \rangle| \leq \varepsilon\}$, $\varepsilon > 0$. If we take the totality of such subsets of X' as a fundamental system of neighborhoods of 0 of X' , then X' is a locally convex topological linear space. We write this space as X'_{w*} and call the topology the **weak* topology** of X' . The topology of X' defined by the norm $\|f\|$ is called the **strong topology** of X' , and to stress the strong topology we write X'_s . The terms "weak" and "weakly" are used in reference to the weak topology, for instance, weak closedness and weakly closed. Similar conventions are used for the weak* and strong topologies.

The unit ball of the dual space of a normed linear space X is weak*-compact (**Banach-Alaoglu theorem**). Then by the Krein-Milman theorem (\rightarrow 424 Topological Linear Spaces) the unit ball of X' is the weak* closure of the convex hull of its extreme points. If X is a Banach space, a convex subset K of X' is weak*-closed if and only if the intersection of K and each weak*-compact subset is weak*-closed (**Krein-Shmul'yan theorem**).

F. The Hahn-Banach Extension Theorem

Let M be a linear subspace of a real linear space X and $p(x)$ a real-valued functional defined on X such that $p(x+y) \leq p(x) + p(y)$ and $p(\lambda x) = \lambda p(x)$ for all $x, y \in X$ and $\lambda \geq 0$. If a linear functional f_1 defined on M satisfies $f_1(x) < p(x)$ for all $x \in M$, then there is a linear functional f on X which extends f_1 and satisfies $f(x) \leq p(x)$ for all $x \in X$ (the **Hahn-Banach**

(extension) theorem). The Hahn-Banach extension theorem has many applications. (1) Let M be a linear subspace of a normed linear space X . Then for any $f_1 \in M'$, we can construct an $f \in X'$ such that $f(x) = f_1(x)$ for all $x \in M$ and $\|f\| = \|f_1\|$. (2) For any $x_0 \neq 0$ of a normed linear space X , we can construct an $f_0 \in X'$ such that $f_0(x_0) = \|x_0\|$ and $\|f_0\| = 1$. (3) For any closed linear subspace M of a normed linear space X and a point $x_0 \notin M$ we can construct $f_0 \in X'$ such that $\|f_0\| = 1$, $f_0(x_0) = \inf_{m \in M} \|x_0 - m\|$ and $f_0(x) = 0$ for all $x \in M$. A proposition more general than (3) is **Mazur's theorem**, which is useful in applications: (4) Let a closed subset M of a normed linear space X be convex. Then for any $x_0 \notin M$ we can construct an $f_0 \in X'$ such that $f_0(x_0) > f_0(x)$ for all $x \in M$. By (4) we can prove, e.g., that a convex set of a normed linear space is weakly closed if it is strongly closed. This proposition has the following corollaries: (5) A convex set A containing 0 is closed if and only if $(A^\circ)^\circ = A$, where A° is the polar of A (the **bipolar theorem**). (6) For two closed convex sets A and B , containing 0, the polar of $A \cap B$ coincides with the weak* closure of the convex hull of $A^\circ \cup B^\circ$. For complex linear spaces, most of the propositions in this section are valid with $\operatorname{Re} f(x)$ instead of $f(x)$.

The Hahn-Banach theorem can also be employed to prove the existence of the **generalized limit** (or **Banach limit**) $\lim_{n \rightarrow \infty} \zeta_n$ defined for all bounded real sequences $\{\zeta_n\}$ such that $\liminf_{n \rightarrow \infty} \zeta_n \leq \lim_{n \rightarrow \infty} \zeta_n \leq \limsup_{n \rightarrow \infty} \zeta_n$ and $\lim_{n \rightarrow \infty} (\alpha \zeta_n + \beta \eta_n) = \alpha \lim_{n \rightarrow \infty} \zeta_n + \beta \lim_{n \rightarrow \infty} \eta_n$.

G. Duality in Normed Linear Spaces

An element x_0 of a normed linear space X gives rise to an element x'_0 of (X'_s) determined by $\langle x_0, x' \rangle = \langle x'_0, x'_0 \rangle$ for all $x' \in X'_s$. If we write $x'_0 = Jx_0$, then J is a linear operator satisfying $\|Jx_0\| = \|x_0\|$ by (2), and so the space X is isometrically isomorphic to a linear subspace of $(X'_s)'_s$. If X_s coincides with $(X'_s)'_s$ under this isomorphism, we call X a **reflexive** (or **regular**) **Banach space**. A necessary and sufficient condition for the normed linear space X to be reflexive is that the unit ball of X be weakly compact. A convenient criterion for the reflexivity of X is that any bounded sequence $\{x_n\}$ of X contains a subsequence weakly convergent to a point of X (**Eberlein-Shmul'yan theorem**). In this connection, a Banach space X is reflexive if and only if each $x' \in X'$ attains its norm, i.e., there is an $x_0 \in X$ such that $\|x_0\| = 1$ and $|\langle x_0, x' \rangle| = \|x'\|$ (**James's theorem**).

A normed linear space is said to be **uniformly convex** if for any $\varepsilon > 0$ there exists a $\delta > 0$ such that $\|x\| \leq 1$, $\|y\| \leq 1$ and $\|x - y\| \geq \varepsilon$

implies $\|x + y\| \leq 2 + \delta$. A normed linear space is said to be **uniformly smooth** if for any $\varepsilon > 0$ there is a $\delta > 0$ such that $\|x\| = 1$ and $\|y\| \leq \delta$ imply $\|x + y\| + \|x - y\| \leq 2 + \varepsilon\|y\|$. A Banach space X is uniformly convex (resp. uniformly smooth) if and only if the dual X' is uniformly smooth (resp. uniformly convex). If a Banach space X is uniformly convex or smooth, it is isomorphic to a Banach space that is uniformly convex and uniformly smooth (P. Enflo). The space L_p with $1 < p < \infty$ is uniformly convex and uniformly smooth. Any uniformly convex or uniformly smooth Banach space is reflexive (**Milman's theorem**).

H. The Resonance Theorem

Let $\{T_n\}$ be a sequence of bounded linear operators from a Banach space X into a normed linear space Y . The **uniform boundedness theorem** (**resonance theorem** or **Banach-Steinhaus theorem**) states that $\sup_{n \geq 1} \|T_n\| < \infty$ if $\sup_{n \geq 1} \|T_n x\| < \infty$ for every $x \in X$. As a corollary, we have $\sup_{n \geq 1} \|x_n\| < \infty$ for any weakly convergent sequence of X . Another corollary states that the set $\{x \in X \mid \limsup_{n \rightarrow \infty} \|T_n x\| < \infty\}$ either coincides with X or is a subset of X of the † first category. This implies the so-called **principle of condensation of singularities**, which gives a general existence theorem for functions exhibiting various kinds of singularities, for example, a continuous function whose † Fourier expansion diverges at every point of a † perfect set of points having the cardinal number of the continuum.

I. The Closed Graph Theorem

Let T be a bounded linear operator from a Banach space X into a normed linear space Y . If the image of the unit ball of X under T is dense in the unit ball of Y , then for any $\varepsilon > 0$ and any $y_0 \in Y$ the equation $Tx = y$, has a solution x with $\|x\| \leq (1 + \varepsilon)\|y\|$, (**Banach's theorem**). By using the † Baire category theorem, we can derive from this the **open mapping theorem**: Every bounded linear operator from a Banach space X onto a Banach space Y maps each open set in X onto an open set in Y . As an application of the open mapping theorem, we can prove the **closed graph theorem**: A linear operator T from the whole of a Banach space into a Banach space is continuous if and only if T is a closed operator, i.e., $s\text{-}\lim_{n \rightarrow \infty} x_n = x$ and $s\text{-}\lim_{n \rightarrow \infty} Tx_n = y$ imply $Tx = y$. This theorem plays an important role in modern treatments of linear partial differential equations.

J. The Closed Range Theorem

Let X and Y be Banach spaces and T a linear closed operator with domain $D(T)$ dense in X and with range $R(T)$ in Y . Under these conditions, the following four propositions are mutually equivalent. (1) $R(T)$ is a closed set in Y . (2) $R(T')$ is a closed set in X' . (3) $R(T) = \{y \in Y \mid \langle y, y^* \rangle = 0 \text{ for all } y^* \in D(T') \text{ such that } T'y^* = 0\}$. (4) $R(T') = \{x^* \in X' \mid \langle x, x^* \rangle = 0 \text{ for all } x \in D(T) \text{ such that } Tx = 0\}$. These four propositions, as a whole, are called the **closed range theorem**. This theorem implies (5) $R(T) = Y$ if and only if T' has a continuous inverse; and (6) $R(T') = X'$ if and only if T has a continuous inverse. The following theorem is of similar nature: the following three propositions on two closed linear subspaces M and N of a Banach space are mutually equivalent. (7) $M + N$ is closed. (8) $M^{\circ} + N^{\circ}$ is strongly closed. (9) $M^{\circ} + N^{\circ}$ is weak*-closed.

The Hahn-Banach theorem, the resonance theorem, the open mapping theorem, the closed graph theorem, and the closed range theorem can be extended to various classes of † locally convex topological linear spaces. By virtue of this extension, we are able not only to treat various fundamental problems of analysis from a unified viewpoint but also to develop the theory of functional analysis itself in a new direction (\rightarrow 424 Topological Linear Spaces; concerning linear operators on a Banach space \rightarrow 68 Compact and Nuclear Operators, 251 Linear Operators, 390 Spectral Analysis of Operators).

K. Differential and Integral Calculus of Functions with Values in Banach Spaces

Calculus involving functions from a set to a Banach space is also an effective tool in various problems. A function $x(t)$ defined on an interval $[a, b]$ with values in a Banach space X is said to be **strongly (weakly) continuous** if $x(t)$ converges strongly (weakly) to $x(t_0)$ as $t \rightarrow t_0$. For a strongly (weakly) continuous function $x(t)$, the **Riemann integral** can be defined in a standard way, using strong (weak) convergence of the Riemann sum

$$\int_a^b x(t) dt = \lim \sum x(t_i')(t_{i+1} - t_i).$$

The † fundamental theorem of calculus, i.e., strong (weak) differentiability of the indefinite integral, remains true. Various definitions of integrals of a Banach space-valued function on a † measure space are discussed elsewhere (\rightarrow 443 Vector-Valued Integrals).

Now let $x(\lambda)$ be defined on a domain Ω in the complex plane with values in a complex

Banach space X . $x(\lambda)$ is said to be **holomorphic** if $f(x(\lambda))$ is holomorphic in Ω for every $f \in X'$. If $x(\lambda)$ is holomorphic, then there exists an X -valued function $y(\lambda)$ on Ω such that

$$\|\zeta^{-1}(x(\lambda + \zeta) - x(\lambda)) - y(\lambda)\| \rightarrow 0 \quad \text{as} \quad \zeta \rightarrow 0.$$

Therefore there is no difference between "strong" and "weak" in analyticity. \dagger Cauchy's integral theorem remains true for a holomorphic function $x(\lambda)$ with values in X , and the \dagger Laurent expansion

$$x(\lambda) = \sum_{n=-\infty}^{\infty} a_n(\lambda - \lambda_0)^n,$$

$$a_n = \frac{1}{2\pi i} \int_C x(\lambda)(\lambda - \lambda_0)^{-n-1} d\lambda,$$

is valid with the integral taken in the Riemannian sense. Banach space-valued holomorphic functions on complex (or real) \dagger analytic manifolds of higher dimension can be defined in a natural way by means of power series expansion. A function $\Theta(\lambda)$ defined on a domain in the complex plane with values in the Banach space $B(X, Y)$ of bounded linear operators from X to Y becomes holomorphic if $f(\Theta(\lambda)x)$ is holomorphic for every $x \in X$ and $f \in Y'$. An operator-valued holomorphic function is often called an **analytic operator function**.

L. The Approximation Property

A Banach space X is said to have the **approximation property** if there is a family $\{S_\lambda\}$ of bounded linear operators of \dagger finite rank in X such that $\inf_\lambda \|(S_\lambda - I)T\| = 0$ for all \dagger compact linear operators T in X . There is a Banach space that fails to have the approximation property (Enflo [9]). More surprisingly, the space of all bounded linear operators on an infinite-dimensional Hilbert space fails to have the approximation property (A. Szankowski). The approximation property plays a decisive role in the theory of \dagger tensor products of Banach spaces. A Banach space X is said to have the **bounded approximation property** if a family $\{S_\lambda\}$ in the definition of the approximation property can be taken bounded, i.e., $\sup_\lambda \|S_\lambda\| < \infty$. The bounded approximation property does not follow from the approximation property. The bounded approximation property is closely related to the existence of a basis. A sequence $\{e_k\}$ in a Banach space X is called a **Schauder basis** or simply a **basis** (or **hase**) for X if to each $x \in X$ there corresponds a unique sequence of numbers $\{c_k\}$ such that $\lim_{n \rightarrow \infty} \|x - \sum_{k=1}^n c_k e_k\| = 0$. Most separable Banach spaces appearing in analysis have bases. A separable Banach space has the bounded approximation property if and only if it is isomorphic to a complemented linear

subspace (\rightarrow Section N) of a Banach space with a basis (A. Pełczyński).

M. Injective and Projective Banach Spaces

Banach spaces of the type $\dagger C(\Omega)$ with compact Ω and of the type $\dagger l_1(\Omega)$ on a set Ω play a special role in the theory of Banach space. This is already seen in the fact that every Banach space is isometrically isomorphic to a subspace of a space $C(\Omega_1)$ as well as to a quotient space of a space $l_1(0, \infty)$. A Banach space X is said to be **injective** if for any Banach space Y and its linear subspace M , each bounded linear operator T from M to X can be extended to a bounded linear operator \tilde{T} from Y to X , that is, $\tilde{T}x = Tx$ for all $x \in M$. A Banach space is **injective** if and only if it is isomorphic to a complemented linear subspace of the space $C(R)$ for a compact Hausdorff space Ω with the property that the closure of every open set is open. Such a topological space is called **extremally disconnected**. The \dagger maximal ideal space of the \dagger Banach algebra $L_\infty(\Omega)$ is extremally disconnected. Hence the Banach space $L_\infty(\Omega)$ is injective. Whether every injective Banach space is isomorphic to a space $C(0)$ is still an open problem. However, a Banach space is isometrically isomorphic to a space $C(Q)$ with Ω extremally disconnected if and only if it is injective with the property of norm-preserving extension, i.e., $\|\tilde{T}\| = \|T\|$ is always possible (Nachbin-Goodner-Kelley theorem). In this connection, the following propositions on a Banach space X are mutually equivalent. (1) X' is isometrically isomorphic to a space $\dagger l_1(\mu)$. (2) For any Banach space Y , its linear subspace M , and $\varepsilon > 0$, each compact linear operator T from M to X can be extended to a compact linear operator \tilde{T} from Y to X with $\|\tilde{T}\| \leq (1 + \varepsilon)\|T\|$ (J. Lindenstrauss). A Banach space X is said to be **projective** if for any Banach space Y and its closed linear subspace M , each bounded linear operator S from X to the quotient space Y/M is lifted to a bounded linear operator \tilde{S} from X to Y , i.e., $\varphi(\tilde{S}x) = Sx$ for all $x \in X$, where φ is the quotient mapping from Y to Y/M . Projectivity of X is characterized by its being isomorphic to the space $l_1(\Omega)$ on a set Ω . A Banach space is isometrically isomorphic to a space $l_1(R)$ if and only if it is projective with the property of norm-preserving lifting, i.e., $\|\tilde{S}\| = \|S\|$ is always possible (\rightarrow [8]).

N. Complemented Subspaces Problems

A linear subspace M of a Banach space X is **complemented**, i.e., there is a closed linear

subspace N such that $M \cap N = \{0\}$ and $M + N = X$ if and only if M is the range of a bounded projection P , i.e., $P^2 = P$ and $R(P) = M$. Each nonzero closed linear subspace of a Hilbert space is complemented, or more precisely, it is the range of a projection of norm one (- 197 Hilbert Spaces). This property distinguishes Hilbert spaces from general Banach spaces: (1) A Banach space of more than 3 dimensions is isometrically isomorphic to a Hilbert space if each nonzero closed linear subspace is the range of a projection of norm one (**Kakutani's theorem**). (2) A Banach space is isomorphic to a Hilbert space if each closed linear subspace is complemented (J. Lindenstrauss and L. Tzafriri [10]).

0. Quasi-Banach Spaces and Fréchet Spaces

Let X be a linear space over the real (or complex) number field. Suppose that a real-valued function $\|x\|$ on X satisfies (i) and (ii) of Section B and (iii') $\|x + y\| \leq k(\|x\| + \|y\|)$ with a constant $k \geq 1$ independent of x and y . Then $\|x\|$ is called the **quasinorm** of x , and X equipped with a quasinorm is called a **quasinormed linear space**. Let $0 < p \leq 1$ be the root of the equation $k = 2^{(1/p)-1}$. Then there is a distance $d(x, y) = d(x - y)$ depending only on $x - y$ such that $d(x - y) \leq \|x - y\|^p \leq 2d(x - y)$. Hence a quasinormed linear space is a metric space in which a sequence x_n converges to x if and only if $\|x_n - x\| \rightarrow 0$. If a quasinormed linear space X is complete under this metric, then X is called a **quasi-Banach space**. The p -function space L_p is a quasi-Banach space for $0 < p < 1$.

If we denote by $\|x\|$ the distance $d(x - 0)$ of a quasinormed linear space, then it satisfies (i) and (iii) of Section B and (ii') $\| -x \| = \|x\|$ and $\lim_{n \rightarrow \infty} \|\alpha_n x_n - \alpha x\| = 0$ whenever $\alpha_n \rightarrow \alpha$ and $\lim_{n \rightarrow \infty} \|x_n - x\| = 0$. A functional $\|x\|$ satisfying (i), (ii'), and (iii) is called a **pseudonorm**. If a linear space X equipped with a pseudonorm is complete, then X is called a **Fréchet space (in the sense of Banach)**. The p -function space $S(\Omega)$ is a Fréchet space. Quasinormed linear spaces and Fréchet spaces are topological linear spaces, but they need not be p -locally convex. Hence it is possible that there is no continuous linear functional except for zero. However, the open mapping theorem and the closed graph theorem hold for linear operators from a Fréchet space into a Fréchet space.

38 (XXI.1 4) Bernoulli Family

The Bernoullis, Protestants who came originally from Holland and settled in Switzerland, were a significant family to the mathematics of the 17th Century. In a single Century, the family produced eight brilliant mathematicians, all of whom played important roles in the development of calculus.

The brothers James (1654-1705) and John (1667-1748) and Daniel (1700-1782), John's second son, were especially outstanding. James and John were close friends of G. W. \dagger Leibniz, with whom they exchanged the correspondence through which it might be said that calculus developed. James studied problems related to the \dagger tautochrone and \dagger brachistochrone, as well as problems in geometry, dynamics, and other fields, including the \dagger isoperimetric problem. He was the first to change the name *calculus summatoris* to *calculus integralis* (1690). His *Ars conjectandi* was published after his death in 1713; in it is found the \dagger law of large numbers, which made his name prominent in the theory of p -probability. James had little guidance, learning mathematics on his own. He was a professor of experimental physics at the University of Basel and later became a professor of mathematics. He taught mathematics to his brother John, who succeeded him as professor at the University. John's many achievements appeared in such publications of the time as *Acta eruditorum* and *Journal des savants*. In 1701, the beginnings of the \dagger calculus of variations were seen in his solution to the isoperimetric problem. He

was the first to use the term *functio*, the root of the present term *function* (1714).

Despite discord between the brothers and also between fathers and sons, the Bernoullis were ardent teachers and brilliant researchers, who instructed not only their sons but also such mathematicians as †Euler. Their achievements were numerous in consolidating the content and form of calculus and also in expanding its application. Daniel was especially outstanding in the theory of probability; he also made contributions to the field of †hydrodynamics and to the †kinetic theory of gases. The eldest John's eldest son Nicolas (1695–1726) achieved distinction as a professor of mathematics in St. Petersburg. Daniel's youngest brother, John (1710–1790), succeeded his father, John Sr., as a professor at the University of Basel. The son of John, Jr., also named John (1744–1807), was the chairman of mathematics at the Academy of Berlin. His brother, another James (1759–1789), was a professor of experimental physics at the University of Basel. Nicolas (1687–1759), a grandson of the founder Nicolas (1623–1708) and son of Nicolas the painter (1662–1716), held Galileo's old chair of mathematics at Padua from 1716 to 1719.

In this article, the first names have been given in English. The German names corresponding to James, John, and Nicolas are Jakob, Johann, and Nikolaus, respectively.

39 (XIV.8) Bessel Functions

A. General Remarks

Bessel functions were first introduced in order to solve †Kepler's equation concerning planetary motions and were systematically investigated by F. W. Bessel in 1824. Since then they have appeared in various problems and have become important.

B. Bessel Functions

Separating variables for the Helmholtz equation $\Delta\Psi + k^2\Psi = 0$ in terms of cylindrical coordinates, we obtain Bessel's differential equation

$$\frac{d^2 w}{dz^2} + \frac{1}{z} \frac{dw}{dz} + \left(1 - \frac{v^2}{z^2}\right)w = 0 \quad (1)$$

for the component of the radius vector. The following two linearly independent solutions of (1):

$$H_v^{(1)}(z) = \frac{1}{\pi} \int_{L_1} e^{-iz \sin \zeta + iv \zeta} d\zeta, \quad H_v^{(2)}(z) = \frac{1}{\pi} \int_{L_2} e^{-iz \sin \zeta + iv \zeta} d\zeta, \quad (2)$$

are called the **Hankel functions of the first and second kind**, respectively, where the contour L_1 of the first integration is a curve from $(-\pi + 0) + i\infty$ to $-0 - i\infty$, and L_2 is a curve from $+0 - i\infty$ to $(\pi - 0) + i\infty$. If both z and v are real, we have

$$H_v^{(1)}(\bar{z}) = H_v^{(2)}(z), \quad \overline{H_v^{(2)}(z)} = H_v^{(1)}(z), \quad (3)$$

where \bar{z} is the complex conjugate of z . Hence

$$J_v(z) = (H_v^{(1)}(z) + H_v^{(2)}(z))/2, \quad N_v(z) \equiv Y_v(z) = (H_v^{(1)}(z) - H_v^{(2)}(z))/2i \quad (4)$$

are real functions. If both z and v are complex, the functions $J_v(z)$ and $N_v(z)$ defined in (4) are also called **Bessel functions** and **Neumann functions**, respectively. The other names for $J_v(z)$, $N_v(z)$, and $H_v(z)$ are **Bessel functions of the first, second, and third kind**, respectively. Each of them satisfies the following recurrence formulas:

$$2 \frac{dC_v(z)}{dz} = C_{v-1}(z) - C_{v+1}(z), \quad (2v/z)C_v(z) = C_{v-1}(z) + C_{v+1}(z). \quad (5)$$

In general, functions satisfying the simultaneous †differential-difference equations (5) are called **cylindrical functions**. Every cylindrical

function $C_v(z)$ is represented in the form $C_v(z) = a_1(v)H_v^{(1)}(z) + a_2(v)H_v^{(2)}(z)$, where $a_1(v)$ and $a_2(v)$ are arbitrary periodic functions of period 1 with respect to v .

If $v = n$ (an integer) we have

$$\begin{aligned} J_{-n}(z) &= (-1)^n J_n(z), \\ N_{-n}(z) &= (-1)^n N_n(z), \end{aligned} \quad (6)$$

which show the linear dependency of J_{-n} and J_n , and N_{-n} and N_n , respectively. If $v \neq n$ (an integer), as the fundamental solutions of (1) we can take a pair J_v and J_{-v} , or N_v and N_{-v} . In (2) if we take as a contour of integration a curve from $(-\pi + 0) + i\infty$ to $(\pi - 0) + i\infty$, we obtain an integral representation for $J_v(z)$, which yields the relations

$$\begin{aligned} J_v(ze^{im\pi}) &= e^{imv\pi} J_v(z), \\ J_{-v}(ze^{im\pi}) &= e^{-imv\pi} J_{-v}(z). \end{aligned} \quad (7)$$

If $v = n$ (an integer) and $\operatorname{Re} z > 0$, we obtain

$$J_n(z) = \frac{1}{2\pi} \int_{-\pi}^{\pi} e^{iz \sin \zeta + in\zeta} d\zeta \quad (8)$$

$$= \frac{1}{\pi} \int_0^{\pi} \cos(z \sin \zeta - n\zeta) d\zeta, \quad (9)$$

which is called **Bessel's integral**. These representations imply the following expansions by means of **generating functions**:

$$e^{iz \sin \zeta} = \sum_{n=-\infty}^{\infty} J_n(z) e^{in\zeta}, \quad (10)$$

$$\cos(z \sin \zeta) = J_0(z) + 2 \sum_{n=1}^{\infty} J_{2n}(z) \cos 2n\zeta, \quad (11)$$

$$\sin(z \sin \zeta) = 2 \sum_{n=0}^{\infty} J_{2n+1}(z) \sin(2n+1)\zeta.$$

Making a change of variable $u = \exp(-i\zeta)$ in (2), we obtain

$$J_v(z) = \frac{1}{2\pi i} \int_L \exp\left(\frac{z}{2}\left(u - \frac{1}{u}\right)\right) u^{-v-1} du, \quad (12)$$

where L is a contour starting at the point at infinity with the argument $-\pi$, encircling the origin in the positive direction, and tending to the point at infinity with the argument π . From (12) we obtain a power series expansion

$$J_v(z) = \frac{z^v}{2^v} \sum_{m=0}^{\infty} \frac{(-1)^m}{m! \Gamma(v+m+1)} \frac{z^{2m}}{2^m}, \quad (13)$$

obtained also from (1) by a power series expansion at $z = 0$, which is a **regular** singular point of (1). Substituting (13) into

$$N_v(z) = (\cos vJ_v(z) - J_{-v}(z))/\sin v\pi, \quad (14)$$

we obtain a power series expansion for $N_v(z)$. A power series expansion for $N_v(z)$ for an integer n is obtained by taking the limit $v \rightarrow n$ (\rightarrow Appendix A, Table 19). In particular, if $v =$

$n + 1/2$ (n is an integer), we have

$$J_{n+1/2}(z) = (-1)^n \frac{(2z)^{n+1/2}}{\sqrt{\pi}} \frac{d^n}{d(z^2)^n} \left(\frac{\sin z}{z} \right),$$

$$n = 0, 1, 2, \dots,$$

which is represented by elementary functions and is sometimes called simply the **half Bessel function**. Bessel functions for half-integers have appeared also as radius vector components when the variables in the Helmholtz equation are separated by spherical coordinates. The function

$$j_n(z) = \sqrt{\pi/2z} J_{n+1/2}(z)$$

is called the **spherical Bessel function**.

We have the following **addition theorem**:

$$H_n^{(\mu)}(k\rho) e^{in\psi} = \sum_{m=-\infty}^{\infty} J_n(kr_2) H_{n+m}^{(\mu)}(kr_1) e^{im\varphi},$$

$$\mu = 1, 2,$$

where

$$\rho = \sqrt{r_1^2 + r_2^2 - 2r_1 r_2 \cos \varphi},$$

$$\rho \cos \psi = r_1 - r_2 \cos \varphi, \quad \rho \sin \psi = r_2 \sin \varphi.$$

C. Zero Points of the Function $J_v(z)$

From the differential equations satisfied by $J_v(\alpha z)$, we have

$$\begin{aligned} (\alpha^2 - \beta^2) \int_0^1 z J_v(\alpha z) J_v(\beta z) dz \\ = \beta J_v(\alpha) J'_v(\beta) - \alpha J'_v(\alpha) J_v(\beta). \end{aligned} \quad (15)$$

By letting $\beta \rightarrow \alpha$ in (15), we have

$$\begin{aligned} \int_0^1 z (J_v(\alpha z))^2 dz \\ = \frac{1}{2} \left(\left(1 - \frac{v^2}{\alpha^2} \right) (J_v(\alpha))^2 + (J'_v(\alpha))^2 \right) \end{aligned} \quad (16)$$

If α and β are distinct roots of $J_v(z) = 0$, we have from (15)

$$\int_0^1 z J_v(\alpha z) J_v(\beta z) dz = 0, \quad \operatorname{Re} v > -1. \quad (17)$$

The integral formulas (15), (16), and (17) are called **Lommel's integrals**.

As for the zero points of $J_v(z)$, the following facts are well known: $J_v(0) = 0$ if $v > 0$. $J_v(z)$ has no multiple zero points other than $z = 0$. $J_v(-\alpha) = 0$ if $J_v(\alpha) = 0$. Every zero point of $J_v(z)$ is real if $v > -1$. Between two adjacent zero points that are positive, there exists one and only one zero point of $J_{v-1}(z)$ and $J_{v+1}(z)$, respectively. $J_v(z)$ has a countably infinite set of zero points on the real axis. When $v \geq 0$ is rational, every zero point of $J_v(z)$ except $z = 0$ is a **transcendental** number. The transcendence of π is a special case of this result for $v = 1/2$.

D. Expansion by means of Bessel Functions

Let $f(r, \varphi)$ be defined for $0 < r < 1$, $-\pi < \varphi < \pi$, and $\alpha_{n,1}, \alpha_{n,2}, \dots, \alpha_{n,s}, \dots$ ($0 < \alpha_{n,s} < \alpha_{n,s+1}$, $s = 1, 2$, for every n) be zero points of $J_n(x)$ ($n = 0, 1, 2, \dots$). Then we have an expansion

$$f(r, \varphi) = \sum_{n=0}^{\infty} \sum_{s=1}^{\infty} (a_{n,s} \cos n\varphi + b_{n,s} \sin n\varphi) J_n(\alpha_{n,s} r), \quad (18)$$

which is called the **Fourier-Bessel series**. The coefficients $a_{n,s}$ and $b_{n,s}$ are determined by the properties of \dagger Fourier series and (16) and (17) as follows:

$$\left. \begin{aligned} a_{n,s} \\ b_{n,s} \end{aligned} \right\} = \frac{\varepsilon_n}{\pi(J_{n+1}(\alpha_{n,s}))^2} \times \int_0^1 \int_{-\pi}^{\pi} f(r, \varphi) J_n(\alpha_{n,s} r) \frac{\cos n\varphi}{\sin n\varphi} r d\varphi dr,$$

$$\varepsilon_0 = 1, \quad \varepsilon_1 = \varepsilon_2 = \dots = 2.$$

The integral transformation

$$g(y) = \int_0^{\infty} x f(x) J_n(xy) dx \quad (19)$$

is called the **Fourier-Bessel transform**. If $f(x)$ is sufficiently smooth and tends rapidly to zero as $x \rightarrow \infty$, the following inversion formula holds:

$$f(x) = \int_0^{\infty} y g(y) J_n(xy) dy. \quad (20)$$

There are other types of series expansions in terms of Bessel functions as follows: **Dini's series**

$$\sum_{m=1}^{\infty} a_m J_v(\lambda_m x)$$

(λ_m is the m th positive root of $xJ'_v(x) + HJ_v(x) = 0$, where H is a real constant); **Kapteyn's series**

$$\sum_{m=1}^{\infty} a_m J_{v+m}((v+m)x);$$

Schlömilch's series

$$\frac{a_0}{2} + \sum_{m=0}^{\infty} a_m J_0(mx);$$

and the **generalized Schlömilch series**

$$\frac{1}{2} \frac{a_0}{\Gamma(v+1)} + \sum_{m=1}^{\infty} \frac{a_m J_v(mx) + b_m H_v(mx)}{(mx/2)^v},$$

where $H_v(mx)$ is the Struve function (-Section F).

E. Asymptotic Expansion

If $|z|$ or v is sufficiently large, the asymptotic representation for Bessel functions is obtained

by applying the \dagger method of the steepest descent for (2). If $|z| > |v|$, we have

$$H_v^{(1)}(z) \sim \sqrt{\frac{2}{\pi z}} \exp i \left(z - \frac{\pi}{2} v - \frac{\pi}{4} \right),$$

$$-\pi < \arg z < 2\pi,$$

$$H_v^{(2)}(z) \sim \sqrt{\frac{2}{\pi z}} \exp \left(-i \left(z - \frac{\pi}{2} v - \frac{\pi}{4} \right) \right),$$

$$-2\pi < \arg z < \pi,$$

$$J_v(z) \sim \sqrt{\frac{2}{\pi z}} \cos \left(z - \frac{\pi}{2} v - \frac{\pi}{4} \right),$$

$$-\pi < \arg z < \pi,$$

$$N_v(z) \sim \sqrt{\frac{2}{\pi z}} \sin \left(z - \frac{\pi}{2} v - \frac{\pi}{4} \right).$$

Hence $H_v^{(1)}(z)$ tends to zero as $|z| \rightarrow \infty$ in the upper half-plane, and becomes large exponentially as $|z| \rightarrow \infty$ in the lower half-plane. The results for $H_v^{(2)}$ are obtained by interchanging "upper half-plane" with "lower half-plane" in this statement.

If both $|z|$ and $|v|$ are sufficiently large, we have the **Debye asymptotic representations**. For example, if $z = v \sec \beta$ ($v > 0$, $\beta > 0$), we have

$$H_v^{(1,2)}(v \sec \beta) \sim (\pi v \tan \beta/2)^{-1/2} \times \exp(\pm i v (\tan \beta - \beta) - \pi/4).$$

If $z = v \operatorname{sech} \alpha$ ($v > 0$, $\alpha > 0$), we have

$$\begin{aligned} J_v(v \operatorname{sech} \alpha) &\sim (2\pi v \tanh \alpha)^{-1/2} \exp v (\tanh \alpha - \alpha), \\ N_v(v \operatorname{sech} \alpha) &\sim (nv \tanh \alpha/2)^{-1/2} \exp v (\alpha - \tanh \alpha), \end{aligned}$$

If $|v| \sim |z|$, we have

$$\begin{aligned} H_v^{(1,2)}(v \sec \beta) &\sim \frac{\tan \beta}{\sqrt{3}} \\ &\times \exp \left(\pm i \left(\frac{\pi}{6} + v \left(\tan \beta - \frac{1}{3} \tan^3 \beta - \beta \right) \right) \right) \\ &\times H_{1/2}^{(1,2)}((v/3) \tan^3 \beta) + O(v^{-1}), \end{aligned}$$

which is called **Watson's formula**.

F. The Wagner Function

As an application of Bessel functions to the theory of nonstationary aircraft wings, T. Theodorsen introduced the function

$$C(z) = H_1^{(2)}(z)/(H_0^{(2)}(z) + H_1^{(2)}(z))$$

[6], and H. Wagner considered the function

$$k_1(s) = \frac{1}{2\pi i} \int_{Br} e^{ws} \frac{2C(-iw)}{w} dw$$

[5], where $H_0^{(2)}(z)$, $H_1^{(2)}(z)$ are Hankel functions, and \int_{Br} means a Bromwich integral giving the inverse Laplace transform. Then $C(z)$ and $k(s)$ are called the **Theodorsen function** and **Wagner function**, respectively. The function $k(s)$ is equal to the lift coefficient when a 2-dimensional flat wing suddenly proceeds forward a distance s at an angle of incidence $1/\pi$.

G. Functions Related to Bessel Functions

The following functions are closely related to Bessel functions (- Appendix A, Table 19.IV).

(1) **Modified Bessel functions.**

$$I_\nu(z) \equiv e^{-i\nu\pi/2} J_\nu(e^{i\pi/2} z),$$

$$K_\nu(z) = \frac{\pi}{2} \frac{I_{-\nu}(z) - I_\nu(z)}{\sin \nu\pi}$$

(2) **Kelvin functions.**

$$\text{ber}_\nu(z) \pm i \text{bei}_\nu(z) \equiv J_\nu(e^{\pm 3\pi i/4} z),$$

$$\text{her}_\nu(z) \pm i \text{hei}_\nu(z) \equiv H_\nu^{(1)}(e^{\pm 3\pi i/4} z),$$

$$\text{ker}_\nu(z) \equiv -(\pi/2) \text{hei}_\nu(z),$$

$$\text{kei}_\nu(z) \equiv (\pi/2) \text{her}_\nu(z).$$

(3) **Struve function.**

$$H_\nu(z) = \sum_{m=0}^{\infty} \frac{(-1)^m (z/2)^{\nu+2m+1}}{\Gamma[m+(3/2)] \Gamma[v+m+(3/2)]}$$

(4) **Anger function.**

$$J_\nu(z) \equiv \frac{1}{\pi} \int_0^\pi \cos(\nu\theta - z \sin \theta) d\theta.$$

When ν is an integer n , we have $J_\nu(z) = J_{-n}(z)$.

(5) **H. F. Weber function.**

$$E_\nu(z) \equiv \frac{1}{\pi} \int_0^\pi \sin(\nu\theta - z \sin \theta) d\theta.$$

The last three functions satisfy certain inhomogeneous Bessel differential equations. Many other functions, such as \dagger Airy's integral, can be represented by Bessel functions.

Biometrics

A. General Remarks

Biometrics is the branch of science that applies mathematical and statistical methods to biological problems, and deals with all the phenomena that affect the physical, social, and psychological well-being of human beings. These phenomena involve the relationships of groups of human beings to other human beings, to animals, microbes, and plants, and to physical and chemical elements in the environment. In dealing with these problems the biometrician encounters such theoretical tasks as analyzing autocorrelated data in time series, and such practical undertakings as cost-vs-benefit evaluations of health programs.

Biometrics began in the middle of the 17th century when Sir William Petty and John Graunt developed a new method of analyzing the London Bills of Mortality. Petty and Graunt essentially invented the field of *vital statistics* by studying the reports of christenings and causes of death and proposed a method called "political arithmetic."

Some fields to which biometrics is relevant are given below.

B. Statistical Genetics

After early development in vital statistics, *statistical genetics* was founded on the new ideas emerging in statistics. Major contributions were made by Charles Darwin (1809–1882), Francis Galton (1822–1911), Karl Pearson (1857–1936), and Ronald A. Fisher (1890–1962).

Galton was the first to use the term "regression" in statistics (\rightarrow 403 Statistical Models D), when he observed that sons regressed linearly on their fathers with respect to stature. He called the phenomenon a "regression to mediocrity" because the deviations of the stature of sons were less than those of fathers. This gave rise to the measurement of correlation in the bivariate normal distribution by means of the coefficient of correlation (Pearson, 1897). Pearson is credited with the

creation of the discipline of biometry (biometrics), and he established the journal *Biometrika* to promote studies in the field. Fisher's major contributions were to genetics and statistical theories. His *General theory of natural selection* appeared in 1930. This landmark book, along with earlier and later publications, represented Fisher's attempts to give quantitative form to Darwin's views and to frame a statistical theory of evolution.

C. Bioassay

Bioassay is a set of techniques for evaluating the effectiveness of dosages of drugs by monitoring biological responses. It entails the use of special transformations, such as probits and logits, as well as the application of regression to the estimation of dosages that are p percent effective within stated confidence limits. Problems to be solved include measuring relative potency, slope-ratio assays, and quantal responses vis-à-vis tolerance distributions.

D. Demography

Demography, which includes traditional vital statistics, rates and ratios, life tables, competing risks, actuarial statistics, and census enumeration techniques, is a part of biometrics. In this category, many tabulations of data consist of time series of events or rates classified by age. For the analysis of such data, the cohort analysis techniques described in Hastings and Berry [3] are employed.

E. Epidemiology

The quantitative description of an epidemic should state the sensitivity and specificity of any diagnostic tests, as well as the true incidence or prevalence of the epidemic from survey results. Within an epidemiological theory, a disease is studied by the use of deterministic and stochastic models, wherein the theory of Markov chains can be applied (- 260 Markov Chains). Differential equations involving probability-generating functions or moment-generating functions can be solved to yield the probability distribution, \bar{x} mean, and σ^2 variance of the number of infected individuals as functions of time [4, 5]. Fundamental to this whole field of application is a clear understanding of causality and association.

When clinical trials are possible, two groups of persons, "treated" and "untreated," are monitored over a period of time with regard to the incidence or recovery from the disease

under study. The techniques in this procedure include compiling reports on persons to be observed, using double-blind techniques, and combining multiple-response variables by use of multivariate analysis (- 280 Multivariate Analysis).

If clinical intervention is forbidden on ethical grounds, e.g., studying congenital malformation by infecting pregnant women with German measles, the relative risk of exposure is estimated from retrospective studies. In practice, almost all statistical studies in epidemiology are retrospective with the sole exception of clinical trials. The research is ex post facto because investigators are mostly confined to describing and analyzing sudden and/or obvious events in the etiology of the disease.

F. Clinical Trials

In clinical trials, many problems have arisen for which biometricians have had to develop special techniques. One such technique takes account of unexpected adverse effects of drugs, and the consequent early termination of a trial. Moreover, when data demonstrate a trend earlier than expected, investigators will desire to end the accession of patients and to stop further treatment with what may be an inferior regimen. This means that the biometrician must be familiar with the problems of multiple examinations of data, multiple comparisons, and other adjustment procedures required by the ex post facto dredging of data.

G. Future Trends

There are two areas in which the biometrician has played a leading role recently. These are pertinent in many different applications and problems, and considerable methodological research has been devoted to the two areas. The areas are "mathematical modeling" and "effects of hazardous substances."

Mathematical Modeling. The relationship between a set of independent variables and the dependent or response variable(s) is usually referred to as a mathematical model. The model may take the form of a standard multiple regression analysis with a single response variable or with multiple response variables as in multivariate analysis (- 280 Multivariate Analysis).

It is generally assumed that specialists with substantive knowledge of the specific field of applications (epidemiology, toxicology, pharmacology, radiology, genetics, etc.) play a

crucial role in determining a model or relationship between a set of independent variables and response variable(s). However, it is mainly the biometrician who finally selects the specific model establishing the functional relationship and who attempts to measure the strength or influence of the independent variables therein. The biometrician is also expected to contribute substantially to the decision as to whether the relationship is causal, or merely one of association or correlation. For example, in the measurement of carcinogenicity of a food additive or drug, questions arise as to whether a substance can be judged harmful if it "accelerates" the appearance of a tumor even though it does not increase the incidence of the abnormal growth. In general, the answer to this question is in the affirmative when an unequivocal dosage-response relationship is indicated between the substance and the tumor.

Effects of Hazardous Substances. With the successful conquest of most of the infectious diseases that have plagued mankind throughout history, health authorities have recently been concentrating on two chronic diseases whose etiology is yet to be determined: cardiovascular disease and cancer. In both cases there is no disagreement with the thesis that heredity exercises a determining influence, but the role of the environment in causing many cases is also unquestioned. Measurement of the risk due to potentially toxic substances in the environment, principally with respect to these two diseases, represents the greatest challenge to the biometrician today. The social benefits of success make this a tantalizing area of research, though exceptional complexities are involved.

41 (XX.20) Boltzmann Equation

A. Introduction

The Boltzmann equation is an equation of motion of a rarefied gas given by L. Boltzmann in 1872 [1]. He used it successfully in his pioneering work on the kinetic theory of gases and on the more general statistical mechanics (- 402 Statistical Mechanics), but the equation was held to be inconsistent with the †classical mechanics used in its derivation; objections were raised by, e.g., J. Loschmidt (1895) and E. Zermelo (1896). Through the controversies it became widely recognized that the Boltzmann equation should be justified by means of the †theory of probability, and many such justifications have been proposed. Also, this equation has been studied extensively as a significant nonlinear partial differential equation.

B. Boltzmann Equation

Let $f = f(t, x, \xi)$ be the density of gas molecules having position $x \in \mathbf{R}^3$ and velocity $\xi \in \mathbf{R}^3$ at time t . The Boltzmann equation is a conservation law for f of the form [1-3]

$$f_t = -\xi \cdot \nabla_x f - a(t, x) \cdot \nabla_\xi f + Q[f]. \quad (1)$$

Here $a(t, x)$ denotes the external force and Q is a quadratic nonlinear integral operator in ξ -space describing binary collisions of the molecules. The integral kernel of Q , called the collision cross section, depends on the intermolecular forces. The two classical examples are the hard ball model (a gas of rigid spheres) and the inverse power law potential (one proportional to r^{-s} , where r is the intermolecular distance and $s > 1$). The latter gives rise to singularities in the kernel, and a cutoff is customarily employed to avoid this difficulty. Grad's hard ($s \geq 5$) and soft ($s < 5$) cutoff potentials may be effectively used in the study of (1) [3].

If the gas is contained in a vessel (domain), then f must also satisfy boundary conditions determined by the assumed law of reflection at the walls (boundaries) (specular reflection, random reflection, etc.). For spatially homogeneous gases with no external forces, (1) reduces to

$$f_t = Q[f], \quad (2)$$

with $f = f(t, \xi)$. The Maxwellians, those solutions satisfying the †Maxwell-Boltzmann distribution law, are the only stationary solutions of (2); they describe equilibrium states.

C. Justification by the Theory of Probability

Consider (2). The collision process is a †Markov process, and the †master equation obtained from the †Chapman-Kolmogorov equality is equivalent to (2) under the assumption of “propagation of molecular chaos” (G. Uhlenbeck (1942)). This assumption becomes valid in the limit as N (total number of molecules) $\rightarrow \infty$ (M. Kac (1955), H. McKean (1967), F. Grünbaum (1971)) [4]. Also, non-linear Markov processes defined by (2) (with probability density f/N) have been studied (McKean (1967), H. Tanaka [5]). No such results have yet been established for (1).

D. Existence of Solutions

T. Carleman [2] gave the first solutions of the Boltzmann equation, solving globally in time the †Cauchy problem for (2) for the hard ball model. His result has been extended to a wide class of potentials.

The spatially inhomogeneous case (1) is also known to have global solutions if $a(t, x) = 0$ and if the initial data for f are nearly Maxwellian. This was first proved by S. Ukai [6] assuming periodicity in x , and then proved for the Cauchy problem by Ukai [7] and T. Nishida and K. Imai [8], and for the initial boundary problem by J. P. Guiraud [9] (random reflection) and Y. Shizuta and K. Asano [10] (specular reflection) for bounded domains, and by Ukai and Asano [11] for exterior domains, all assuming Grad's hard cutoff potentials. The case of soft cutoff potentials was also solved (Ukai and Asano, R. Caflisch (1980)). All the solutions are unique and tend to Maxwellians as $t \rightarrow \infty$, with certain decay rates. There are some results also on 1-dimensional shock wave solutions (B. Nicolaenko (1975)) and stationary solutions (J. P. Guiraud (1972) (bounded domains), Ukai and Asano (1980) (exterior domains)).

For initial data far from the Maxwellian, (1) remains unsolved even locally in time for hard cutoff potentials. As for noncutoff potentials, the existence theorem in [5] is the only result known so far for either (1) or (2).

E. Hilbert Expansion

Put $f^\varepsilon = f/N$ with $\varepsilon = 1/N$. If f^ε has a power series expansion in ε , then (1) gives an infinite system of equations for the coefficients. D. Hilbert (1912) proposed a method of solving this system as an application of his theory of integral equations, initiating the attempt to

solve the Boltzmann equation. No proofs of convergence exist, but his expansion and the improved one by S. Chapman (1917) and D. Enskog (1917) made possible the applications of (1) to hydrodynamics. The zeroth-order approximation to the expansion gives rise to the compressible Euler equation, and the first-order approximation yields the compressible Navier-Stokes equation. The solutions f^ε of the Cauchy problem for (1) with nearly Maxwellian initial data converge to those of the compressible Euler equation locally in t as $\varepsilon \rightarrow 0$ (Nishida [12], Caflisch (1980)), and to those of the compressible Navier-Stokes equation asymptotically as $t \rightarrow \infty$ when $\varepsilon > 0$ is fixed [13].

42 (11.15) Boolean Algebras

A. Boolean Algebras

Boolean algebra was introduced by G. Boole to study logical operations (- 411 Symbolic Logic). It is now included within the more general concept of †lattice or lattice-ordered set (- 243 Lattices) and appears not only in logic but also very often in analysis in the form of a particular lattice of sets, e.g., the lattice of †measurable sets.

Let L be a given set and suppose that to any pair of its elements x, y there correspond two elements $x \cup y, x \cap y$ of L (called **join** and **meet** of x and y , respectively) such that the following laws are valid: (1) $x \cup y = y \cup x, x \cap y = y \cap x$ (commutative law); (2) $x \cup (y \cap z) = (x \cup y) \cap z, x \cap (y \cup z) = (x \cap y) \cup z$ (associative law); (3) $x \cup (y \cap x) = (x \cup y) \cap x = x$ (absorption law); (4) $x \cup (y \cap z) = (x \cup y) \cap (x \cup z), x \cap (y \cup z) = (x \cap y) \cup (x \cap z)$ (distributive law); ($x, y, z \in L$). From (1), (2), and (3) it follows further that $x \cup x = x \cap x = x$ (idempotent law). If $x \leq y$ is defined to mean $x \cup y = y$, L becomes an †ordered set with respect to the ordering \leq . Now suppose, moreover, that the following law holds: (5) there exist a least element 0 and a greatest element 1 , and for any element x there exists an element x' satisfying $x \cup x' = 1, x \cap x' = 0$ (**law of complementation**). Then L is called a **Boolean algebra** (or †**Boolean lattice**). In this case x' is uniquely determined by x and is called the **complement** of x . The binary operations $(x, y) \mapsto x \cup y, x \cap y$ together with the operation $x \mapsto x'$ are called **Boolean operations**. These operations obey **de Morgan's law** $(x \cup y)' = x' \cap y', (x \cap y)' = x' \cup y'$.

B. Generalized Boolean Algebras

Suppose that $a \leq b$ holds for two given elements a, b of an ordered set. Then the set of all elements x satisfying $a \leq x \leq b$ is denoted by $[a, b]$ and is called an **interval**. An interval of a

Boolean algebra is also a Boolean algebra with respect to the induced operations \cup and \cap , where the least and greatest elements are a and b , respectively, and the complement of x in $[a, b]$ is equal to $a \cup (x' \cap b) = (a \cup x') \cap b$. More generally, if a set L with two operations \cup, \cap satisfying (1)–(4) above has a least element 0 and if each interval of L satisfies (5) (i.e., is a Boolean algebra), then L is called a **generalized Boolean algebra**.

C. Boolean Rings

A ring L satisfying the condition $xx = x$ for all $x \in L$ (i.e., all of its elements are †idempotent) is called a **generalized Boolean ring**, and if it has a unity element then it is called a **Boolean ring**. A generalized Boolean ring L satisfies $x + x = 0$ for all $x \in L$ and is necessarily a commutative ring. A (generalized) Boolean algebra L becomes a (generalized) Boolean ring if for any elements x, y of L the sum $x + y$ is defined to be the complement of $x \cap y$ in the interval $[0, x \cup y]$, and the product xy is defined to be $x \cap y$. A nonempty subset J of a (generalized) Boolean algebra L is an ideal with respect to the corresponding structure of the ring if and only if $x \cup y \in J$ for $x, y \in J$ and $x \cap y \in J$ for $x \in J, y \in L$. More generally, in any lattice, a nonempty subset that satisfies these conditions is sometimes called an **ideal** of the lattice.

D. Representation of a Boolean Algebra

Any Boolean algebra L is isomorphic to a Boolean lattice of subsets in a set X . If L is of finite height, then L is isomorphic to the Boolean lattice $\mathfrak{P}(X)$ of all subsets of X . In general X can be taken to be the set of all maximal ideals of L . Let $a \in L$ and let $O(a) = \{m \mid m \in X, a \notin m\}$. The isomorphism is obtained by the mapping $a \mapsto O(a)$. If we define a topology in X such that $\{O(a) \mid a \in L\}$ is the †open base, then X is a compact, totally disconnected T_1 space and $O(a)$ is characterized as a compact open set in X . Such a space X is called a **Boolean space** (M. H. Stone [3, 4]).

In any complete Boolean algebra L , the complete distributive laws hold: $(\sup_I x_i) \cap y = \sup_I (x_i \cap y)$ and its dual. These are equivalent to the stronger relations: $(\sup_I x_i) \cap (\sup_J y_j) = \sup_{IJ} (x_i \cap y_j)$ and its dual. In order for a Boolean algebra L to be isomorphic to the Boolean algebra $\mathfrak{P}(X)$ of all subsets of X , it is necessary and sufficient that the following strongest complete distributive laws hold: $\inf_I (\sup_{J(i)} x_{ij}) = \sup_F (\inf_{I, \varphi(i)} x_{i, \varphi(i)})$ (where F is the set of all functions φ assigning to each $i \in I$ a value $\varphi(i) \in J(i)$) and its dual.

43 (X1.4) Bounded Functions

A. General Remarks

A complex-valued function defined on a subset E of the complex z -plane is called a **bounded function** defined on E if its range $f(E)$ is bounded, that is, if there exists a positive constant M such that $|f(z)| \leq M$ on E . However, when studying the theory of bounded functions, we usually restrict ourselves to the consideration of \dagger analytic or \dagger harmonic functions. On the other hand, the classes of functions $f(z)$ satisfying conditions such as $\operatorname{Re} f(z) > 0$ or $\alpha < \arg f(z) < \beta$ rather than $|f(z)| \leq M$ are studied by a method similar to that applied to the study of bounded functions.

\dagger Schwarz's lemma, \dagger Liouville's theorem, and \dagger Riemann's theorem on the removability of singularities (which will be explained later) are among the classical theorems in the theory of bounded functions.

B. Maximum Principle

When a function $f(z)$ is holomorphic and not constant in a domain D of the complex plane, $|f(z)|$ never attains its maximum in the interior of D . In particular, when $f(z)$ is continuous on the bounded closed domain $\bar{D} = D \cup \partial D$, the maximum of $|f(z)|$ on D is taken on its boundary ∂D . This fact is called the **maximum (modulus) principle**.

As a direct application of the maximum principle, we can deduce **Schwarz's lemma**: If a holomorphic function $f(z)$ in $|z| < R$ satisfies $|f(z)| \leq M$ and $f(0) = 0$, we have $|f(z)| \leq M \cdot |z|/R$ ($|z| < R$). The equality at z_0 , $0 < |z_0| < R$, occurs only for the functions $f(z) = e^{i\lambda} Mz/R$ (where A is a real constant).

C. Lindelöf's Principle

E. Lindelöf extended Schwarz's lemma and obtained various extensions of the maximum principle, from which he, together with E. Phragmén, deduced several useful theorems on the behavior of a function that is single-valued and holomorphic in a neighborhood of the boundary. We mention some representative theorems:

Let $z = \varphi(\zeta)$ and $w = \psi(\zeta)$ both be \dagger meromorphic and \dagger univalent functions in $|\zeta| < 1$ that map $|\zeta| < 1$ onto D_z and D_w , respectively. Set $\varphi(0) = z_0$ and $\psi(0) = w_0$. Let $D_z(\rho)$ and $D_w(\rho)$ denote the images of $|\zeta| \leq \rho$ ($0 < \rho < 1$) under the mappings φ and ψ , respectively. Under these circumstances, if a function $f(z)$ that is holomorphic in D_z satisfies $f(D_z) \subset D_w$ and $f(z_0) = w_0$, then $f(D_z(\rho)) \subset D_w(\rho)$. Furthermore, unless $f(z)$ maps D_z onto D_w univalently, $f(D_z(\rho))$ is contained in the interior of $D_w(\rho)$ (an extension of Schwarz's lemma).

Let $f(z)$ be analytic in a bounded domain D but not necessarily single-valued. Suppose that $|f(z)|$ is single-valued. Suppose, furthermore, that there is a positive constant M such that, for each boundary point ζ of D , except for a finite number of boundary points and for each $\varepsilon > 0$, the inequality $|f(z)| < M + \varepsilon$ holds on the intersection of D with a suitable neighborhood of ζ , and suppose also that each of the exceptional points has a neighborhood such that $f(z)$ is bounded on the intersection of D with this neighborhood. Under these assumptions we have $|f(z)| \leq M$. Moreover, if $|f(z_0)| = M$ at a point z_0 of D , then $f(z)$ is a constant (an extension of the maximum principle).

Let $f(z)$ be holomorphic in an angular domain W : $\arg z| < \alpha\pi/2$. Suppose that there is a constant M such that, for each $\varepsilon > 0$, each finite boundary point has a neighborhood such that $|f(z)| < M + \varepsilon$ on the intersection of D with this neighborhood, and that for some positive number $\beta > \alpha$ and for sufficiently large $|z|$ the inequality $|f(z)| < \exp|z|^{1/\beta}$ holds. Under these assumptions we have $|f(z)| \leq M$ in D (**Phragmén-Lindelöf theorem**).

Let $f(z)$ be a function that is holomorphic and bounded in a closed angular domain W : $\alpha \leq \arg z \leq \beta$ except for the point at infinity. Suppose that $f(z) \rightarrow a$ as $z \rightarrow \infty$ along a side of the angle and that $f(z) \rightarrow b$ as $z \rightarrow \infty$ along the other side of it. Then we have $a = b$ and $f(z) \rightarrow a$ uniformly as $z \rightarrow \infty$ in W (**Lindelöf's asymptotic value theorem**).

D. Bounded Functions in a Disk

If $f(z)$ is a bounded holomorphic function in the unit disk $|z| < 1$, it has a limit at every

point z_0 on the circle $C: |z|=1$, except for a set of 1-dimensional measure zero, as z tends to z_0 from within an angle with vertex at z_0 and contained in $|z|<1$ (or along a *Stolz's path at z_0) (**Fatou's theorem**). Under the same assumption, if the boundary value function $f(e^{i\theta}) = \lim_{r \rightarrow 1-0} f(re^{i\theta})$, which exists by Fatou's theorem, is equal to a constant a for a set of positive measure on the circle C , then $f(z) \equiv a$ in $|z|<1$ (**F. and M. Riesz theorem**). These theorems are valid for some kinds of meromorphic functions in $|z|<1$ (- 272 Meromorphic Functions D).

E. Three-Circle Theorem and Related Theorems

Let $f(z)$ be a function that is single-valued, holomorphic, and not identically zero in an annulus $\rho < |z| < R$. Set $M(r) \equiv \max_{|z|=r} |f(z)|$ ($\rho < r < R$) for $f(z)$. Then $\log M(r)$ is a \dagger convex function of $\log r$ in $\log \rho < \log r < \log R$ (**Hadamard's three-circle theorem**). The same assertion holds for a function $f(z)$ that is not necessarily single-valued, as long as $|f(z)|$ is single-valued. When $f(z)$ is single-valued, a stronger assertion can be obtained (O. Teichmüller). The following theorems are regarded as the analog of Hadamard's three-circle theorem for the respective basic regions:

Set $L(\sigma) \equiv \sup_{-\infty < t < \infty} |f(\sigma + it)|$ ($\alpha < \sigma < \beta$) for a function that is bounded and regular in a strip $\alpha < \operatorname{Re} z < \beta$. Then $\log L(\sigma)$ is a convex function of σ in $\alpha < \sigma < \beta$ (**Doetsch's three-line theorem**).

Set $I(\sigma) = \limsup_{t \rightarrow \infty} |f(\sigma + it)|$ ($\alpha < \sigma < \beta$) for a function that is holomorphic and bounded in a half-strip $\alpha < \operatorname{Re} z < \beta$, $\operatorname{Im} z > 0$. Then $\log I(\sigma)$ is a convex function of σ in $\alpha < \sigma < \beta$ (**Hardy-Littlewood theorem**).

Set

$$I_p(r) = \frac{1}{2\pi} \int_0^{2\pi} |f(re^{i\theta})|^p d\theta$$

for a holomorphic function in a disk $|z| < R$. Then for every $p > 0$, $\log I_p(r)$ is an increasing convex function of $\log r$ for $-\infty < \log r < \log R$ (**Hardy's theorem**).

F. Hardy Class

Hardy's theorem motivates us to introduce a class of functions. An analytic function f in the unit disk is said to belong to the **Hardy class** H^p ($0 < p < \infty$) if $I_p(r, f) = (2\pi)^{-1} \int_0^{2\pi} |f(re^{i\theta})|^p d\theta$ remains bounded as $r \rightarrow 1$. For the case $p = \infty$, $f \in H^\infty$ if $I_\infty(r, f) = \max_{|z|=r} |f(z)|$ is bounded.

An analytic function f is said to be of the class N if $\int_0^{2\pi} \log^+ |f(re^{i\theta})| d\theta$ is bounded for $r < 1$. $f \in N$ if and only if $f = \varphi/\psi$, where $\varphi, \psi \in H^\infty$. $f \in H^p$ if and only if $|f|^p$ has a \dagger harmonic majorant. If $1 \leq p \leq \infty$, H^p is a \dagger Banach space with the norm $\|f\|_p = (\sup_{r < 1} I_p(r, f))^{1/p}$ for $p < \infty$ and $\|f\|_\infty = \sup_{r < 1} I_\infty(r, f)$ for $p = \infty$, and if $0 < p < 1$, H^p is a complete metric space with the metric $\sup_{r < 1} I_p(r, f - g)$. For $0 < p < q < \infty$ the inclusion relation $N \supset H^p \supset H^q \supset H^\infty$ holds, so that Fatou's theorem and that of F. and M. Riesz are valid for functions of H^p ($p > 0$).

For a nonnegative integer p and a sequence of nonzero complex numbers a_n , $|\alpha_n| < 1$, the infinite product $B(z) = z^p \prod_{n=1}^\infty (\bar{\alpha}_n(\alpha_n - z)/|\alpha_n| (1 - \bar{\alpha}_n z))$ converges locally uniformly in the unit disk if and only if $\sum_{n=1}^\infty (1 - |\alpha_n|) < \infty$. Then $B(z)$ is called a **Blaschke product** and $\{a_n\}$ a **Blaschke sequence**. If the sequence $\{a_n\} \cup \{0\}$ is the set of zeros of an analytic function f (an m -tuple zero appears m times in $\{\alpha_n\}$, and $z = 0$ is a p -tuple zero), $B(z)$ is said to be generated by the zeros of f . If $f \in N$, then $\sum_{n=1}^\infty (1 - |\alpha_n|) < \infty$ for the set $\{a_n\}$ of zeros off: An analytic function f in the unit disk is called an **inner function** if its modulus is less than 1 and its nontangential limit on the unit circle is of modulus 1 almost everywhere. A Blaschke product is an inner function. An inner function f without zeros is said to be singular if $f(0) > 0$. A **singular inner function** f can be represented by $f(z) = \exp \left\{ - \int_0^{2\pi} (e^{i\theta} + z)/(e^{i\theta} - z) d\mu(\theta) \right\}$ with a positive measure μ \dagger singular with respect to Lebesgue measure. An **outer function** $F(z)$ for H^p ($p > 0$) is an analytic function that can be represented by

$$F(z) = e^{ir} \exp \left\{ \frac{1}{2\pi} \int_0^{2\pi} \frac{e^{i\theta} + z}{e^{i\theta} - z} \log \psi(\theta) d\theta \right\},$$

where r is a real number and $\psi(\theta)$ is a nonnegative function such that $\psi(\theta) \in L^p$ and $\log \psi(\theta) \in L^1$. An H^p -function f ($p > 0$) is factorized uniquely as $f(z) = B(z)S(z)F(z)$, where $B(z)$ is a Blaschke product (generated by the zeros off), $S(z)$ a singular inner function, and $F(z)$ is an outer function for H^p (with $\psi(\theta) = |f(e^{i\theta})|$) (**factorization theorem**). Conversely, such a product belongs to H^p . The **interpolation problem** raised by R. C. Buck asks whether or not there exists a sequence of distinct points $\{z_n \mid |z_n| < 1\}$ such that, given any bounded sequence of complex numbers $\{w_n\}$, there is a function $f \in H^\infty$ for which $f(z_n) = w_n$. The sequence $\{z_n\}$ in the problem is called an **interpolating sequence**. L. Carleson proved that a necessary and sufficient condition for $\{z_n\}$ to be an interpolating sequence is that there be a $\delta > 0$ such that $\prod_{n \neq k} |(z_n - z_k)/(1 - \bar{z}_k z_n)| \geq \delta$ ($k = 1, 2, \dots$). An interpolating sequence is a Blaschke sequence, and any sequence $\{z_n \mid |z_n| \rightarrow 1\}$ contains an interpolating subsequence

tending to the unit circle. An analogous theorem is obtained for a function of H^p ($p \geq 1$).

G. Corona Problem

The Hardy space H^∞ on the unit disk D is furthermore a commutative † Banach algebra with identity. Let M denote the † maximal ideal space of H^∞ . It is a compact Hausdorff space with respect to the † Gel'fand topology. To each point $z \in D$, there correspond a homomorphism $\varphi_z: \varphi_z(f) = f(z)$ for $f \in H^\infty$, and a maximal ideal $M_z = \{f \in H^\infty | f(z) = 0\}$ as its kernel. This correspondence gives a continuous injection of D into the maximal ideal space M of H^∞ . By identifying z and M_z , D is regarded as an open subset of M , and the **corona problem** then asks: Are there points of M outside the closure of D ? The negative answer was given by L. Carleson, that is, D is dense in A_4 (**corona theorem**). The corona theorem is obtained as a direct consequence of the following theorem and is equivalent to it. For functions $f_i \in H^\infty$, $i = 1, 2, \dots, n$, satisfying $\sum |f_i(z)| > \delta$ in D with some $\delta > 0$, there exist $g_i \in H^\infty$, $i = 1, \dots, n$, such that $\sum f_i(z)g_i(z) = 1$ in D . As a trivial consequence of the corona theorem, we have the following **cluster value theorem**: Let $C(f, \zeta)$ denote the † cluster set of $f \in H^\infty$ at ζ with $|\zeta| = 1$; then $C(f, \zeta) = \hat{f}(M_\zeta)$, where \hat{f} is the Gel'fand transform off and M_ζ is the † fiber of M over ζ . M is decomposed into pairwise disjoint † Gleason parts. A Gleason part is a connected open set or a singleton according as each point of it is captured in the closure of an interpolating sequence or not. Each point of the † Shilov boundary Γ of M forms by itself a trivial Gleason part, and Γ is † adherent to a sequence S in D with the property that the set of its nontangential limit points covers the unit circle (**Brown-Shield-Zeller theorem**). Let D be, in turn, a general bounded domain. The corona theorem is proved for some classes of such domains. A Shilov boundary Γ lies only over the set of points on ∂D which are not † removable for bounded analytic functions. It is adherent to a sequence S in D on which $\sup_S |f(z)| = \|f\|_\infty$. For any $f \in H^\infty$ and $\zeta \in \partial D$, the boundary of $\hat{f}(M_\zeta)$ is contained in $\hat{f}(\Gamma_\zeta)$ if $\Gamma_\zeta = \Gamma \cap M_\zeta$ is not empty. This, together with the cluster value theorem, has an important implication in the theory of cluster sets. The extremal problem of maximizing $f'(z_0)$, $z_0 \in D$, among all $f \in H^\infty$ satisfying $\|f\|_\infty \leq 1$ has the unique normalized solution G such that $G'(z_0) = \max |f'(z_0)|$. $G(z)$ is called the **Ahlfors function**. The Ahlfors function has unit modulus on the Shilov boundary (**Fisher's theorem**). The theory of H^∞ is also applied to the problem of

† rational approximation of bounded analytic functions.

H. Applications of the Maximum Principle

Theorems of the following type are useful for some problems of holomorphic functions:

Let D be a domain. Suppose that there exists an arc of angular measure α that is on a circle of radius R centered at a point z_0 of D and not contained in D . Let C denote the intersection of the boundary of D with the disk $|z - z_0| < R$. If $f(z)$ is a single-valued holomorphic function that satisfies $|f(z)| \leq M$, and if $\limsup_{z \rightarrow \zeta} |f(z)| \leq M$ for every $\zeta \in C$, then the inequality $|f(z_0)| \leq M^{1-1/n} m^{1/n}$ holds for every positive integer n satisfying $2\pi/n \leq \alpha$ (**Lindelöf's theorem**).

Let D be a domain bounded by two segments OA , OB both starting from 0 and making an angle $\pi\alpha$, and a Jordan arc \widehat{AB} , and let R be the maximal distance between 0 and the points on \widehat{AB} . Suppose that $f(z)$ is holomorphic in D and that $\limsup |f(z)|$ as $z \rightarrow \zeta \in \partial D$ with $z \in D$ is not greater than M for $\zeta \in OA \cup OB$ and m for $\zeta \in \widehat{AB}$. Then we have $|f(z)| \leq M^{1-\lambda} m^\lambda$ (where $\lambda = (|z|/R)^{1/\alpha}$) at every point on the bisector of the angle $\angle AOB$ in D (**Carleman's theorem**).

I. Holomorphic Functions with Positive Real Parts

Holomorphic functions with positive real parts are intimately connected with bounded functions. Concerning these functions we have the following classical result, which is equivalent to Schwarz's lemma: If $f(z)$ is holomorphic in $|z| < R$, $\operatorname{Re} f(z) \geq 0$ in the same domain, and $f(0) = 1$, then $(R - |z|)/(R + |z|) \leq \operatorname{Re} f(z) \leq (R + |z|)/(R - |z|)$ ($|z| < R$). The right or left inequality becomes equality for some z_0 , $0 < |z_0| < R$, only if $f(z) = (Rz_0 \mp z_0z)/(R \pm z_0z)$, respectively.

In order to prove various results for the class of functions with positive real part, **Herglotz's integral representation**, which is based on Poisson's integral representation and unique to this class, can be used effectively. It is given by

$$f(z) = \int_0^{2\pi} \frac{e^{i\varphi} + z}{e^{i\varphi} - z} d\rho(\varphi), \quad |z| < R,$$

where $\rho(\varphi)$ is monotone increasing (real-valued) with total variation 1 and is determined uniquely up to an additive constant by $f(z)$. An analogous integral representation is introduced for a holomorphic function in an annulus.

Similar to the case of holomorphic functions is the notion of Hardy classes to harmonic

functions, that is, a harmonic function u in the unit disk is said to be of the class h^p ($0 < p \leq \infty$) if $I_p(r, u)$ is bounded for $r < 1$. $u \in h^p$ if and only if $u + iv \in H^p$, where v is conjugate to u . h^1 is equal to the vector space of functions which are representable as a difference of two non-negative harmonic functions. The Herglotz theorem stated above is then a corollary of the theorem of integral representation for h^1 -functions.

J. Coefficient Problems

There are many classical results for partial sums and coefficients of the Taylor expansion of bounded functions in a disk. Let $f(z) = \sum_{n=0}^{\infty} c_n z^n$ be the Taylor expansion of a bounded function in $|z| < 1$. Set its partial sum $s_n(z) = \sum_{v=0}^n c_v z^v$ ($n=0, 1, \dots$), and let $t_n(z) = (1/(n+1)) \sum_{v=0}^n s_v(z)$ ($n=0, 1, \dots$), which is the sequence of the arithmetic means of the partial sums (the Fejér sums). Then $|f(z)| \leq 1$ in $|z| < 1$ if and only if $|t_n(z)| \leq 1$ for $|z| = 1$ ($n=0, 1, \dots$) (L. Fejér). Thus the sequences $\{t_n(z)\}$ for bounded functions $f(z)$ are uniformly bounded, whereas the sequences $\{s_n(z)\}$ are not uniformly bounded. Indeed the maximum value of $|s_n(1)|$ over the set of function f satisfying $|f(z)| \leq 1$ for $|z| < 1$ is

$$G_n = 1 + \sum_{j=1}^n \binom{-1/2}{j}^2 = \sum_{j=0}^n \left(\frac{1 \cdot 3 \cdot \dots \cdot (2j-1)}{2 \cdot 4 \cdot \dots \cdot 2j} \right)^2$$

($G_n \sim \pi^{-1} \log n$ as $n \rightarrow \infty$).

The following result is decisive for coefficient problems: Set $h_{\mu\nu} = \sum_{j=0}^{\mu} \bar{c}_{\mu-j} c_{\nu-j}$ ($\mu \leq \nu$), $h_{\nu\mu} = h_{\mu\nu}$ for $f(z) = \sum_{n=0}^{\infty} c_n z^n$, let m_n^2 be the maximal eigenvalue (a nonnegative real number) of the Hermitian matrix $(-h_{\mu\nu})_{\mu, \nu=0}^n$, and let $m = \lim m_n (\geq 0)$.

Let H be a Hermitian form in infinitely many variables given by

$$H = m^2 \sum_{\nu=0}^{\infty} \bar{x}_{\nu} x_{\nu} - \sum_{\mu, \nu=0}^{\infty} h_{\mu\nu} \bar{x}_{\mu} x_{\nu} = m^2 \sum_{\nu=0}^{\infty} |x_{\nu}|^2 - \sum_{\mu=0}^{\infty} \left| \sum_{\nu=0}^{\infty} c_{\nu} x_{\mu+\nu} \right|^2.$$

Then a necessary and sufficient condition for $|f(z)| \leq 1$ when $|z| < 1$ is that H be positive semidefinite, i.e., the sequence of the principal minor determinants of H ,

$$\Delta \begin{pmatrix} 1 & 2 & \dots & m \\ 1 & 2 & \dots & m \end{pmatrix}, \quad m=1, 2, \dots,$$

is all positive or positive for an initial finite number of them and zero for the remainder (I. Schur).

A corresponding result for functions with positive real part in a disk can be stated in a simpler form: A holomorphic function $f(z) = 1/2 + \sum_{n=1}^{\infty} c_n z^n$ in $|z| < 1$ satisfies $\operatorname{Re} f(z) \geq 0$ if and only if

$$\begin{vmatrix} 1 & c_1 & \dots & c_n \\ \bar{c}_1 & 1 & \dots & c_{n-1} \\ \vdots & \vdots & \ddots & \vdots \\ c_n & \bar{c}_{n-1} & \dots & 1 \end{vmatrix} \geq 0, \quad n=1, 2, \dots$$

(C. Carathéodory). Furthermore, for $n = 1, 2, \dots$, when we regard (c_1, \dots, c_n) as a point of complex n -dimensional Euclidean space, we can determine the domain of existence of points satisfying this criterion by Carathéodory. This result is generalized for coefficients of the Laurent expansion of a function that is holomorphic and single-valued in an annulus.

Next, there are some results for a function that omits two values: If $f(z) = a + a_1 z + \dots$ ($a_1 \neq 0$) is holomorphic in $|z| < R$ and $f(z) \neq 0, 1$ in the same domain $|z| < R$, then there exists a constant $L(a_0, a_1)$, depending only on a , and a_1 , such that $R \leq L(a_0, a_1)$ (Laudau's theorem). Under these circumstances, $|f(z)| \leq S(a_0, \theta)$ in $|z| \leq \theta R$ for $0 < \theta < 1$, where $S(a_0, 0)$ is a constant depending only on a , and θ (Schottky's theorem). These theorems have applications in value distribution theory. On the other hand, coefficient problems have been investigated as extremal problems in H^p -spaces under general conditions.

K. Angular Derivative

Let $f(z)$ be holomorphic in $|z| < 1$. If $f(z) \rightarrow w_0$ uniformly as $z \rightarrow z_0$ along Stolz paths with end point at z_0 and if the limit $\lim_{z \rightarrow z_0} ((f(z) - w_0)/(z - z_0)) \equiv D$ exists, we call D the **angular derivative** of $f(z)$ at z_0 . In the case of the half-plane $\operatorname{Re} z > 0$, the angular derivative at the point z_0 on the imaginary axis is similarly defined. It should be noted that $f(z) \rightarrow w_0$ is replaced by $1/f(z)$ for $w_0 = \infty$ and $1/(z - z_0)$ by z for $z_0 = \infty$. In the latter case, a Stolz path is a path contained in an angular domain $|\arg z| \leq \alpha$ ($\alpha < \pi/2$) and tending to ∞ . The study of angular derivatives was initiated by G. Julia (1920) and J. Wolff (1926) and was further advanced by Carathéodory (1929) and E. Landau and G. Varilon (1929).

A fundamental theorem for angular derivatives can be stated as follows: If a holomorphic function $f(z)$ in $\operatorname{Re} z > 0$ satisfies $\operatorname{Re} f(z) \geq 0$, there exists a constant c ($0 \leq c < +\infty$) such that $f(z)/z \rightarrow c$ and $f'(z) \rightarrow c$ uniformly as $z \rightarrow \infty$ along every Stolz path. Moreover, the p th derivative of $f(z)$ for an arbitrary positive p , denoted by $D^p f(z)$, has the property that $z^{p-1} D^p f(z) \rightarrow c/\Gamma(2-p)$ uniformly. Further-

Bounded Functions

more, the inequality $\operatorname{Re} f(z) \geq c \operatorname{Re} z$ holds everywhere in $\operatorname{Re} z > 0$. An analogous theorem is valid for the unit disk.

An important problem in the theory of conformal mapping is to find some condition for a mapping $w = f(z)$ of the unit disk (or half-plane) G onto a simply connected domain B to have a nonzero and finite angular derivative at a boundary point z_0 , that is, the condition for conformality at the boundary point. Carathéodory showed that a sufficient condition is the existence of two circles that are mutually inscribed and circumscribed at the boundary point $w_0 = f(z_0) \neq \infty$ of B and that lie inside and outside of B , respectively. Ahlfors later established a necessary and sufficient condition for the existence of the angular derivative by making use of his †distortion theorem for a strip domain. The angular derivative was used by Wolff in his research on the iteration of conformal mappings.

44 (XVII.1 0) Branching Processes

A. General Remarks

A **branching process** is a mathematical model for random motion of a family of particles each of which is in an isolated process of multiplication and death. Examples of such random motions are population growth, miosis of genes, growth of the numbers of neutrons in an atomic chain reaction, and cascade showers of cosmic rays. The simplest and most fundamental branching process is discussed in Section B. For a historical introduction to the study of branching processes \rightarrow Kendall [2] and Harris [3].

B. Galton-Watson Processes

Although there is a similar process with continuous parameter $t \in \mathbf{R}$, we consider here only the case of a discrete time parameter ($i = 0, 1, 2, \dots$). Suppose that we are given a family of particles of the same kind. Each member of the family splits into several particles according to a given probability law independently of the other members and its own past history. Let Z_n be the number of particles of the family at a moment (or generation) n ; then $\{Z_n\}$ gives rise to a †Markov chain. This is called the **Galton-Watson process**. A precise mathematical description of the process is as follows: A Galton-Watson process is a Markov chain $\{Z_n, n = 0, 1, \dots\}$ on the nonnegative integers with †transition probability defined in terms of a given †probability distribution $\{p_k, k = 0, 1, \dots, p_k \geq 0, \sum_{k=0}^{\infty} p_k = 1$, by

$$p_{ij} = P[Z_{n+1} = j | Z_n = i] = \begin{cases} p_i^{*j} & \text{if } i \geq 1, j \geq 0, \\ \delta_{ij} & \text{if } i = 0, j \geq 0, \end{cases}$$

where the probability distribution $\{p_k^{*i}, k = 0, 1, \dots\}$ denotes the i -fold †convolution of the probability distribution $\{p_k, k = 0, 1, \dots\}$ and δ_{ij} is the †Kronecker delta. Then p_k is interpreted as the probability that an object existing in the n th generation has k children in the $(n+1)$ th generation. We assume that $Z_0 = 1$ a.s. for the rest of this section. An important tool in the analysis of the process is the †generating function $f(s) = \sum_{j=0}^{\infty} p_j s^j, |s| \leq 1$. Denote the generating function $\sum_{k=0}^{\infty} P(Z_n = k) s^k$ ($s \leq 1$) of Z_n by $f_n(s)$. Then we have $f_0(s) = s$, $f_1(s) = f(s)$, $f_{i+j}(s) = f_i(f_j(s))$ ($i, j = 0, 1, 2, \dots$), and the †expectation of Z_n is given by $E(Z_n) = m^n$, where $m = f'(1) = E(Z_1)$ is the expectation of Z_1 . A Galton-Watson process is said to be **subcritical**, **critical**, or **supercritical** if $m < 1$, $= 1$, or > 1 , respectively. If we have $Z_n =$

0 for some n , then $Z_{n+1} = Z_{n+2} = \dots = 0$. The probability $q = P(\lim_n Z_n = 0)$ is called the **extinction probability**. The case $f_1(s) \equiv s$ is excluded in the following. The extinction probability q of the process $\{Z_n\}$ is the smallest nonnegative solution of the equation $s = f(s)$. It is 1 if $m \leq 1$ and < 1 if $m > 1$. Moreover, $P(\lim_n Z_n = \infty) = 1 - q$ when $m > 1$, and hence the process $\{Z_n\}$ is \dagger transient.

If we put $W_n = Z_n/m^n$ when $m < \infty$, $\{W_n\}$ gives rise to a \dagger martingale, and the limit $W = \lim_{n \rightarrow \infty} W_n$ exists with probability 1. If $m > 1$, then the \dagger moment-generating function $\varphi(s) = E(\exp(-sW))$ of W satisfies the **Königs-Schröder equation** $\varphi(ms) = f(\varphi(s))$, $\text{Re } s \geq 0$. If $m \leq 1$, then $P(Z_n = 0 \text{ for some } n) = 1$. The following theorem on the conditional distribution of Z_n , given that $Z_n \neq 0$, was first proved by Yaglom [6] under moment restrictions. If $m < 1$, there exist $b_k = \lim_n P(Z_n = k | Z_n \neq 0)$, $k = 1, 2, \dots$. Then $\{b_k | k = 1, 2, \dots\}$ is a probability distribution and its generating function $g(s) = \sum_{k=1}^{\infty} b_k s^k$, $|s| \leq 1$, is the unique solution of the equation $g(f(s)) = mg(s) + 1 - m$, $|s| \leq 1$, among generating functions vanishing at 0. Furthermore, when $m < 1$, $\sum_{j=1}^{\infty} j b_j < \infty$ if and only if $\sum_{j=1}^{\infty} p_j(j \log j) < \infty$ (i.e., $E[Z_1 \log Z_1] < \infty$).

If $m = 1$ and $\sigma^2 = \text{variance of } Z_1 < \infty$, then $\lim_n P[Z_n/n > u | Z_n \neq 0] = \exp[-2u/\sigma^2]$, $u \geq 0$. If $\sigma^2 = \infty$, then this result is still correct with the interpretation that the limit in the left-hand side equals 1.

For further details regarding the theory of Galton-Watson processes \rightarrow [3, S].

C. Multitype Galton-Watson Processes

These are generalizations of the Galton-Watson process, involving k types of particles ($k \geq 2$), say, T_1, T_2, \dots, T_k . Let $p^i(r_1, r_2, \dots, r_k)$ be the probability that a particle of type T_i splits into r_m particles of type T_m ($m = 1, 2, \dots, k$), and set $f^i(s_1, s_2, \dots, s_k) = \sum_r p^i(r_1, r_2, \dots, r_k) s_1^{r_1} s_2^{r_2} \dots s_k^{r_k}$. The number of particles $Z_n = (Z_n^1, Z_n^2, \dots, Z_n^k)$ at a moment n gives rise to a \dagger Markov chain over Z_+^k , and its transition probability is determined by $p^i(r_1, r_2, \dots, r_k)$ as for Galton-Watson processes. Here Z_+^k denotes the space of all k -dimensional \dagger lattice points whose components are nonnegative integers. We now define a mathematical model of the process mentioned above. A Markov chain $\{Z_n | n = 0, 1, \dots\}$ on Z_+^k is called a **multi (k)-type Galton-Watson process** if its transition probability is given by

$$P(i, j) = P[Z_{n+1} = j | Z_n = i] = \text{coefficient of} \\ \prod_{i=1}^k s_i^{j_i} \text{ in } \prod_{l=1}^k (f^l(s_1, s_2, \dots, s_k))^{i_l}$$

for $i = (i_1, i_2, \dots, i_k), j = (j_1, j_2, \dots, j_k) \in Z_+^k, n = 0, 1, \dots$ and $s = (s_1, s_2, \dots, s_k) \in D_k$, where $D_k = \{s = (s_1, s_2, \dots, s_k) \in \mathbf{R}^k | |s_l| \leq 1, l = 1, 2, \dots, k\}$.

When $m_{ij} = \partial f^i(1, \dots, 1) / \partial s_j < \infty$ ($i, j = 1, 2, \dots, k$), the \dagger conditional expectation of Z_{n+m} , given Z_m , is given as $E[Z_{m+n} | Z_m] = Z_m M^n$, where M is the matrix (m_{ij}) . From now on we assume that $m_{ij} < \infty$ ($i, j = 1, 2, \dots, k$). A multi-type Galton-Watson process $\{Z_n | n = 0, 1, \dots\}$ is said to be singular if the generating functions $f^l(s_1, s_2, \dots, s_k)$, $l = 1, 2, \dots, k$, are all linear in s_1, s_2, \dots, s_k with no constant terms. We assume nonsingularity throughout. If there is a positive integer N such that every component of M^N is positive, the process Z_n is said to be **positively regular**. In this case, M has a positive \dagger eigenvalue λ that is simple, and $\lambda > |\mu|$ for all other eigenvalues μ . The eigenvalue λ plays the role of m in the case of the Galton-Watson process. For every i , $1 \leq i \leq k$, set $q^i = P[Z_n = 0 \text{ for some } n | Z_0 = e_i]$, where $e_i = (e_i^1, e_i^2, \dots, e_i^k)$, $e_i^j = \delta_{ij}$. Then q^i is called the extinction probability of the process $\{Z_n | n = 0, 1, \dots\}$ starting with a single particle of type T_i ; let $\mathbf{q} = (q^1, q^2, \dots, q^k)$. Suppose that the process $\{Z_n | n = 0, 1, \dots\}$ is positively regular and not singular. Then $\mathbf{q} = (1, 1, \dots, 1)$ if $\lambda \leq 1$, and $0 \leq q^i < 1$ ($i = 1, 2, \dots, k$) if $\lambda > 1$, and \mathbf{q} satisfies the equation $\mathbf{q} = (f^1(\mathbf{q}), f^2(\mathbf{q}), \dots, f^k(\mathbf{q}))$. Furthermore, the process $\{Z_n | n = 0, 1, \dots\}$ is \dagger transient, i.e., $P[Z_n = \mathbf{j} \text{ infinitely often}] = 0$ for any $\mathbf{j} \neq \mathbf{0}, \mathbf{j} \in Z_+^k$. Moreover, if $\lambda > 1$, then $W_n = Z_n/\lambda^n$ converges with probability 1, and

$$\lim_{n \rightarrow \infty} Z_n/\lambda^n = v W \quad \text{a.s.,}$$

where v denotes the positive left \dagger eigenvector $v = (v_1, \dots, v_k)$ for λ of the matrix M , and W is a nonnegative \dagger random variable. $P[W > 0] > 0$ holds if and only if

$$E[Z_{ij}^{(i)} \log Z_{ij}^{(i)}] < \infty \text{ for all } 1 \leq i, j \leq k. \quad (1)$$

Here $Z_{ij}^{(i)}$ denotes the number of type T_j particles in the first generation for a process with $Z_0 = e_i$, $1 \leq i \leq k$. If condition (1) holds, the \dagger moment-generating functions of W , $\varphi_i(\alpha) = E[\exp[-\alpha W] | Z_0 = e_i]$, $i = 1, 2, \dots, k$, $\alpha > 0$, satisfy $\varphi_i(\alpha) = f^i(\varphi_1(\alpha/\lambda), \varphi_2(\alpha/\lambda), \dots, \varphi_k(\alpha/\lambda))$, $1 \leq i \leq k$.

When $\lambda \leq 1$, a theorem analogous to Yaglom's holds. For further information \rightarrow Joffe and Spitzer (*J. Math. Anal. Appl.* 19 (1967)) and Athreya and Ney [S].

D. Markov Branching Processes

The branching processes dealt with in Sections B and C are limited in the sense that generation times are fixed. We now formulate a continuous-time version of branching processes. The treatment in this section is limited

to Markov processes that are extensions to continuous time of the Galton-Watson process. A Markov process $\{X_t, P_t\}$ on \mathbf{Z}_+^1 is called a **Markov branching process** if the transition probability $P(t, i, j) = P_t[X_t = j] (i, j \in \mathbf{Z}_+^1, t \geq 0)$ satisfies

$$\sum_{j=0}^{\infty} P(t, i, j) s^j = \left(\sum_{j=0}^{\infty} P(t, 1, j) s^j \right)^i$$

for all $i \in \mathbf{Z}_+^1$ and $|s| \leq 1$. Then there exist a positive constant a and a probability distribution $\{p_k; k = 0, 2, 3, \dots\}$ such that $\lim_{t \downarrow 0} (1 - P(t, i, i))/t = ia$ if $i \in \mathbf{Z}_+^1$ and $\lim_{t \downarrow 0} P(t, i, j)/t = iap_{j-i+1}$ if $j \geq i-1, j \neq i$. The +Kolmogorov equations are

$$\frac{d}{dt} P(t, i, j) = -jaP(t, i, j) + a \sum_{l=1, l \neq j}^{j+1} lp_{j-l+1} P(t, i, l) \quad (\text{forward equation})$$

and

$$\begin{aligned} \frac{d}{dt} P(t, i, j) &= -iaP(t, i, j) \\ &+ ia \sum_{l=i-1, l \neq i}^{\infty} p_{l-i+1} P(t, l, j) \end{aligned} \quad (\text{backward equation}).$$

Then a and $\{p_k; k = 0, 2, 3, \dots\}$ are interpreted as follows. An object existing at t has a probability adt of dying in the time interval $[t, t+dt]$ of length dt . If it dies at any time t , the probabilities are p_0, p_2, p_3, \dots that it is replaced by $0, 2, 3, \dots$ objects. When $\sum_{k=0}^{\infty} P(t, i, k) < 1$, the number of particles attains $+\infty$ in a finite time interval with positive probability. In order that $\sum_{k=0}^{\infty} P(t, i, k) = 1$ for all $i \in \mathbf{Z}_+^1$, it is necessary and sufficient that for each $1 > \varepsilon > 0, \int_{1-\varepsilon}^1 (f(u) - u)^{-1} du = \infty$, where $f(s) = \sum_{j=0, j \neq 1}^{\infty} p_j s^j$ for $|s| \leq 1$.

Most of the theory of the Galton-Watson process carries over to the continuous case. In particular, concerning the limit distribution of X_t , more precise results have been obtained. (For detailed discussion of Markov branching processes $\rightarrow [3, 8]$.)

Some work has also been done on the asymptotic behavior for temporally inhomogeneous cases of multitype Markov branching processes.

E. Branching Markov Processes

We now give a systematic treatment of general branching processes in which an object is characterized by a parameter x in a compact Hausdorff space S with a countable open base. The results are formulated in terms of strong Markov processes. Set $S^0 = \{\partial\}$, where

∂ is an extra point. For every positive integer n , let $S^n = \underbrace{S \times S \times \dots \times S}_n / \sim$, where \sim is the

*equivalence relation given by the *permutations of coordinates. S^n is compact with respect to the *quotient topology, and its *topological direct sum $S = \sum_{n=0}^{\infty} S^n$ is *locally compact. Let $\hat{S} = S \cup \{A\}$ be the one-point *compactification of S . A point $x \in \hat{S}$ is denoted by $\mathbf{x} = [x_1, x_2, \dots, x_n]$ if \mathbf{x} is the *equivalence class containing $(x_1, x_2, \dots, x_n) \in S^n$. $x = [x]$ is denoted simply by x . Set $\mathbf{B}(S) = \{f | f \text{ a bounded Borel measurable function on } S\}$, $\mathbf{B}^*(S) = \{f \in \mathbf{B}(S) | \|f\| < 1\}$, $\mathbf{C}(S) = \{f | f \text{ a bounded continuous function on } S\}$, and $\mathbf{C}^*(S) = \mathbf{C}(S) \cap \mathbf{B}^*(S)$. $\mathbf{B}(\hat{S}), \mathbf{C}(\hat{S}), \dots$ are defined similarly. For $f \in \mathbf{B}^*(S)$, define $\hat{f} \in \mathbf{B}(\hat{S})$ by $\hat{f}(\mathbf{x}) = 1$ if $\mathbf{x} = \partial, = \prod_{j=1}^n f(x_j)$ if $\mathbf{x} = [x_1, x_2, \dots, x_n] \in S^n$, and $= 0$ if $\mathbf{x} = A$. A *strong Markov process $X = \{X_t, \mathbf{P}_t\}$ on \hat{S} is called a **branching Markov process** if its semigroup $\{T_t\}$ (- 261 Markov Processes) satisfies

$$T_t \hat{f}(\mathbf{x}) = (\widehat{T_t f})_{\mathbf{S}}(\mathbf{x}) \quad \text{for every } \mathbf{x} \in \hat{S} \text{ and } f \in \mathbf{B}^*(S),$$

where for $g \in \mathbf{B}(\hat{S}), g|_S$ is the restriction of g on S [10-12]. We set (i) $Z_t = n$ if $X_t \in S^n, n = 0, 1, \dots, \infty$, where $S^\infty = \{A\}$, and (ii) $\tau = \inf\{t | Z_t \neq Z_0\}$. Z_t and τ are called the number of particles and the **first splitting time**, respectively. Let $X = \{x_t, P_x\}$ be a strong Markov process on S . We assume that the semigroup $\{H_t\}$ of X is a strongly continuous semigroup on $\mathbf{C}(S)$. Let φ_t be a nonnegative continuous *additive functional of X . Let $p_n(x), n = 0, 2, 3, \dots$ be a sequence of nonnegative functions in $\mathbf{B}(S)$ such that $\sum_{n=0, n \neq 1}^{\infty} p_n(x) = 1$. Consider a sequence of stochastic kernels $\pi_n(x, dy), n = 0, 2, 3, \dots$ on $S \times S^n$, i.e., for fixed $A \in \mathfrak{B}(S^n), \pi_n(x, A)$ is a measurable function of x , and for fixed x it is a probability on $(S^n, \mathfrak{B}(S^n))$, where $\mathfrak{B}(S^n)$ is the *topological σ -field on S^n . Set $\pi(x, D) = \sum_{n=0, n \neq 1}^{\infty} p_n(x) \pi_n(x, D \cap S^n)$ for $D \in \mathfrak{B}(\hat{S}), x \in S$, where $S(S)$ is the topological σ -field on \hat{S} . Then there exists a unique branching Markov process $X = \{X_t, \mathbf{P}_t\}$ on \hat{S} satisfying the following: (i) The Markov process $\{X_t, t < \tau, \mathbf{P}_x\}$ on S obtained from X by shortening its *lifetime is equivalent to the Markov process obtained by *killing X at a rate $d\varphi_t$ (- 261 Markov Processes). (ii) For any DE $S(S)$ and $\lambda > 0, E_x[\exp[-\lambda\tau]; X_t \in D | X_{t-}] = E_x[\exp[-\lambda\tau] | X_{t-}] \pi(X_{t-}, D)$ a.s. on $\{\tau < \infty\}$ for every $x \in S$. (iii) With probability one, $X_t = A$ for all $t \geq \lim_{n \uparrow \infty} \tau_n$, where τ_n denotes the n th splitting time [10]. This process $X = \{X_t, \mathbf{P}_t\}$ is referred to as the $\{x_t, \varphi_t, \pi\}$ -branching Markov process.

Example 1. Let $S = \{a_1, a_2, \dots, a_k\}$; then S can

be identified with \mathbf{Z}_+^k and $\hat{\mathbf{S}}$ with $\widehat{\mathbf{Z}}_+^k = \mathbf{Z}_+^k \cup \{\infty\}$. Therefore a branching Markov process X on $\hat{\mathbf{S}}$ is a Markov process on $\widehat{\mathbf{Z}}_+^k$ such that its transition probability $P(t, \mathbf{i}, \mathbf{j}), \mathbf{i}, \mathbf{j} \in \mathbf{Z}_+^k$ satisfies

$$\sum_{j_1, j_2, \dots, j_k \in \mathbf{Z}_+^k} P(t, \mathbf{i}, (j_1, j_2, \dots, j_k)) s_1^{i_1} s_2^{i_2} \dots s_k^{i_k} \\ = \prod_{l=1}^k \sum_{(j_1, j_2, \dots, j_k) \in \mathbf{Z}_+^k} P(t, e_l, (j_1, j_2, \dots, j_k)) \\ \times s_1^{j_1} s_2^{j_2} \dots s_k^{j_k} \Big)^{i_l},$$

$$P(t, \infty, \infty) = 1 \quad \text{for } \mathbf{i} = (i_1, i_2, \dots, i_k) \in \mathbf{Z}_+^k,$$

$$s = (s_1, s_2, \dots, s_k) \in D_k.$$

Then the process X is called a **multi (Q-type) Markov branching process**.

Example 2. Let $S = [0, \infty]$, $k(x)$ be a non-negative locally integrable function on $[0, \infty)$, and $p_n(x)$, $n = 0, 1, \dots$, be a sequence of non-negative measurable functions on $[0, \infty)$ such that $\sum_{n=0}^{\infty} p_n(x) = 1$ and $p_1(x) = 0$. We extend $k(x)$ and $p_n(x)$ ($n \neq 2$) as functions on $[0, \infty]$ by setting them to 0 at ∞ , and set $p_2(\infty) = 1$. Define a stochastic kernel $\pi(x, dy)$ on $S \times \hat{\mathbf{S}}$ by

$$\pi(x, D) = \begin{cases} \sum_{n=0}^{\infty} p_n(x) \delta_{\{[0, 0, \dots, 0]\}}^{(n)} (D \cap S^n) & \text{if } x \in [0, \infty), \\ \delta_{\{[\infty, \infty]\}} (D \cap S^2) & \text{if } x = \infty. \end{cases}$$

Let $X = \{x_t, P_x\}$ be the uniform motion on S with the semigroup $\{H_t\}$ such that for $f \in \mathbf{C}(S)$, $H_t f(x) = f(x+t)$ if $x \in [0, \infty)$ and $= f(\infty)$ if $x = \infty$. Set $\varphi_t = \int_0^t k(x_s) ds$. Then we have a $\{x_t, \varphi_t, n\}$ -branching Markov process, and we call it an **age-dependent branching process**.

We now discuss some fundamental properties of $\{x_t, \varphi_t, n\}$ -branching Markov processes. For the sake of simplicity we assume the following: (i) $\varphi_t = \int_0^t k(x_s) ds, k \in \mathbf{C}^+(S) = \{f \in \mathbf{C}(S) | f \geq 0\}$, (ii) $p_n(x) \in \mathbf{C}^+(S)$ and

$$\pi_n(x, D) = \delta_{\{[x, x, \dots, x]\}}(D)$$

for $D \in \mathcal{B}(S^n)$. Then $\{T_t\}$ is a strongly continuous semigroup on $\mathbf{C}(S) = \{f \in \mathbf{C}(\hat{\mathbf{S}}) | \lim_{x \rightarrow \infty} f(x) = 0\}$. Let A be the infinitesimal generator of $\{H_t\}$ (-261 Markov Processes) and $\mathcal{D}(A)$ be the domain of A . If $f \in \mathcal{D}(A) \cap \mathbf{C}^*(S)$, then $u(t, x) = (T_t \hat{f})_S(x) \in \mathcal{D}(A)$, and it satisfies $\partial u / \partial t = Au + k(F(\cdot; u) - u)$, $u(0+, x) = f(x)$, where $F(x; g) = \int_S g(y) \pi(x, dy)$ [10].

Let \mathcal{M} be the space of all nonnegative \dagger Radon measures on S and \mathcal{M}_0 be the subspace of \mathcal{M} consisting of all probability Radon measures on S endowed with the topology of weak convergence. Set $\mathcal{M} = \mathcal{M}_0 \cup \{\delta\}$, where δ is an extra point and $\tilde{\mathcal{M}} = [0, \infty] \times \mathcal{M}_0$. Define

a mapping $\rho: \tilde{\mathcal{M}} \ni (\bar{\lambda}, \lambda_0) \mapsto \rho(\bar{\lambda}, \lambda_0) \in \tilde{\mathcal{M}}$ by $\rho(\bar{\lambda}, \lambda_0) = \bar{\lambda} \lambda_0$ if $\lambda < \infty$ and $= \delta$ if $\lambda = \infty$, and define the topology of \mathcal{M} as the strongest of all the topologies rendering ρ continuous. Set $\mathbf{C}^{++}(S) = \{f \in \mathbf{C}(S) | f > 0\}$, and for $f \in \mathbf{C}^{++}(S)$, define a function $\Phi_f(\lambda)$ on $\tilde{\mathcal{M}}$ by $\Phi_f(\lambda) = \exp[-(\lambda, f)]$ if $\lambda \in \mathcal{M}$ and $= 0$ if $\lambda = \delta$, where $(\lambda, f) = \int_S f(x) \lambda(dx)$. Consider a mapping $\psi: \hat{\mathbf{S}} \rightarrow \tilde{\mathcal{M}}$ defined by $\psi(x) = 0$ if $x = \infty$, $= \sum_{k=1}^n \delta_{\{x_k\}}$ if $x = [x_1, x_2, \dots, x_n] \in S^n$, and $= \delta$ if $x = A$. Let \mathcal{M}_p be the subspace of $\tilde{\mathcal{M}}$ consisting of all non-negative integer-valued Radon measures on S , i.e., $\mathcal{M}_p = \{\psi(x) | x \in \hat{\mathbf{S}}\}$. We denote by \mathcal{D} the space of all right-continuous mappings $v: [0, \infty) \rightarrow \mathcal{M}_p$ whose discontinuities are at most of the first kind and such that $v_t = \delta$ for $t \geq \varsigma$ if $v_s = \delta$. Consider a branching Markov process $\{X_t, P_x\}$, and let P_{μ_x} be the probability law on \mathcal{D} of the stochastic process $\{v_t = \psi(X_t); 0 \leq t < \infty\}$ with $X_t = x$, where $\mu_x = \psi(x)$. Then the branching property can be rewritten as follows: For every $t \geq 0$, $f \in \mathbf{C}^{++}(S)$ and $\mu_1, \mu_2 \in \mathcal{M}_p$, $E_{\mu_1 + \mu_2}[\exp[-(v_t, f)]] = E_{\mu_1}[\exp[-(v_t, f)]] E_{\mu_2}[\exp[-(v_t, f)]]$ (\rightarrow Silverstein, Z. *Wahrscheinlichkeitstheorie und Verw. Gebiete*, 9 (1968); for a treatment of branching processes in the framework of \dagger martingale problems \rightarrow Holley and Stroock, *Publ. Inst. Math. Sci.*, 14 (1978)).

There are analogous processes which preserve the basic features of the branching property. A Markov process $\{\mu_t, P_\mu\}$ on $\tilde{\mathcal{M}}$ with δ as a \dagger trap is called a **continuous-state branching process** if it satisfies the property that for every $t \geq 0$, $f \in \mathbf{C}^{++}(S)$, and $\mu_1, \mu_2 \in \mathcal{M}$, $E_{\mu_1 + \mu_2}[\exp[-(\mu_t, f)]] = E_{\mu_1}[\exp[-(\mu_t, f)]] E_{\mu_2}[\exp[-(\mu_t, f)]]$. This concept was introduced by Jiiina [15] for some special cases. For further information \rightarrow Jifina (*Third Prague Conf.*, 1964), Lamperti (*Bull. Amer. Math. Soc.*, 73 (1967)), Watanabe (*J. Math. Kyoto Univ.*, 8 (1968)), and Fujimagari and Motoo (*Kôdai Math. Sem. Rep.*, 23 (1971)).

45 (XVII.7) Brownian Motion

A. General Remarks

R. Brown, an English botanist, observed in 1827 that the minute particles comprising the pollen of plants, when suspended in water, exhibit peculiarly erratic movements [1]. The physical explanation of this phenomenon is that haphazard impulses are given to the suspended particles by collisions with molecules of the fluid. Let $X(t)$ be the x -coordinate of a particle at time t . Then $X(t)$ is treated as a random variable, and the distribution of $X(t) - X(s)$ is a normal distribution $N(0, D|t-s|)$, with mean 0 and variance $D|t-s|$, where D is a positive constant. To be more exact, such a family of random variables $\{X(t)\}$ is now considered as the family of random variables determining a stochastic process. Various aspects of the theory were analyzed by A. Einstein [2], L. Bachelier, N. Wiener, P. Lévy, and others.

B. Wiener Processes

Let T be the real line \mathbf{R}^1 or a subinterval. A stochastic process $\{X(t)\}_{t \in T}$, defined on a probability space $(\Omega, \mathfrak{B}, P)$ is called a **Wiener process** on \mathbf{R}^d if it satisfies the following three conditions: (1) $X(t, \omega) \in \mathbf{R}^d$ ($t \in T, \omega \in \Omega$). (2) The \mathbf{R}^d -valued random variables $X(t_1), X(t_j) - X(t_{j-1}), j = 2, 3, \dots, n$, are independent for any $t_1 < t_2 < \dots < t_n, t_j \in T$ ($j = 1, 2, \dots, n$), where n is an arbitrary positive integer. (3) If $X_i(t)$ is the i th component of the vector $X(t)$, then the $\{X_i(t)\}_{t \in T}$ ($1 \leq i \leq d$) are independent as stochastic processes and every increment $X_i(t) - X_i(s)$ is normally distributed with mean 0 and variance $|t-s|$. A Wiener process is also called a **Brownian motion**. A Wiener process is a temporary homogeneous additive process. A separable Wiener process has continuous paths with probability 1. Conversely, if $\{X(t)\}_{t \in T}$ is a temporary homogeneous additive process on \mathbf{R}^1 whose sample function is continuous with probability 1 and the increment $X(t) - X(s)$ has mean 0 and variance $|t-s|$, then it is a Wiener process (-407 Stochastic Processes, 406 Stochastic Differential Equations). Let $\{\mathcal{F}_t\}_{t \geq 0}$ be an increasing family of σ -subfields of \mathfrak{B} . We assume that $\{\mathcal{F}_t\}$ is right continuous. A d -dimensional continuous process $X = (X(t))_{t \geq 0}$, is called a d -dimensional $\{\mathcal{F}_t\}$ -**Brownian motion** if it is $\{\mathcal{F}_t\}$ -adapted and satisfies

$$E[\exp\{i\langle \xi, X(t) - X(s) \rangle\} | \mathcal{F}_s] \\ = \exp[-(t-s)|\xi|^2/2]$$

a.s. for every $\xi \in \mathbf{R}^d, 0 \leq s < t$,

where $|\xi|$ denotes the norm of $\xi \in \mathbf{R}^d$ [9]. Then X satisfies conditions (1)–(3) mentioned above, and hence it is a Brownian motion on \mathbf{R}^d (-406 Stochastic Differential Equations).

Let $\{X_k(\omega)\}$ ($k = 0, 1, \dots$) be a sequence of independent random variables defined on a probability space $(\Omega, \mathfrak{B}, P)$ such that each X_k has the normal distribution $N(0, 1)$ with mean 0 and variance 1. Then the series

$$\frac{t}{\sqrt{\pi}} X_0(\omega) + \sqrt{\frac{2}{\pi}} \sum_{n=1}^{\infty} X_n(\omega) \frac{\sin nt}{n}, \quad t \in [0, \pi] \equiv T,$$

converges uniformly in $t \in T$ with probability 1, and its limit, denoted by $X(t, \omega)$, is a Wiener process [3, 10].

Let $W^d = C([0, \infty) \rightarrow \mathbf{R}^d)$ be the space of all continuous functions $w: [0, \infty) \rightarrow \mathbf{R}^d$ endowed with the topology of uniform convergence on finite intervals and $\mathfrak{B}(W^d)$ be the topological σ -field. Let $X = (X(t))_{t \geq 0}$ be a Brownian motion on \mathbf{R}^d and μ be the probability law of $X(0)$. The probability law P^X of the Brownian motion X on $(W^d, \mathfrak{B}(W^d))$ is called the d -

dimensional Wiener measure with the initial distribution μ [9, 11, 12]. For a probability μ on $(\mathbf{R}^d, \mathfrak{B}(\mathbf{R}^d))$ the d -dimensional Wiener measure P_μ with the initial distribution μ is a probability on $(W^d, \mathfrak{B}(W^d))$ characterized by the property that for every $0 = t_0 < t_1 < \dots < t_n$ and $A_j \in \mathfrak{B}(\mathbf{R}^d)$, $j = 1, 2, \dots, n$,

$$P_\mu[w(t_1) \in A_1, w(t_2) \in A_2, \dots, w(t_n) \in A_n] \\ = \int_{\mathbf{R}^d} \int_{A_1} \dots \int_{A_n} \prod_{j=1}^n \left(\frac{1}{\sqrt{2\pi(t_j - t_{j-1})}} \right)^d \\ \times \exp \left[-\frac{|x_j - x_{j-1}|^2}{2(t_j - t_{j-1})} \right] \mu(dx_0) dx_1 \dots dx_n,$$

where $\mathfrak{B}(\mathbf{R}^d)$ denotes the topological σ -field on \mathbf{R}^d .

C. Brownian Motion as a Diffusion Process

In terms of the general framework of \dagger Markov processes, Brownian motion is a typical example of a diffusion process (\rightarrow 115 Diffusion Processes). Let $X = \{X_t(w), \mathbf{R}^d, P_x\}$ be a continuous Markov process on \mathbf{R}^d (\rightarrow 261 Markov Processes) with the \dagger transition probability

$$P(t, x, B) = \int_B (2\pi t)^{-d/2} e^{-\frac{1}{2t}|x-y|^2} dy, \\ t > 0, \quad x \in \mathbf{R}^d, \quad B \in \mathfrak{B}(\mathbf{R}^d).$$

For each $x \in \mathbf{R}^d$, the process $\{X_t(w), P_x\}$ is a Wiener process in the sense mentioned above. The Markov process X , which is a collection of Wiener processes $\{X_t, P_x\}$ starting at x , is said to be a **d-dimensional Brownian motion**. A d -dimensional Brownian motion possesses the \dagger strong Markov property. Let \mathfrak{G} be the \dagger generator of the \dagger semigroup T_t corresponding to X . A bounded uniformly continuous function f defined on \mathbf{R}^d belongs to the domain of \mathfrak{G} if its partial derivatives $\partial f / \partial x_i$ and $\partial^2 f / \partial x_i \partial x_j$, $i, j = 1, 2, \dots, d$, are bounded and uniformly continuous. For such a function f we have $\mathfrak{G}f(x) = (1/2)\Delta f(x)$, where Δ is the \dagger Laplacian [8, 12].

D. Brownian Motions and Potentials

For $\alpha > 0$, the function $G_\alpha(x)$ defined by

$$G_\alpha(x) = \frac{1}{2} \int_0^\infty e^{-\alpha t} (2\pi t)^{-d/2} \exp \left(-\frac{1}{2t}|x|^2 \right) dt$$

is said to be the **cc-order Green's function**.

Since Brownian motion is \dagger nonrecurrent for $d \geq 3$, the limit $G_{0+}(x) = \lim_{\alpha \downarrow 0} G_\alpha(x)$, $x \in \mathbf{R}^d$, exists for $d \geq 3$, and $G_{0+}(x)$ is equal to $K_\alpha(x) = (\Gamma(d/2 - 1)/4\pi^{d/2})|x|^{-d+2}$, which is the kernel for the \dagger Newtonian potentials. Brownian motion is \dagger recurrent when $d \leq 2$ and $G_{0+}(x) = +\infty$, $x \in \mathbf{R}^d$. In this case, $K_\alpha(x)$ is defined by

$K_0(x) = \lim_{\alpha \downarrow 0} (G_\alpha(x) - G_\alpha(x_0))$, and $K_0(x) = (1/2\pi) \log(1/|x|)$, when $d = 2$ and $|x_0| = 1$.

This is the kernel for the \dagger logarithmic potentials. When $d = 1$ and $x_0 = 0$, $K_\alpha(x) = -|x|/2$. Using this relationship, we can express many concepts of classical potential theory in an elegant form in probability language. Let $X = \{X(t), P_x\}$ be the d -dimensional Brownian motion. Given a set A , set $\sigma_A = \inf\{t \geq 0, X(t) \in A\}$, where the infimum over the empty set is understood to be $+\infty$. Then σ_A is called the \dagger hitting time of X for the set A (\rightarrow 261 Markov Processes). For a Green domain (i.e., a domain which is a \dagger Green space) D in \mathbf{R}^d ($d \geq 2$), set $2g^D(t, x, y)dy = P_x(X(t) \in dy, \sigma_{\partial D} > t)$, $x, y \in D$. Then the right-hand side of this equation is the \dagger transition probability of the Brownian motion on D with the \dagger absorbing barrier ∂D . Then $G^D(x, y) = \int_0^\infty g^D(t, x, y)dt$ is \dagger Green's function of D . If B is a compact subset of a Green domain D or an open subset with compact closure $\bar{B} \subset D$, then the hitting probability $p(x) = P_x(\sigma_B < \sigma_{\partial D})$ is the equilibrium potential of B relative to D .

Suppose A is an \dagger analytic subset of \mathbf{R}^d . \dagger Blumenthal's O-I law implies that $P_x(\sigma_A = 0) = 1$ or 0 . The point x is said to be **regular** for A if this probability is 1 and **irregular** for A otherwise. Let B be a compact subset in \mathbf{R}^d ($d \geq 2$). Then \dagger Wiener's test (\rightarrow 120 Dirichlet Problem) states that x is regular or irregular for B according as the following series diverge or converge:

$$\sum_{k=1}^\infty 2^{k(d-2)} C(B_k), \quad d \geq 3, \\ \sum_{k=1}^\infty k C(B_k), \quad d = 2,$$

where $C(B_k)$ is the \dagger Newtonian capacity (the logarithmic capacity relative to a bounded domain when $d = 2$) of the set $B_k = \{y \mid 2^{-(k+1)} \leq |y-x| < 2^{-k}\} \cap B$ [12]. Suppose D is a bounded domain in \mathbf{R}^d ($d \geq 2$). A point $x \in \partial D$ is regular or irregular for $\mathbf{R}^d - D$ according as x is regular or irregular in the sense of the \dagger Dirichlet problem for D . Given a continuous boundary function f on ∂D , $u(x) = E_x(f(X(\sigma_{\partial D}))$ is the solution of the generalized Dirichlet problem for D . Given $x \in D$, the distribution $h(x, B) = P_x(X(\sigma_{\partial D}) \in B)$ ($B \in \mathfrak{B}(\partial D)$) used in the solution $u(x) = \int_{\partial D} f(y)h(x, dy)$ of the generalized Dirichlet problem is the \dagger harmonic measure of ∂D as viewed from x .

E. 1-Dimensional Brownian Motion

In his monograph [6], P. Lévy gave a profound description of the fine structure of the individual 1-dimensional Brownian path

$\{X(t, \omega)\}_{t \geq 0}$. Let us set

σ_a = the hitting time to the point a in \mathbf{R}' ,

$$m(t, \omega) = \min_{\sigma_0 \leq s \leq t} X(s, \omega),$$

$$M(t, \omega) = \max_{\sigma_0 \leq s \leq t} X(s, \omega),$$

$$Y_0(t, \omega) = |X(t, \omega)|,$$

$$Y_1(t, \omega) = \begin{cases} X(t, \omega), & t < \sigma_0(\omega), \\ M(t, \omega) - X(t, \omega), & t \geq \sigma_0(\omega), \end{cases}$$

and

$$Y_2(t, \omega) = \begin{cases} X(t, \omega), & t < \sigma_0(\omega), \\ X(t, \omega) - m(t, \omega), & t \geq \sigma_0(\omega). \end{cases}$$

Then we have (1) $P_0(M(t) > a) = 2P_0(M(t) > a, X(t) > a) = 2P_0(M(t) > a, X(t) < a) = P_0(|X(t)| > a)$ (reflection principle of D.André).

(2) The stochastic process $\{\sigma_a, 0 \leq a < \infty, P_0\}$ is a †one-sided stable process with exponent $1/2$, that is, it is additive and homogeneous with the law

$$\begin{aligned} P_0(\sigma_b - \sigma_a \leq t) &= P_0(\sigma_{b-a} \leq t) \\ &= \int_0^t \frac{b-a}{\sqrt{2\pi s^3}} e^{-(b-a)^2/2s} ds, \\ &0 \leq a < b, \quad t \geq 0. \end{aligned}$$

(3) Let $\varphi^{-1}(t, \omega)$ be the right continuous inverse function of

$$\varphi(t, \omega) = \int_0^t \chi_{[0, \infty)}(X(s, \omega)) ds,$$

where $\chi_{[0, \infty)}(\cdot)$ is the †indicator function of the interval $[0, \infty)$. Set $Y_3(t, \omega) = X(\varphi^{-1}(t, \omega), \omega)$. Then the four processes $\{Y_i(t, \omega), 0 \leq t < \infty, P_x\}$ ($x \in [0, \infty), 0 \leq i \leq 3$) on $[0, \infty)$ have the same probability law. Each of them is a diffusion process with transition probability

$$\begin{aligned} P(t, x, B) &= \int_B \frac{1}{\sqrt{2\pi t}} (e^{-|x-y|^2/2t} + e^{-|x+y|^2/2t}) dy, \\ B &\in \mathfrak{B}([0, \infty)), \quad t > 0, \quad x \in [0, \infty), \end{aligned}$$

and is said to be a Brownian motion on $[0, \infty)$ with a †reflecting barrier at the origin. (4) As a consequence of (3), if $X(0, \omega) = 0$ a.s., then, for fixed t , $M(t)$, $-m(t)$, and $Y_i(t)$ ($0 \leq i \leq 3$) have a common distribution. For example,

$$\begin{aligned} P_0(M(t) \geq a) &= P_0(\sigma_a \leq t) = 2P_0(X(t) > a) \\ &= \sqrt{\frac{2}{\pi t}} \int_a^\infty e^{-x^2/2t} dx \quad a > 0, \\ P_0(X(t) \in da, M(t) \in db) &= \sqrt{\frac{2}{\pi t^3}} (2b-a) e^{-(2b-a)^2/2t} da db, \quad 0 \leq a < b. \end{aligned}$$

(5) The diffusion process $\{X(t, \omega), 0 \leq t < \sigma_0, P_x\}$ ($x \in (0, \infty)$) obtained from a 1-dimensional Brownian motion by shortening its †lifetime is called a Brownian motion on $(0, \infty)$ with an †absorbing barrier at the origin, and its transition probability is given by

$$\begin{aligned} P(t, x, B) &= \int_B \frac{1}{\sqrt{2\pi t}} (e^{-|x-y|^2/2t} - e^{-|x+y|^2/2t}) dy, \\ B &\in \mathfrak{B}([0, \infty)), \quad t > 0, \quad x \in (0, \infty). \end{aligned}$$

The **arcsin law** is valid for many functionals of 1-dimensional Brownian motion. For example,

$$P_0\left(\int_0^t \chi_{[0, \infty)}(X(s, \omega)) ds \leq \theta\right) = \frac{2}{\pi} \arcsin \sqrt{\frac{\theta}{t}}, \quad 0 < \theta \leq t,$$

$$P_0(\tau_t(\omega) \leq s) = (2/\pi) \arcsin \sqrt{s/t}, \quad 0 < s \leq t,$$

where $\tau_t(\omega) = \sup\{s | X(s, \omega) = 0, 0 \leq s \leq t\}$.

The visiting set $\mathcal{Z}(\omega) = \{t | X(t, \omega) = 0\}$ of a Brownian path is a †totally disconnected set. Its †Lebesgue measure is 0, and the †Hausdorff-Besikovich dimension number of $\mathcal{Z}(\omega)$ is $1/2$.

Consider a 1-dimensional Wiener process $\{X(t)\}_{0 \leq t < \infty}$ starting at the origin. Let us set

$$B_1(t) = \begin{cases} 0 & t = 0, \\ tX(1/t) & t > 0, \end{cases}$$

and

$$B_2(t) = cX(t/c^2), \quad t \geq 0, \quad (c > 0).$$

Then the stochastic processes $\{B_1(t)\}_{0 \leq t < \infty}$ and $\{B_2(t)\}_{0 \leq t < \infty}$ are likewise 1-dimensional Wiener processes starting at the origin. Hence the properties of the Wiener process starting at the origin in a neighborhood of $t = 0$ ($t = \infty$) can be obtained from those in a neighborhood of $t = \infty$ ($t = 0$).

F. d-Dimensional Brownian Motion

Almost all paths of d-dimensional Brownian motion are continuous but are not of †bounded variation on any finite interval. Accordingly, they cannot have lengths. A positive, continuous, increasing function φ defined on $[t_0, \infty)$ with $t_0 > 0$ is said to **belong to the upper (lower) class with respect to local continuity** if $P_0(\{(\inf\{t | |X(t, \omega)| > \sqrt{t} \varphi(1/t), t > 0\}) > 0\}) = 1$ (0). Kolmogorov's test states that φ belongs to the upper class or to the lower class with respect to local continuity according as

$$\int_{t_0}^{\infty} t^{-1} (\varphi(t))^d e^{-\varphi^2(t)/2} dt$$

converges or diverges. For example,

$$\varphi(t) = (2 \log_{(2)} t + (d+2) \log_{(3)} t + 2 \log_{(4)} t + \\ + 2 \log_{(n-1)} t + (2+\delta) \log_{(n)} t)^{1/2}$$

belongs to the upper or lower class with respect to local continuity according as $\delta > 0$ or $\delta \leq 0$, where $\log_{(n)} t = \log \log_{(n-1)} t$ and $\log_{(1)} t = \log t$. The law of the iterated logarithm for 1-dimensional Brownian motion,

$$P_0 \left(\limsup_{t \rightarrow s} \frac{|X(t, \omega) - X(s, \omega)|}{\sqrt{2|t-s| \log \log 1/|t-s|}} = 1 \right) = 1,$$

is a special case of this example. For the case $d = 1$, consider the **space-time Brownian motion** $\{(-t, X(t)), P_0\}$. Set $D_\varphi = \{(s, x) | -1/t_0 \leq s \leq 0, \sqrt{-s} \varphi(-1/s) \leq x < \infty\}$. Then $O = (O, O)$ is a regular point of D_φ or an irregular point of D_φ for the space-time Brownian motion according as φ belongs to the lower or upper class with respect to local continuity. (- 261 Markov Processes). Thus Kolmogorov's test is the Wiener test for space-time Brownian motion. Let ψ be a positive, continuous decreasing function defined on $[t_0, \infty)$ with $t_0 > 0$. Then

$$P_0 \left(\left(\inf \{t | |X(t, \omega)| < \sqrt{t} \psi(1/t), t > 0\} \right) > 0 \right)$$

= 0 or 1.

We have

$$\int_{t_0}^{\infty} \frac{1}{t} (\psi(t))^{d-2} dt = \infty \text{ or } < \infty \quad \text{when } d \geq 3,$$

and

$$\int_{t_0}^{\infty} \frac{dt}{t |\log \psi(t)|} = \infty \text{ or } < \infty \quad \text{when } d = 2.$$

To describe uniform continuity of a path on the interval $[0, 1]$, take a positive, continuous increasing function ψ defined on $[t_0, \infty)$ with $t_0 > 0$ and set $\varphi(t) = \sqrt{t} \psi(1/t)$. Then ψ is said to **belong to the upper class with respect to uniform continuity** if almost all paths $X(t, \omega)$ ($0 \leq t \leq 1$) satisfy the \dagger Lipschitz condition relative to φ , that is, for almost all ω there exists an $\varepsilon(\omega) > 0$ such that $0 < t-s < \varepsilon(\omega)$ implies $|X(t, \omega) - X(s, \omega)| < \varphi(|t-s|)$. And ψ is said to **belong to the lower class with respect to uniform continuity** if almost all paths $X(t, \omega)$ ($0 \leq t \leq 1$) do not satisfy the Lipschitz condition relative to φ . Then ψ belongs to the upper or lower class with respect to uniform continuity according as

$$\int_{t_0}^{\infty} \psi(t)^{d+2} e^{-\psi^2(t)/2} dt$$

converges or diverges [16]. For example,

$$\psi(t) = (2 \log t + (d+4) \log_{(2)} t + 2 \log_{(3)} t + \\ + 2 \log_{(n-1)} t + (2+\delta) \log_{(n)} t)^{1/2}$$

belongs to the upper or lower class with respect to uniform continuity according as $\delta > 0$ or $\delta \leq 0$. The following theorem on the uniform continuity of 1-dimensional Brownian motion is a special case of this criterion:

$$P_0 \left(\limsup_{\substack{t-s \rightarrow 0 \\ 0 \leq t, s \leq 1}} \frac{|X(t, \omega) - X(s, \omega)|}{\sqrt{2|t-s| \log 1/|t-s|}} = 1 \right) = 1.$$

Now we state some other properties of Brownian paths. Let A be a set of zero \dagger outer capacity in \mathbf{R}^d ($d \geq 2$). Then $P_x(X(t) \in A \text{ for some } t > 0) = 0$ for any $x \in \mathbf{R}^d$. Let A be a plane set with positive \dagger inner capacity. Then $P_x(X(t) \in A \text{ for infinitely many } t \text{ larger than any given } s > 0) = 1$ for any $x \in \mathbf{R}^2$. With probability 1, the Lebesgue measure of the set $\{X(t, \omega) | 0 \leq t < \infty\}$ in \mathbf{R}^d is zero for $d \geq 2$. With probability 1 this set is everywhere dense in \mathbf{R}^2 when $d = 2$ and nowhere dense in \mathbf{R}^d when $d \geq 3$ [13, 15, 17]. Almost all 2-dimensional Brownian paths have k -fold multiple points for any integer $k \geq 2$. In the 3-dimensional case, almost all paths have \dagger double points but cannot have any triple point. In the $d(\geq 4)$ -dimensional case, almost all paths have no double point [18-20].

G. Itô's Formula and Brownian Local Time

The following formula of Itô [21] is of fundamental importance in the theory of stochastic processes.

Itô's formula. Let $X = \{X(t) = (X_1(t), X_2(t), \dots, X_d(t)), P_x\}$ be a d -dimensional Brownian motion and $f(x) = f(x_1, x_2, \dots, x_d)$ be a C^2 -function defined on \mathbf{R}^d . Let us set $\langle p(t) = f(X(t)) - f(X(0))$. Then $\{\varphi(t)\}_{t \geq 0}$ is a continuous \dagger additive functional of the Brownian motion X (- 261 Markov Processes), and we have

$$f(X(t)) - f(X(0)) = \sum_{i=1}^d \int_0^t \left(\frac{\partial}{\partial x_i} f \right) (X(s)) dX_i(s) \\ + \frac{1}{2} \int_0^t (\Delta f)(X(s)) ds, \quad t \geq 0,$$

where the first term in the right-hand side is a \dagger stochastic integral with respect to the Brownian motion X [22] (- 406 Stochastic Differential Equations). In particular, if f is a C^3 -function defined on \mathbf{R}^d , Itô's formula can be rewritten as

$$f(X(t)) - f(X(0)) = \sum_{i=1}^d \int_0^t \left(\frac{\partial}{\partial x_i} f \right) (X(s)) \circ dX_i(s), \quad t \geq 0,$$

where the right-hand side is a stochastic integral of the \dagger Stratonovich type with respect to

the Brownian motion X [9] (- 406 Stochastic Differential Equations).

Consider a 1-dimensional Brownian motion $X = (X(t), P_x)$. By the **local time** or the **sojourn time density** of X we mean a family of non-negative random variables $\{\varphi(t, x)\}$ ($t \in [0, \infty)$, $x \in \mathbf{R}^1$) such that, with probability 1, the following holds:

- (a) the mapping $[0, \infty) \times \mathbf{R}^1 \ni (t, x) \mapsto \varphi(t, x) \in \mathbf{R}^1$ is continuous,
- (b) for every Borel subset A of \mathbf{R}^1 and $t \geq 0$,

$$\int_0^t \chi_A(X(s)) ds = 2 \int_A \varphi(t, x) dx.$$

The notion of the local time of Brownian motion was first introduced by Lévy [6]. The family of random variables $\{\varphi(t, x)\}$ ($t \geq 0$, $x \in \mathbf{R}^1$) defined by

$$\varphi(t, x) = (X(t) - x)^+ - (X(0) - x)^+$$

$$- \int_0^t \chi_{(x, \infty)}(X(s)) dX(s)$$

satisfies properties (a) and (b) mentioned above and hence it is a local time [9, 22]. Here a^+ is the bigger of a and 0. It is clear that the local time $\varphi(t, x)$ of X is given by

$$\varphi(t, x) = \lim_{\varepsilon \downarrow 0} \frac{1}{4\varepsilon} \int_0^t \chi_{(x-\varepsilon, x+\varepsilon)}(X(s)) ds$$

for every $x \in \mathbf{R}^1$, $t \geq 0$.

Furthermore, we have

$$P_0 \left(\limsup_{b-a=\delta \downarrow 0, a < b} \frac{|\varphi(t, b) - \varphi(t, a)|}{\sqrt{\delta \log 1/\delta}} \leq 2 \sqrt{\max_{a \in \mathbf{R}^1} \varphi(t, a)} \right) = 1,$$

and

$$P_0 \left(\limsup_{\delta \downarrow 0} \frac{|\varphi(t, \delta) - \varphi(t, 0)|}{\sqrt{\delta \log 1/\delta}} \leq 2 \sqrt{\varphi(t, 0)} \right) = 1.$$

Lévy [6] studied the fine structure of the local time. Define the visiting sets $\mathcal{Z}^+ = \{t \mid Y_0(t, \omega) = 0\}$ and $\mathcal{Z}^- = \{t \mid Y_1(t, \omega) = 0\}$, where $Y_0(t, \omega)$ and $Y_1(t, \omega)$ are the stochastic processes defined in Section E above. Then we have

$$P_0 \left(\lim_{\varepsilon \downarrow 0} \sqrt{\frac{\pi \varepsilon}{2}} \times [\text{the number of flat stretches of } M(s, \omega) (0 \leq s \leq t) \text{ of length } \geq \varepsilon] = M(t, \omega), t \geq 0 \right) = 1.$$

Since the two diffusion processes $X^+ = \{Y_0(t), 0 \leq t < \infty, P_x\}$ and $X^- = \{Y_1(t), 0 \leq t < \infty, P_x\}$ define the same probability law on $W([0, \infty))$, there exists a functional $\varphi^+(t, \omega)$ of X^+ corresponding to $M(t, \omega)$ of X^- . Here,

$W([0, \infty))$ denotes the space of all continuous functions $w: [0, \infty) \rightarrow [0, \infty)$. The flat stretches of the graph of $\varphi^+(t, \omega)$ are the open intervals \mathcal{Z}_n ($n \geq 1$) such that $\sum_{n \geq 1} \mathcal{Z}_n = [0, \infty) - \mathcal{Z}^+$. Then we have

$$P_0 \left(\lim_{\varepsilon \downarrow 0} \sqrt{\frac{\pi \varepsilon}{2}} \times [\text{the number of intervals } \mathcal{Z}_n \subset [0, t) \text{ of length } \geq \varepsilon] = \varphi^+(t, \omega), t \geq 0 \right) = 1.$$

Furthermore, we have

$$P_0 \left(\lim_{\varepsilon \downarrow 0} \sqrt{\frac{\pi}{2\varepsilon}} \times [\text{the total length of the intervals } \mathcal{Z}_n \subset [0, t) \text{ of length } < \varepsilon] = \varphi^+(t, \omega), t \geq 0 \right) = 1$$

and

$$P_0 \left(\lim_{\varepsilon \downarrow 0} (2\varepsilon)^{-1} \int_0^t \chi_{[0, \varepsilon)}(Y_0(s, \omega)) ds = \varphi^+(t, \omega), t \geq 0 \right) = 1.$$

Let $d_\varepsilon(t, \omega)$ be the number of times that the reflecting Brownian path $Y_0(s, \omega)$ crosses down from $\varepsilon > 0$ to 0 before time t . Then

$$P_0 \left(\lim_{\varepsilon \downarrow 0} \varepsilon d_\varepsilon(t, \omega) = \varphi^+(t, \omega), t \geq 0 \right) = 1.$$

H. Flows and Random Distributions

The flow derived from the 1-dimensional Wiener process $\{X_s\}_{-\infty < t < \infty}$ is \dagger Kolmogorov's flow. It has \dagger mixing properties of all orders and is \dagger ergodic (- 136 Ergodic Theory, 39.5 Stationary Processes). The \dagger stationary process with independent values at every point corresponding to the \dagger characteristic functional

$$\exp \left(-\frac{1}{2} \int_{-\infty}^{\infty} \varphi(t)^2 dt \right)$$

on the \dagger Schwartz space \mathcal{Y} defines the same probability law with the stationary process obtained by differentiation of the Wiener process in the \dagger distribution sense [23] (- 395 Stationary Processes, 407 Stochastic Processes).

I. Generalizations of Brownian Motion

In addition to the Brownian motion described above, there are several stochastic processes that are also called Brownian motion. A Gaussian system $\{X(a)\}_{a \in \mathbf{R}^n}$ defined on a probability space $(\Omega, \mathfrak{B}, P)$ is said to be a **Brownian motion** with an N -dimensional time parameter

if (i) $E(X(a))=0$, (ii) $E(X(a)X(b))=\frac{1}{2}(|a|+|b|-|a-b|)$, (iii) $P(X(0)=0)=1$. Let a^* be the spherical inversion of $a \in \mathbf{R}^N$ with respect to the unit sphere. Set $X^*(a)=|a|X(a^*)$ ($a \neq 0$) and $X^*(0)=0$. Then $\{X^*(a)\}_{a \in \mathbf{R}^N}$ defines the same probability law with a Brownian motion with an N -dimensional time parameter. Almost all paths of a Brownian motion with an N -dimensional time parameter are continuous. A positive, continuous, increasing function φ defined on $[t_0, \infty)$ with $t_0 > 0$ is said to belong to the upper (lower) class with respect to local continuity if the probability that the closure of the set $\{a \mid |X(a, \omega)| > \sqrt{|a|} \varphi(1/|a|), |a| > 0\}$ contains the origin 0 is equal to 0 (1). Then φ belongs to the upper or lower class with respect to local continuity according as the integral

$$\int_{t_0}^{\infty} \frac{1}{t} (\varphi(t))^{2N-1} e^{-\varphi^2(t)/2} dt$$

converges or diverges. For example,

$$\varphi(t) = (2 \log_{(2)} t + (2N-1) \log_{(3)} t + 2 \log_{(4)} t + 2 \log_{(n-1)} t + (2+\delta) \log_{(n)} t)^{1/2}$$

belongs to the upper or lower class with respect to local continuity according as $\delta > 0$ or $\delta \leq 0$. As a special case, we have

$$P\left(\limsup_{a \rightarrow 0} \frac{|X(a, \omega)|}{\sqrt{2|a| \log \log 1/|a|}} = 1\right) = 1.$$

Take a positive, continuous increasing function φ defined on $[t_0, \infty)$ with $t_0 > 0$, and set $\psi(t) = \sqrt{t} \varphi(1/t)$. If almost all paths $X(a, \omega)$ ($|a| \leq 1$) satisfy the Lipschitz condition relative to $\psi(t)$, then φ is said to belong to the upper class with respect to uniform continuity. It is said to belong to the lower class with respect to uniform continuity if, with probability 1, these paths do not satisfy the Lipschitz condition relative to $\psi(t)$. Then φ belongs to the upper or lower class with respect to uniform continuity according as

$$\int_{t_0}^{\infty} t^{N-1} (\varphi(t))^{4N-1} e^{-\varphi^2(t)/2} dt$$

converges or diverges (T. Sirao, *Nagoya Math. J.*, 17 (1960)). For example,

$$\varphi(t) = (2N \log t + (4N+1) \log_{(2)} t + 2 \log_{(3)} t + \dots + 2 \log_{(n-1)} t + (2+\delta) \log_{(n)} t)^{1/2}$$

belongs to the upper or lower class with respect to uniform continuity according as $\delta > 0$ or $\delta \leq 0$. As a special case,

$$P\left(\limsup_{\substack{|a-b| \rightarrow 0, |a|, |b| \leq 1}} \frac{|X(a, \omega) - X(b, \omega)|}{\sqrt{2N|a-b| \log 1/|a-b|}} = 1\right) = 1$$

(For general information about Brownian motion with a multidimensional time parameter \rightarrow P. Lévy [6] and H. P. McKean, *Theory of Prob. Appl.* 8 (1963).)

Let $X(t)$ be a Wiener process. L. S. Ornstein and G. E. Uhlenbeck based their investigation of the irregular movements of small particles immersed in a liquid on Langevin's equation

$$dU(t) = -\alpha U(t)dt + \beta dX(t),$$

where $U(t)$ is the velocity of a particle. The first term on the right-hand side of this †stochastic differential equation (- 406 Stochastic Differential Equations) is due to frictional resistance or its analog, which is thought to be proportional to the velocity. The second term represents random external force. The stationary solution of this equation is given by

$$U(t) = \int_{-\infty}^t \beta e^{-\alpha(t-u)} dX(u).$$

The stochastic process $\{U(t)\}_{-\infty < t < \infty}$ is a stationary †Gaussian Markov process with covariance function $\gamma(t) = (\beta^2/2\alpha)e^{-\alpha|t|}$. This process is called Ornstein-Uhlenbeck Brownian motion [24] (\rightarrow 176 Gaussian Processes).

Brownian motion has been defined on state spaces that are †Riemannian spaces or +Lie groups, and its properties are being investigated (\rightarrow 5 Additive Processes, 115 Diffusion Processes).

C

46 (X.32) Calculus of Variations

A. General Remarks

One of the first objects of differential calculus was to systematize the theory of the extrema of functions of a finite number of independent variables. In the calculus of variations we consider **functionals** (i.e., real-valued or complex-valued functions defined on a function space $\{u\}$ consisting of functions defined on a certain domain B), originally so named by J. Hadamard. Such a functional is denoted by $J[u]$ (or simply $J[u]$). A function u , which is considered an independent variable of the functional, is called an **argument function** (or **admissible function**).

Concrete examples of functionals are the length of a curve $y = f(x)$ and the area of a surface $z = z(x, y)$, which are expressed by

$$L[y] = \int_{x_0}^{x_1} \sqrt{1 + (y'(x))^2} dx$$

and

$$S[z] = \iint_B \sqrt{1 + z_x^2 + z_y^2} dx dy,$$

respectively. Furthermore, consider a curve $y = y(x)$ connecting two given points (x_0, y_0) and (x_1, y_1) with $y_1 > y_0$. The time in which a particle slides down without friction from (x_0, y_0) to (x_1, y_1) along this curve under constant gravity acting in the direction of the positive y -axis is expressed by the functional

$$J[y] = k \int_{x_0}^{x_1} \sqrt{(1 + y'^2)/(y - y_0)} dx, \quad k \text{ constant. (1)}$$

Let $F(\dots)$ be a known real-valued function that depends on a certain number of independent variables and on argument functions of these variables, together with derivatives of these functions up to a certain order. Then a typical problem in the calculus of variations is formulated as an extremal problem of a functional that is expressed by the integral with $F(\dots)$ as the integrand, for example,

$$J[u] = \int_{x_0}^{x_1} F(x, u(x), u'(x), \dots, u^{(m)}(x)) dx,$$

$$J[u, v] = \iint_{S \text{ or } B} F(x, y, u(x, y), u_x, u_y, \dots, v(x, y), v_x, v_y, \dots) dx dy.$$

For instance, a curve minimizing (1) is the **curve of steepest descent**.

In extremal problems, suitable boundary conditions can be assigned to argument func-

tions. On the other hand, there are so-called **conditional problems in the calculus of variations**. A typical example of this sort is the **isoperimetric problem**, i.e., the determination of the curve that bounds a domain with maximal area among all curves on a plane with given length. In general, an extremal problem of a functional under a subsidiary condition that the value of another given functional remain fixed is called a **generalized isoperimetric problem**. In addition to these, there are **Lagrange's problem**, in which a finiteness condition is imposed, and **Hilbert's problem**, in which a condition consisting of differential equations is imposed.

The birth of the calculus of variations was almost simultaneous with that of differential and integral calculus. Johann Bernoulli, Jakob Bernoulli, L. Euler, and others had dealt with several concrete problems of the calculus of variations when in 1760, J. L. Lagrange introduced a general method of dealing with variational problems connected with mechanics. Then an equation bearing the name of Euler or Lagrange was introduced.

B. Euler's Equation

As an example, consider the simplest variational problem

$$J[y] = \int_{x_0}^{x_1} F(x, y(x), y'(x)) dx = \min. \quad (2)$$

Let the boundary condition $y(x_0) = y_0, y(x_1) = y_1$ be assigned to the argument function $y(x)$. Consider a family of admissible functions $Y(x; \varepsilon) = y(x) + \varepsilon \eta(x)$, where $\eta(x)$ is any fixed function vanishing at both endpoints and ε is a parameter. If $y(x)$ gives the minimum of $J[y]$, then the function of $\varepsilon, J[Y]$, must attain a minimum for $\varepsilon = 0$. The condition $(\partial J[Y]/\partial \varepsilon)_{\varepsilon=0} = 0$ is written in the form

$$0 = \int_{x_0}^{x_1} (F_y \eta + F_{y'} \eta') dx \\ = \int_{x_0}^{x_1} \eta \left(F_y - \frac{d}{dx} F_{y'} \right) dx$$

by taking into account the boundary condition. By making use of the arbitrariness of $\eta(x)$, we conclude that

$$0 = F_y - \frac{d}{dx} F_{y'} = F_y - F_{y'x} - y' F_{y'y} - y'' F_{y'y'} \quad (3)$$

holds, in view of the following lemma: Let $\varphi(x)$ be continuous in $[x_0, x_1]$ and $\eta(x)$ be a function of class C^p that satisfies $\eta(x_0) = \eta(x_1) = \dots = \eta^{(q)}(x_0) = 0, \eta(x_1) = \eta'(x_1) = \dots = \eta^{(q)}(x_1) = 0$ ($0 \leq q \leq p$). If $\int_{x_0}^{x_1} \eta(x) \varphi(x) dx = 0$ holds for any such $\eta(x)$, then $\varphi(x) = 0$. (Here class C^p can be

replaced by class C^ω when q is supposed finite. If $\eta \in C^\omega$, then $q = \infty$ is admitted.) This is called the **fundamental lemma in the calculus of variations**. We call (3) the **Euler-Lagrange differential equation** (or **Euler's equation** for the extremal problem). Since this equation is of the second order, $y(x)$ can be determined by means of the boundary condition.

The quantity $[F]_y = F_y - \frac{d}{dx} F_{y'}$ contained in equation (3) is called the **variational derivative** of F with respect to y . Furthermore, $\delta y = \eta d\epsilon$ and $\delta J = (\partial J / \partial Y) \delta Y$, $d\epsilon$ are called the **first variations** of the argument function y and of the functional $J[y]$, respectively. If $\eta(x)$ is not subject to the condition that it must vanish at the endpoints, then the **first variation** of J becomes

$$\delta J = \int_{x_0}^{x_1} [F]_y \delta y dx + [F_{y'} \delta y]_{x_0}^{x_1}.$$

In comparison with an ordinary extremal problem $f(x_1, \dots, x_n) = \min$ in differential calculus, $[F]_y$ and δJ correspond to df , respectively. In general, a solution of the Euler-Lagrange differential equation $[F]_y = 0$ is called a **stationary function** for the variational problem, and its graph is called a **stationary curve**.

For a variational problem involving several argument functions, we have only to write the system of Euler-Lagrange differential equations corresponding to them. For a problem

$$J[y] = \int_{x_0}^{x_1} F(x, y, y', \dots, y^{(m)}) dx = \min$$

whose integrand involves derivatives of higher orders of an argument function, the Euler-Lagrange differential equation is

$$[F]_y = \sum_{\mu=0}^m (-1)^\mu \frac{d^\mu}{dx^\mu} F_{y^{(\mu)}} = 0.$$

For a problem involving a double integral

$$J[u] = \iint_{S_B} F(x, y, u, u_x, y_y) dx dy = \min,$$

the equation is

$$0 = [F]_u = F_u - \frac{\partial}{\partial x} F_{u_x} - \frac{\partial}{\partial y} F_{u_y}.$$

For a generalized isoperimetric problem, for example $J[y] = \min$, $K[y] = c$, the Euler-Lagrange equation becomes

$$[F + \lambda G]_y = 0$$

with the so-called **Lagrange multiplier** λ , where F and G denote the integrands of J and K , respectively. Two integration constants contained in a general solution of this differential equation of the second order and an undeter-

mined constant λ can be determined, for instance, by the boundary condition $y(x_0) = y_0$, $y(x_1) = y_1$, and a subsidiary condition $K[y] = c$. As an example, for the classical proper isoperimetric problem $F = y$, $G = \sqrt{1 + y'^2}$, the equation is $1 - \lambda(y' / \sqrt{1 + y'^2})' = 0$, which after integration leads to $(x - \alpha)^2 + (y - \beta)^2 = \lambda^2$ (\rightarrow 228 Isoperimetric Problems).

Besides the case of fixed endpoints, there is a boundary condition, for instance, that an endpoint (x_1, y_1) of the argument function $y = y(x)$ must lie on a given curve $T(x, y) = 0$. For the case of such a movable endpoint, the extremal function is subject to the **condition of transversality**,

$$(F - y' F_{y'}) T_y - F_{y'} T_x = 0, \quad x = x_1.$$

C. Sufficient Conditions

A. M. Legendre introduced the notion of the second variation, corresponding to differential quotients of the second order in differential calculus, in order to discuss **sufficient conditions**. Concerning the simplest problem (2), the inequality $F_{y'y'}(x, y_0(x), y'_0(x)) \geq 0$ is necessary in order for $y_0(x)$ to give the minimum. Conversely, the inequality $F_{y'y'} > 0$ and Jacobi's condition (which is stated below) imply that $y = y_0(x)$ gives a **weak minimum**. Here "weak minimum" means the minimum when a family of admissible functions $\{y - y_0, < \epsilon, y' - y'_0 < \epsilon\}$ is considered a neighborhood of y_0 .

Jacobi's condition: Let u be a solution of a linear ordinary differential equation of the second order,

$$\frac{d}{dx} \left(F_{y'y'} \frac{du}{dx} \right) - \left(F_{yy} - \frac{d}{dx} F_{yy'} \right) u = 0,$$

$$u(x_0) = 0;$$

then the smallest zero of u that is greater than x_0 (i.e., the **conjugate point** of x_0) is greater than the right endpoint x_1 .

K. Weierstrass derived sufficient conditions for a strong minimum by extending the range of admissible functions to $\{y - y_0 < \epsilon\}$. Results that were obtained until about that time constitute the content of what is usually called the **classical theory of the calculus of variations**.

If for the variations problem (2) there exists a unique curve through every point in a domain on the xy -plane that belongs to a one-parameter family of stationary curves of the functional

$$J[y] = \int_{x_0}^{x_1} F(x, y, y') dx,$$

then the domain is called a **field** of stationary curves. Let the parameter value of the curve through a point (x, y) in such a family of

stationary curves $y = \varphi(x; a)$ be denoted by $\alpha = \alpha(x, y)$. The slope $p(x, y) = [\varphi'(x; \alpha)]_{x=\alpha(x, y)}$ is called the slope of the field at the point (x, y) or, by regarding x, y as variables, the **slope function** of the field. The value of a curvilinear integral

$$I_C = I[y] = \int_C (F(x, y, p) - (y' - p)F_y(x, y, p)) dx$$

is then determined and depends only on the two endpoints of the curve C . We call I_C **Hilbert's invariant integral**. In view of the property mentioned above, we can denote the value of the functional J for a function $y = y(x)$ representing a curve C by J_C . Then any admissible curve C that passes through a field embedding a stationary curve C_0 satisfies

$$0 \leq \Delta J = J_C - J_{C_0} = \int_C \mathcal{E}(x, y; p, y') dx.$$

Here

$$\begin{aligned} \mathcal{E}(x, y; p, y') \\ = F(x, y, y') - F(x, y, p) - (y' - p)F_y(x, y, p) \end{aligned}$$

is the \mathcal{E} -function introduced by Weierstrass. For C_0 to give the minimum of $J[y]$, it suffices that $\mathcal{E} \geq 0$ hold for every point (x, y) in the field and every value y' (\rightarrow 279 Morse Theory).

D. Optimal Control

Let a system of differential equations

$$\begin{aligned} dx_i/dt &= f_i(x_1, \dots, x_n; u_1, \dots, u_k), \\ (u_1, \dots, u_k) &\in \Omega; \quad x_i(t_0) = x_i, \quad i = 1, \dots, n, \end{aligned} \quad (4)$$

be given, where u_1, \dots, u_k are parameters. In general, a problem of **optimal control** is to determine $u_j = u_j(t)$ ($t_0 \leq t \leq t_1$) such that the value of a functional

$$J[u] = \int_{t_0}^{t_1} F(x_1, \dots, x_n; u_1, \dots, u_k) dt$$

assumes a minimum, where $x_i(t)$ are the solutions of (4) and are considered functions in u_1, \dots, u_k , and t . Such a problem is a kind of conditional variational problem. But since the existence region of u is restricted, certain conditions in the form of inequalities are imposed, and furthermore u is not necessarily continuous, and in many cases the problem cannot be treated within the classical theory of the calculus of variations (\rightarrow 86 Control Theory).

E. The Direct Method in the Calculus of Variations

In mathematical physics \dagger variational principles are derived from discussions of formal corre-

spondence between a functional $J[u]$ to be minimized and Euler's equation for $J[u]$. This is certainly one of the important methods in the calculus of variations, but it is also possible to investigate a stationary function u_0 on the basis of its stationary character and independently of Euler's equation. This is called the **direct method** in the calculus of variations. It plays an important role in the theoretical treatment of the existence and uniqueness of solutions, and it is also significant as a technique for approximate or numerical solutions. When a differential equation is given independently of the calculus of variations, it is possible to apply the direct method if a functional whose Euler's equation is the given differential equation can be constructed.

Let D be a bounded domain in m -dimensional space and $f \in L_2(D)$ be a real-valued function. Consider the variational problem of minimizing the functional

$$J[u] = \int_D |\text{grad } u|^2 dx - 2 \int_D f u dx.$$

Here we suppose the set of admissible functions, denoted by A_J , to be the Hilbert space obtained by completing the function space $C_0^\infty(D)$ with respect to the norm

$$N(u) = \left(\int_D |\text{grad } u|^2 dx + \int_D u^2 dx \right)^{1/2}$$

Utilizing F. Riesz's representation theorem in Hilbert spaces, it can be shown that there exists a minimum value l in A , which is uniquely realized by certain $u_0 \in \bar{A}_J$. Since the function u_0 belongs to A , it can be shown that the boundary condition

$$u|_{\partial D} = 0 \quad (5)$$

is satisfied in a generalized sense. Furthermore, in view of $J[u_0] \leq J[u_0 + \varphi]$ being valid for any $\varphi \in C_0^\infty(D)$, it can be verified that the equation

$$-\Delta u = f \quad (6)$$

is satisfied in D in the sense of differentiation of \dagger distributions. In other words, the stationary function u_0 is a solution in the wide sense (a tweak solution) of the classical boundary value problem for \dagger Poisson's equation formulated by (6) and (5). If a function space A , with $\bar{A}_J \supset A_J \supset C_0^\infty(D)$ is taken as the set of admissible functions, the value $l = J[u_0]$ becomes the greatest lower bound of J in A_J .

In this case, if $\{u_n\}_{n=1}^\infty$ is any **minimizing sequence** from A_J , that is, if $u_n \in A$, $n = 1, 2, \dots$; $J[u_n] \rightarrow l$ ($n \rightarrow \infty$), then it converges to u_0 in the sense that

$$N(u_n - u_0) \rightarrow 0 \quad (n \rightarrow \infty). \quad (7)$$

In other words, the solution in the wide sense

u_0 of the boundary value problem can be constructed as the limit of a minimizing sequence that consists of sufficiently smooth functions vanishing on the boundary. In the proof of the fact that a solution in the wide sense u_0 coincides with the classical solution of the boundary value problem under an assumption of suitable smoothness for f and ∂D , a standard argument has been established for proving the regularity of a solution in the wide sense.

The technique of obtaining the solution of the boundary value problem as the limit of a minimizing sequence was proposed by B. Riemann concerning the classical [†]Dirichlet problem and was completed by D. Hilbert. This pioneering work led to the recent treatment of boundary value problems by utilizing Hilbert spaces. For ⁺Self-adjoint boundary value problems, the method stated for the above example has been generalized almost directly to the cases of differential operators of higher order and with variable coefficients (-323 Partial Differential Equations of Elliptic Type). By making use of some auxiliary arguments, this technique can be applied extensively to the construction of several kinds of mapping functions in the theory of functions of a complex variable, to the solution of [†]integral equations of the second kind, and also in other fields [3, 4].

The eigenvalue problem, which is formulated by

$$Hu = \lambda u, \quad u \neq 0, \quad (8)$$

with a ⁺Self-adjoint operator H in a Hilbert space, can also be transformed into a variational problem for the [†]Rayleigh quotient

$$R[u] = (Hu, u) / \|u\|^2 \quad (9)$$

(→ 298 Numerical Computation of Eigenvalues).

F. Solution of Differential Equations by the Direct Method

In view of the convergence shown in (7), a minimizing sequence can be regarded as an approximating sequence for a solution of the boundary value problem or a stationary function u_0 . Let a function

$$u_n = u_n(x; c) = u_n(x; c_1, \dots, c_n) \quad (10)$$

involving an n -vector $c = (c_1, \dots, c_n)$ as a parameter be admissible for any c . If $J[u_n(\cdot; c)] = F(c)$, obtained by substituting u_n into J , is minimized at $c = c^0$, then $u_n(\cdot; c^0)$ is considered as a function that approximates u_0 most precisely within the family $u_n(\cdot; c)$. This vector c^0 is obtained, in general, by solving the simulta-

neous equations

$$\partial J[u_n(\cdot; c)] / \partial c_j = 0, \quad j = 1, \dots, n. \quad (11)$$

The function u_n appearing in (10) is often taken to be a so-called linear admissible function.

For instance, in the example above, let $\{\varphi_k\}_{k=1}^{\infty}$ be a system of independent functions complete in \tilde{A}_j , and set

$$u_n = c_1 \varphi_1 + \dots + c_n \varphi_n. \quad (12)$$

The method that constructs a minimizing sequence u_1, u_2, \dots by determining the value of the c_k in (12) by (11) is called **Ritz's method**, and φ_k is called a coordinate function in this method. As for the rate of convergence in approximation by Ritz's method, as well as for the estimation of errors, there are several results by the Soviet school in addition to those of E. Trefftz [3, 5]. (Other methods of constructing minimizing sequences are stated in detail in [3]; concerning a connection with [†]Galerkin's method → 304 Numerical Solution of Partial Differential Equations.)

Ritz's method applied to eigenvalue problems is called the **Rayleigh-Ritz method**. Since a stationary value of the Rayleigh quotient is itself an eigenvalue in this case, the precision of approximation is far better for eigenvalues than for eigenfunctions, so that it is a convenient method for the approximate computation of eigenvalues.

47 (XXI.1 5) Cantor, Georg

George Cantor (March 3, 1845–January 6, 1918), the founder of set theory, was born in St. Petersburg into a Jewish merchant family that settled in Germany in 1856. He studied mathematics, physics, and philosophy in Zurich and at the University of Berlin. After receiving his degree in 1867 in Berlin, he became a lecturer at the University of Halle and served as a professor at that university from 1879 to 1905. In 1884, under the strain of opposition to his ideas and his efforts to prove the \dagger continuum hypothesis, he suffered the first of many attacks of depression which continued to hospitalize him from time to time until his death.

The thesis he wrote for his degree concerned the theory of numbers; however, he arrived at set theory from his research concerning the uniqueness of \dagger trigonometric series. In 1874, he introduced for the first time the concept of \dagger Cardinal numbers, with which he proved that there were “more” \dagger transcendental numbers than \dagger algebraic numbers. This result caused a sensation in the mathematical world and became the subject of a great deal of controversy. Cantor was troubled by the opposition of L. \dagger Kronecker, but he was supported by J. W. R. \dagger Dedekind and G. Mittag-Leffler. In his note on point-set theory, he wrote, in connection regard with his concept of infinity, “The essence of mathematics lies in its freedom!” In addition to his work on cardinal numbers, he laid the basis for the concepts of \dagger order types, \dagger transfinite ordinals, and the theory of real numbers by means of \dagger fundamental sequences. He also studied general point sets in Euclidean space and defined the concepts of \dagger accumulation point, \dagger closed set, and \dagger open set. He was a pioneer of the point-set theory that led to the development of general \dagger topology.

48(X.31) Capacity

A. General Remarks

The electric capacity of a conductor in the 3-dimensional Euclidean space \mathbf{R}^3 is defined as the ratio of a given positive charge on the conductor to the value of the potential on the surface. This definition of capacity is independent of the given charge. The capacity of a set as a mathematical notion was defined first by N. Wiener (1924) and was developed by O. Frostman, C. J. de La Vallée Poussin, and several other French mathematicians in connection with \dagger potential theory.

B. Energy

Let Ω be a \dagger locally compact Hausdorff space and $\Phi(x, y)$ be a \dagger lower semicontinuous function on $\Omega \times \Omega$ such that $-\infty < \Phi \leq \infty$. A measure μ will mean a nonnegative \dagger Radon measure with compact \dagger support S_μ . Denote by $\Phi(x, \mu)$ the \dagger potential $\int \Phi(x, y) d\mu(y)$ of a measure μ with kernel Φ and by (μ, μ) the \dagger energy $\int \int \Phi d\mu d\mu$ of μ . Let X be a set in Ω , and denote by \mathcal{U}_X the class of normalized measures μ (i.e., of measures μ satisfying $\mu(\Omega) = 1$) with $S_\mu \subset X$. Let K be a nonempty compact set in Ω . Set $W(K) = \inf(\mu, \mu)$ for $\mu \in \mathcal{U}_K$, and $W(\emptyset) = \infty$ for the empty set \emptyset . For $\Phi(x, y) = 1/|x - y|$ in $\Omega = \mathbf{R}^3$, the general solution $u(x)$ of the \dagger Dirichlet problem (\dagger exterior problem) for the boundary function 1 in the unbounded component of $\mathbf{R}^3 - K$ is equal to the potential of an \dagger equilibrium mass-distribution. Therefore, if S is a smooth surface surrounding K and normals are drawn outward to S , the integral $-(1/4\pi) \cdot \int_S (\partial u / \partial n) d\sigma$ of the normal derivative is equal to $1/W(K)$. This is the **capacity** of K defined by N. Wiener (*J. Math. Phys.*, MIT, 3 (1924)) when K is a closed region. Vallée-Poussin (*Ann. Inst. H. Poincaré*, 2 (1932)) called the supremum of $\mu(\mathbf{R}^3)$ the Newtonian capacity of a bounded \dagger Borel set E , where μ runs through the class of measures μ with $S_\mu \subset E$ whose \dagger Newtonian potentials are not greater than 1 in \mathbf{R}^3 . If E is compact, the Newtonian capacity coincides with Wiener's capacity. For the \dagger logarithmic potential in \mathbf{R}^2 , $e^{-W(K)}$ is called the **logarithmic capacity**. When \dagger Green's function $g(z, \infty)$ with the pole at the point at infinity exists in the unbounded component of $\mathbf{R}^2 - K$, $\lim_{z \rightarrow \infty} (g(z, \infty) - \log |z|)$ is called **Robin's constant** and can be shown to be equal to $W(K)$. (For the relation between Robin's constant and \dagger reduced extremal distance \rightarrow 143 Extremal Length.) In the case of a general

kernel it is difficult to define capacity as above by means of $W(K)$, and hence the value of $W(K)$ itself instead of the capacity of K is often used. When $W(K) = \infty$, we can say that K is of capacity zero. The minimum value of the † Gauss integral $(\mu, \mu) = 2 \iint d\mu$ is a generalization of $W(K)$, where $\mu \in \mathcal{U}_K$ and f is an upper semicontinuous function bounded above on K .

C. Minimax Value

Suppose that we are given the kernel Φ as above. For a set $X \subset \Omega$ and a measure μ , set $U(\mu; X) = \sup_{x \in X} \Phi(x, \mu)$ and $V(\mu; X) = \inf_{x \in X} \Phi(x, \mu)$. Next, for $Y \subset \Omega$, set $U(Y) = \inf_{\mu \in \mathcal{U}_Y} U(\mu; X)$, $V(Y) = \sup_{\mu \in \mathcal{U}_Y} V(\mu; X)$, $U(X, Y) = \inf_{\mu \in \mathcal{U}_Y} U(\mu; X)$, and $V(X, Y) = \sup_{\mu \in \mathcal{U}_Y} V(\mu; X)$, where $\mu \in \mathcal{U}_Y$. If $\check{\Phi}(x, y) = \Phi(x, y)$ is taken as a kernel instead of $\Phi(x, y)$, then the notations $u(K)$, $\check{U}(\mu; X)$, $\check{V}(\mu; X)$, are used correspondingly. For any compact set K the following relations hold:

$$W(K) = \check{W}(K) \leq CI(K) = \check{u}(K)$$

$$\leq \left\{ \begin{array}{l} U(K, K) = \check{V}(K, K) \\ \check{U}(K, K) = V(K, K) \end{array} \right\} \leq \left\{ \begin{array}{l} U(\Omega, K) = \check{V}(K, \Omega) \\ \check{U}(\Omega, K) = V(K, \Omega) \\ V(K) = \check{V}(K) \end{array} \right\}$$

Examples show that all the inequalities can be strict. The † minimax theorem in the † theory of games plays an important role in the proof of these inequalities [7]. Even if the kernel is symmetric, the inequalities can be strict except for the equality $W(K) = U(K)$. When the kernel is positive, we can define the quantities which correspond to $U(Y)$, $V(Y)$, $U(X, Y)$, $V(X, Y)$ by considering the class of μ with $S_{\mu} \subset Y$ and $(\mu, \mu) = 1$ instead of \mathcal{U}_Y .

D. Transfinite Diameter

As $k \rightarrow \infty$,

$$D_k(K) = k^{-1}(k-1)^{-1} \inf_{x_1, \dots, x_k \in K} \sum_{i \neq j} \Phi(x_i, x_j)$$

decreases and the limit $D(K)$ is equal to $W(K)$. For the logarithmic kernel in \mathbf{R}^2 , M. Fekete defined $D(K)$ and called $e^{-D(K)}$ the **transfinite diameter** of K (1923). F. Leja and his school in Poland studied relations between transfinite diameter and † conformal mapping. Next, set

$$kR_k(X, Y) = \sup_{x_1, \dots, x_k \in X} \inf_{y \in Y} \sum_{i=1}^k \Phi(x_i, y).$$

Then $R(X, Y) = \lim_{k \rightarrow \infty} R_k(X, Y)$ exists as $k \rightarrow \infty$, and we have $R(K, Y) = V(K, Y)$.

Fekete introduced $R(K) = R(K, K)$ in \mathbf{R}^2 (1923). G. Polya and G. Szegő computed $D(K)$ and $R(K)$ for special K and cc-kernel $r^{-\alpha}$ ($\alpha \geq 0$) in \mathbf{R}^2 and \mathbf{R}^3 [12]. The equality $D(K) = R(K)$ holds for the logarithmic kernel in \mathbf{R}^2 and the

Newtonian kernel in \mathbf{R}^3 . The maximum of the absolute value on K of † Chebyshev's polynomial (\rightarrow 336 Polynomial Approximation) of order k with respect to K in \mathbf{R}^2 is equal to $\exp(-kR_k(K))$.

E. Evans's Theorem

In order that K be of Newtonian capacity zero, it is necessary and sufficient that there exist a measure μ on K such that the Newtonian potential of μ is equal to ∞ at every point of K . This result was proved by G. C. Evans and H. Selberg independently (1935) and is called **Evans's theorem** (or the **Evans-Selberg theorem**). The corresponding theorem in \mathbf{R}^2 is often applied in the theory of functions [15, 16]. A similar potential exists in case of a general kernel if and only if $R(K, K) = \infty$.

F. Nonadditivity of Capacity

Many kinds of capacity satisfy the inequality $\text{cap}(\bigcup_n X_n) \leq \sum_n \text{cap } X_n$, where a capacity is denoted by cap . Even the Newtonian capacity C is not necessarily additive, but it satisfies $C(K_1 \cup K_2) + C(K_1 \cap K_2) \leq C(K_1) + C(K_2)$ (G. Choquet [2]). Choquet [3] proved that X can be divided into mutually disjoint sets X , and X_2 such that $C_i(X) = C_i(X_1) = C_i(X_2)$, where $C_i(X)$ is the **Newtonian inner** (or **interior**) **capacity** defined to be $\sup_{K \subset X} C(K)$ if $X \neq \emptyset$ and 0 if $X = \emptyset$.

G. Relation to Hausdorff Measure

There are many studies of relations between capacity and † Hausdorff measure [1]. Frostman [6] introduced the notion of **capacity dimension** and observed that it coincides with the Hausdorff dimension. The capacity of product sets has been evaluated from above and below [11]. For compact sets $K \subset \mathbf{R}^n$, $K' \subset \mathbf{R}^m$, their dimensions α , β , and the dimension γ of $K \times K'$, we have the relation $\alpha + \beta \leq \gamma \leq \min(m + \alpha, n + \beta)$, where the equalities are attained by general † Cantor sets. There are also works on the evaluation of capacities of general Cantor sets [10, 15]. If K is a continuum of logarithmic capacity 1 in a plane, then its diameter d satisfies $2 \leq d \leq 4$, and its area A satisfies $A < n$ [S]. Consider the sum $K = \{z_1 + \dots + z_n | z_k \in K_k, 1 \leq k \leq n\}$ of continua K_1, \dots, K_n in a plane. The logarithmic capacity of K is strictly greater than the sum of the logarithmic capacities of K_1, \dots, K_n except when all K_k are convex and mutually similar [14]. By various † symmetrizations the logarithmic capacity decreases in general (\rightarrow 228 Isoperimetric Problems; also [133]).

H. Capacitability

The **Newtonian outer** (or **exterior**) capacity $C_*(X)$ is defined by $\inf C_i(G)$, where G ranges over an open set containing X . The inequality $C_i(X) \leq C_*(X)$ holds, in general. When the equality holds, X is called **capacitable**. Choquet (1955) [2] proved that all \aleph_1 -analytic sets and hence \aleph_1 -Borel sets are capacitable but there exists an analytic set whose complement is not capacitable. He himself generalized his result on capacitability in the following way [4]: Let Ω be an abstract space, φ a nondecreasing function defined on the family of all subsets of Ω , and \mathcal{H} some family of subsets of Ω that is closed under the formation of finite unions and countable intersections. Assume that $\varphi(H_n) \downarrow \varphi(H)$ as H_n in \mathcal{H} decreases to H and that $\varphi(X_n) \uparrow \varphi(X)$ as $X_n \uparrow X$. When $\varphi(X)$ is equal to $\sup\{\varphi(H) \mid H \in \mathcal{H}, H \subset X\}$, X is called (φ, \mathcal{H}) -capacitable. Choquet defined \mathcal{H} -Suslin sets and showed that they are (φ, \mathcal{H}) -capacitable. M. Kishi [9], Choquet [5], and B. Fuglede [7] investigated capacitability with respect to several kinds of capacity more general than Newtonian capacity. We can discuss capacitability with respect to quantities defined in connection with the \aleph_1 -Gauss variational problem.

49 (11.6)
Cardinal Numbers

A. Definition

The general concept of cardinal number is an extension of that of natural number (Cantor [1]). When there exists a \aleph_1 -one-to-one correspondence whose \aleph_1 -domain is a set A and whose \aleph_1 -range is a set B , this set B is said to be **equipotent** (or **equipollent**) to A , and this relation is denoted by $A \sim B$. The relation \sim is an \aleph_1 -equivalence relation, and each equivalence class under this relation is said to be a **cardinal number**. The class of all sets equipotent to a set A is denoted by A (or $|A|$) and is said to be the **cardinal number** (power, cardinality, or **potency**) of the set A . When A is a finite set, A is said to be **finite**, and when A is an infinite set, A is said to be **infinite** (or **transfinite**). When the cardinal number of a set A is m , A is also said to consist of m members (or m elements). In this sense, 0 and the natural numbers are considered to express finite cardinal numbers. For example, $0 = \emptyset$, $1 = \{0\}$, $2 = \{0, 1\}$, etc. Examples of infinite cardinal numbers: A set A which is equipotent to the set N of all natural numbers is said to be **countably infinite**, and the cardinal number of the set N is denoted by \aleph_0 . A set A which is finite or countably infinite is said to be **countable**. The cardinal number of the set of all real numbers is denoted by c and is called the **cardinal number of the continuum**. Moreover, the cardinal number of the set of all real-valued functions whose domain is the interval $[0, 1]$ is denoted by \mathfrak{f} . These three cardinal numbers are known to be distinct. Henceforth in this article, lower-case German letters denote cardinal numbers. For a definition of cardinal numbers using the concept of ordinal numbers \rightarrow 312 Ordinal Numbers.

B. Ordering of Cardinal Numbers

$m \geq n$ or $n \leq m$ will mean that there exist sets A and B such that $m = \bar{A}$, $n = \bar{B}$, and $A \supset B$. $A \neq B$ does not necessarily imply $m \neq n$. For example, the cardinal number of the set of all positive even numbers is also \aleph . $m \geq n$ and $n \geq m$ imply $m = n$ (**Bernshtein's theorem**). Since the \dagger reflexive and \dagger transitive laws for the relation \leq between cardinal numbers are obvious, the relation is an \dagger ordering relation. The \dagger well-ordering theorem implies that \geq is a \dagger total ordering (**comparability theorem for cardinal numbers**). $m > n$ means that $m \geq n$ and $m \neq n$. When $B \leq m$, B is said to be at **most** m .

C. Sum, Product, and Power of Cardinal Numbers

For cardinal numbers m and n , choose sets A and B so that $m = \bar{A}$, $n = \bar{B}$, and $A \cap B = \emptyset$, and put $s = \overline{A \cup B}$. Then s is uniquely determined by m and n . The s is said to be the **sum** of the cardinal numbers m and n and is denoted by $m + n$. If the sets A, B are chosen as described above, the cardinal numbers of the \dagger Cartesian product $A \times B$ and of the set of functions A^B are called the **product** of m and n and the n th **power** of m , denoted by mn and m^n , respectively. These operations are also determined by m and n . For these three operations, the following laws are valid: **commutative laws** $m + n = n + m$, $mn = nm$; **associative laws** $(m + n) + p = m + (n + p)$, $(mn)p = m(np)$; **distributive law** $p(m + n) = pm + pn$; **exponential laws** $m^{n+p} = m^n m^p$, $m^{np} = (m^n)^p$, $(mn)^p = m^p n^p$. In particular, if $\bar{A} = m$, then 2^m is the cardinal number of the \dagger power set $\mathfrak{P}(A)$ of A .

Addition and multiplication of more than two cardinal numbers can be defined as follows. Let Λ be any set, and suppose that to any element λ of Λ there corresponds a unique cardinal number m_λ . Let M_λ be a set such that $\bar{M}_\lambda = m_\lambda$, and $M_\lambda \cap M_{\lambda'} = \emptyset$ for $\lambda \neq \lambda'$. Then the cardinal number of the \dagger disjoint union $\sum_\lambda M_\lambda$ is said to be the **sum** of all m_λ and is denoted by $\sum_\lambda m_\lambda$. The cardinal number of the Cartesian product $\prod_\lambda M_\lambda$ is said to be the **product** of all m_λ ($\lambda \in \Lambda$) and is denoted by $\prod_\lambda m_\lambda$. The axiom of choice can be stated as follows: If $m_\lambda \neq 0$ for all $\lambda \in \Lambda$, then $\prod_\lambda m_\lambda \neq 0$.

D. The Continuum Hypothesis

For \aleph , \mathfrak{c} , and \mathfrak{f} defined as before, $\mathfrak{f} = 2^{\mathfrak{c}} > \mathfrak{c} = 2^{\aleph}$. In general, $2^m > m$ holds for any cardinal

number m (Cantor). The hypothesis which asserts that for any m , there does not exist an n such that $2^m > n > m$ is called the **generalized continuum hypothesis**. In particular, this hypothesis restricted to the case where $m = \aleph$ is called the **continuum hypothesis**. After Cantor stated this hypothesis (*J. Reine Angew. Math.*, 84 (1878)), it remained an open question for many years. In particular, Cantor himself repeatedly tried to prove it, and W. Sierpiński pursued various related hypotheses. Finally, the continuum hypothesis and the generalized continuum hypothesis were proved to be independent of the axioms of set theory by K. Gödel (1940) [3] and P. J. Cohen (1963) [4] (\rightarrow 33 Axiomatic Set Theory).

E. Cardinality of Ordinal Numbers

Lower-case Greek letters will stand here for \dagger ordinal numbers. The cardinal number of $\{\xi \mid \xi < \alpha\}$ will be denoted by $\bar{\alpha}$, which is called the **cardinality of the ordinal number α** or the **cardinal number corresponding to α** . When a cardinal number m corresponds to some ordinal number, the minimum among ordinal numbers α with $\bar{\alpha} = m$ is called the **initial ordinal number** corresponding to m . An initial ordinal number corresponding to an infinite cardinal number is called a **transfinite initial ordinal number**. There exists a unique correspondence $\beta \rightarrow \omega_\beta$ from the class of ordinal numbers onto the class of all transfinite initial ordinal numbers such that $\beta > \gamma$ implies $\omega_\beta > \omega_\gamma$. In particular, $\omega_0 = \omega$, and an ordinal number ξ such that $\xi < \omega_1$ is called a **countable ordinal number**. ω_β is called the β th transfinite initial ordinal number. The cardinality of ω_β is denoted by \aleph_β (\aleph is the Hebrew letter **aleph**). In particular, \aleph is denoted by \aleph_0 (**aleph zero**). We have $\aleph_\beta \geq \aleph_\gamma$ if and only if $\beta \geq \gamma$, and in this case $\aleph_\beta + \aleph_\gamma = \aleph_\beta$, $\aleph_\beta \aleph_\gamma = \aleph_\beta$. The axiom of choice implies that every infinite cardinal number is an \aleph_β . Hence, in this case, the continuum hypothesis can be formulated as $2^{\aleph_0} = \aleph_1$, and the generalized continuum hypothesis can be formulated as $2^{\aleph_\beta} = \aleph_{\beta+1}$ for every ordinal number β .

F. Finiteness and Infiniteness

Dedekind [5] defined a set A to be **infinite** if A is equipotent to a proper subset of itself, and to be **finite** otherwise. It is also possible to define finiteness and infiniteness of sets as follows: A set A is finite if there exists a \dagger well-ordering of A such that its \dagger dual ordering is also a well-ordering, and A is infinite other-

wise. If a set is finite in the latter sense, then it is also finite in the sense of Dedekind. Under the axiom of choice, these two definitions can be shown to be equivalent.

50 (XXI.16) Cartan, Elie

Elie Cartan (April 9, 1869–May 6, 1951) was born at Dolomieu in the French province of Isère. He entered the Ecole Normale Supérieure in Paris in 1888 and graduated in 1891, having at the same time qualified in the agrégé examination. Beginning his research immediately, he completed his thesis on the structure of continuous transformation groups [2] in 1894 at the age of 25.

Cartan was a professor first at the University of Montpellier, later at the University of Lyon, then the University of Nancy, and finally in 1912 at the University of Paris. He freely used the †moving coordinate system introduced by J. G. Darboux, and contributed to many areas, such as the theory of †Lie groups, the theory of †Pfaffian forms, the theory of †invariant integrals, †topology, †differential geometry (especially the geometry of †connections), and theoretical physics. His doctoral thesis is still an object of interest among young researchers today, and the concept of connection introduced by him is fundamental in the field of differential geometry. Henri Cartan (1904–) is his eldest son.

51 (IX.24) Catastrophe Theory

A. General Remarks

Catastrophe theory was originally proposed by R. Thom [1, 2] in late 1960. This theory provides certain mathematical models for the evolution of forms in nature, in particular in biology and the natural languages. In recent years, E. C. Zeeman and others have developed and applied the theory to various fields, including the physical sciences, medicine, economics, and sociology; a detailed bibliography may be found in [3, 9, 10].

B. Static Models

The basic concept of the theory is the **static model**. This is a family of potential functions $f_u: X \rightarrow \mathbf{R}$, where X is a subset of \mathbf{R}^n , containing a neighborhood of the origin, and the parameter u lies in a neighborhood U of the origin in \mathbf{R}^r .

We regard \mathbf{R}^n as the **internal space** or **state space**, which is parametrized by the various variables that are relevant to the process under study, and \mathbf{R}^r is the **external space** or **control space**, which can be either the physical space-time continuum in which the process under consideration takes place or a space of control parameters that govern the process. As a rule, we assume that the dimension $r \leq 4$, although the dimension n can be arbitrary large.

The static model is local in nature, and any one of the local minima of f_u , called a **local regime** at $u \in U$, is a candidate for the state of the model corresponding to the control point u .

Mathematically, a static model is a germ of C^∞ -functions $f: \mathbf{R}^n \times \mathbf{R}^r \rightarrow \mathbf{R}$ at 0 that is an unfolding (r -dimensional extension family) of a germ of C^∞ -functions $\eta = f|_{\mathbf{R}^n \times \{0\}}: \mathbf{R}^n \rightarrow \mathbf{R}$ at 0; further details are given in Section D.

C. Classification of Singularities

Let $\mathcal{E}(n, m)$ be the vector space of \dagger germs of C^∞ -functions $f: \mathbf{R}^n \rightarrow \mathbf{R}^m$ at 0, and let $\mathcal{B}(n) \subset \mathcal{E}(n, n)$ be the subset of invertible germs $\mathbf{R}^n \rightarrow \mathbf{R}^n$ mapping 0 to 0.

The germs $\eta, \xi \in \mathcal{E}(n, m)$ are called **right equivalent** if there exists an $h \in \mathcal{B}(n)$ such that $\eta \circ h = \xi$. Let $\mathcal{E}(n) = \mathcal{E}(n, 1)$. Then it follows in the usual manner that $\mathcal{E}(n)$ is a local algebra with the unique maximal ideal $\mathcal{M} = \mathcal{M}(n) = \{\eta \in \mathcal{E}(n) \mid \eta(0) = 0\}$. A germ $\eta \in \mathcal{E}(n)$ such that $\eta(0) = D\eta(0) = 0$ is called a **singularity**. For any singularity η , we define the **codimension** of η by $\text{codim } \eta = \dim_{\mathbf{R}}(\mathcal{M} / \langle \partial \eta / \partial x_i \rangle_{\mathcal{E}(n)})$,

where $\langle \partial \eta / \partial x_i \rangle_{\mathcal{E}(n)}$ is the ideal of $\mathcal{E}(n)$ generated by $\partial \eta / \partial x_1, \dots, \partial \eta / \partial x_n$ and $x = (x_1, \dots, x_n)$ denotes the coordinate system of \mathbf{R}^n .

The following result was proved by J. N. Mather [4]: Up to the addition of a nondegenerate quadratic form in other variables, and up to multiplication by ± 1 , a singularity of codimension ≤ 4 and ≥ 1 is right equivalent to one of the η appearing in Thom's list of the seven elementary catastrophes below.

D. Unfoldings

Let η be a singularity. An **r -unfolding** of η is a germ $f \in \mathcal{M}(n+r)$ such that $f|_{\mathbf{R}^n \times \{0\}} = \eta$; this unfolding is denoted by (r, f) . Let (r, f) and (s, g) be unfoldings of η . A **morphism** $(\varphi, \Phi, \varepsilon): (r, f) \rightarrow (s, g)$ consists of (i) a germ $\varphi \in \mathcal{E}(n+r, n+s)$ such that $\varphi|_{\mathbf{R}^n \times \{0\}} = \text{identity}$, (ii) a germ $\Phi \in \mathcal{E}(r, s)$ such that $\pi_s \circ \varphi = \Phi \circ \pi_r$, (iii) a germ $\varepsilon \in \mathcal{M}(r)$ such that $f = g \circ \varphi + \varepsilon \circ \pi_r$, where $\pi_r: \mathbf{R}^n \times \mathbf{R}^r \rightarrow \mathbf{R}^r$ is the projection. In this case we say that the unfolding (r, f) is **induced** by $(\varphi, \Phi, \varepsilon)$ from (s, g) . A morphism is an **isomorphism** if φ and Φ are diffeomorphic germs.

The **addition** of unfoldings (r, f) and (s, g) of η is defined by $(r, f) + (s, g) = (r+s, f+g-\eta)$, where the last term on the right is given by $(f+g-\eta)(x, u, v) = f(x, u) + g(x, v) - \eta(x)$.

Thus if the **constant unfolding** (s, η) of η is

defined by $\eta(x, u) = \eta(x)$, we have $(r, f) + (s, \eta) = (r+s, f)$.

An unfolding (r, f) of η is said to be **versal** if any unfolding of η is induced by (r, f) and a suitable morphism. A versal unfolding (r, f) with minimal r is said to be **universal**. The following facts have also been proved by Mather [4]:

A singularity $\eta \in \mathcal{M}(n)$ has a versal unfolding if and only if $\text{codim } \eta$ is finite. Any two r -versal unfoldings of η are isomorphic. Every versal unfolding is isomorphic to $(r, f) + \text{constant}$, where $r = \text{codim } \eta$ and (r, f) is a universal unfolding defined as follows: If $\{b_1, \dots, b_r\} \subset \mathcal{M}(n)$ is a system of representatives for a basis of $\mathcal{M}(n) / \langle \partial \eta / \partial x_i \rangle_{\mathcal{E}(n)}$, then the unfolding f of η is defined by $f(x, u) = \eta(x) + b_1(x)u_1 + \dots + b_r(x)u_r$.

E. The Seven Elementary Catastrophes

Let f and g be germs in $\mathcal{E}(n+r)$. We say that f and g are **equivalent** as r -unfoldings if there exist $h \in \mathcal{B}(r)$, a family of $H_u \in \mathcal{B}(n)$, where $u \in U \subset \mathbf{R}^r$, and an $\varepsilon \in \mathcal{M}(r)$ such that $f(x, y) = g(H_u(x), h(u)) + \varepsilon(u)$.

We say that a static model (r, f) is **stable** if any small perturbation (r, g) of (r, f) in $\mathcal{E}(n+r)$ (with the Whitney C^∞ -topology) is equivalent to (r, f) . The following is the main result observed by Thom and proved by Mather and others (for references see the bibliography in [3]). Suppose that $r \leq 4$. Then the set of stable static models (r, f) is an open dense subset of $\mathcal{E}(n+r)$, and up to the addition of a nondegenerate quadratic form and multiplication by ± 1 , any stable static model (r, f) is equivalent to one of the models with the standard potentials F , which are the universal unfoldings of singularities η in Table 1 (x, y denote internal variables, and u, v, w, t denote external variables).

The static models with these standard potentials are known as the **elementary catastrophes** and can serve as qualitative models of various natural processes.

Table 1. Thom's List of the Seven Elementary Catastrophes

r	Singularity η	Standard Potential F	Name
1	x^3	$x^3 + ux$	Fold
2	x^4	$x^4 + ux^2 + vx$	Cusp (Riemann-Hugo-Niot)
3	x^5	$x^5 + ux^3 + vx^2 + wx$	Swallowtail (Dovetail)
3	$x^3 + y^3$	$x^3 + y^3 + uxy + vx + wy$	Hyperbolic umbilic
3	$x^3 - xy^2$	$x^3 - xy^2 + u(x^2 + y^2) + vx + wy$	Elliptic umbilic
4	x^6	$x^6 + tx^4 + ux^3 + vx^2 + wx$	Butterfly
4	$x^2y + y^4$	$x^2y + y^4 + ux^2 + vy^2 + wx + ty$	Parabolic umbilic

F. Catastrophe Sets

A **process** for the static model $f \in \mathcal{E}(n+r)$ is a subset s of $X \times U$, where X and U are neighborhoods of the origin in \mathbf{R}^n and \mathbf{R}^r , respectively. If s is a process and $u \in U$, we define $s_u = s \cap (X \times \{u\})$. We say that $u \in U$ is a **regular point** for s if there exists a neighborhood V of u in U and a homeomorphism $h: X \times V \rightarrow X \times V$ such that $\pi_r \circ h = \pi_r$ on $X \times V$ and $h(s \cap (X \times V)) = s_u \times V$. A **catastrophe point** is a non-regular point in U . The set of all catastrophe points is called the **catastrophe set**.

There are several conventions with regard to the definition of a process for the unfolding (r, f) . One of these is the **Maxwell convention**, which requires that s_u be a least local regime at $u \in U$. The catastrophe set of the model (r, f) according to the Maxwell convention consists of those points u of the control space \mathbf{R}^r where the least minimum of f_u is attained for at least two points or where this minimum is attained at a unique point but is not stable.

Another is the **perfect delay convention**, which assigns to each path τ in U a mapping (possibly discontinuous) $m_\tau: \tau \rightarrow X \times \tau$ such that $\pi_r(m_\tau(u)) = u$, $(m_\tau(u), u)$ is a local regime, and m_τ remains continuous for a maximum interval on the path τ . Consider the set

$$\Delta = \{(x, u) \in \mathbf{R}^n \times \mathbf{R}^r \mid d_x^2 f(x, u) \text{ is degenerate}\}$$

and its image $B = \pi_r(\Delta)$, called the **bifurcation set**, under the projection $\pi_r: \mathbf{R}^n \times \mathbf{R}^r \rightarrow \mathbf{R}^r$. Then the points of the bifurcation set B are important candidates for catastrophe points of the static model with respect to the perfect delay convention.

For geometrical studies of the elementary catastrophes \rightarrow [6–8]. The static models have been generalized to **metabolic models**, the structure of which largely remains an open question [2]. In this connection, the bibliographies of [3, 9, 10] appear to be fairly complete.

52 (II.24)
Categories and Functors

A. Categories

Consider the family of all \dagger groups. Given two groups X and Y , denote the set of all \dagger homomorphisms of X to Y by $\text{Hom}(X, Y)$. If X, Y , and Z are groups and if $f: X \rightarrow Y$ and $g: Y \rightarrow Z$ are homomorphisms, we can compose them to get a homomorphism $g \circ f: X \rightarrow Z$.

In general, suppose that we are given, as in this example, (1) a family \mathfrak{M} of **mathematical objects**, and (2) for every pair (X, Y) of objects in \mathfrak{M} , a set $\text{Hom}(X, Y)$ whose elements are called **morphisms**; and let $f \in \text{Hom}(X, Y)$ and $g \in \text{Hom}(Y, Z)$ determine a morphism $g \circ f \in \text{Hom}(X, Z)$, which is called their **composite**. A morphism $f \in \text{Hom}(X, Y)$ is also written $f: X \rightarrow Y$. Suppose further that these morphisms satisfy the following axioms: (1) if $f: X \rightarrow Y, g: Y \rightarrow Z$, and $h: Z \rightarrow W$ are morphisms, then $(h \circ g) \circ f = h \circ (g \circ f)$; (2) for each object $X \in \mathfrak{M}$ there exists a morphism $1_X: X \rightarrow X$ such that for any $f: X \rightarrow Y$ and $g: Z \rightarrow X$ we have $f \circ 1_X = f$ and $1_X \circ g = g$; (3) $\text{Hom}(X, Y)$ and $\text{Hom}(X', Y')$ are disjoint unless $X = X'$ and $Y = Y'$. Then we call the whole system (i.e., the family of objects \mathfrak{M} , the morphisms, and the composition of morphisms) a **category**. The elements in \mathfrak{M} are called the **objects** of the category.

By axioms (1) and (2), the set $\text{Hom}(X, X)$ is a semigroup (with respect to the composition of morphisms) which has 1_X as the identity element. Hence 1_X is determined uniquely by X . On the other hand, axiom (3) implies that a morphism f determines the objects X and Y such that $f \in \text{Hom}(X, Y)$. From these facts we can give an alternative definition of category using only the morphisms and their composition.

The totality of the objects (or morphisms) in a category \mathcal{C} is denoted by **Ob**(\mathcal{C}) (or **FI**(\mathcal{C});

the notation Fl comes from the French word *flèche*. The relation $x \in \text{Ob}(\mathcal{C})$ is often abbreviated to $x \in \mathcal{C}$, while $\text{Hom}(X, Y)$ is written $\text{Hom}_{\mathcal{C}}(X, Y)$ if necessary. A **subcategory** of a category \mathcal{C} is a category \mathcal{C}' with $\text{Ob}(\mathcal{C}') \subset \text{Ob}(\mathcal{C})$, such that for $X, Y \in \mathcal{C}'$ we have $\text{Hom}_{\mathcal{C}'}(X, Y) \subset \text{Hom}_{\mathcal{C}}(X, Y)$ and the composition in \mathcal{C}' is the restriction of \mathcal{C} to \mathcal{C}' . If $\text{Hom}_{\mathcal{C}'}(X, Y) = \text{Hom}_{\mathcal{C}}(X, Y)$ for all $X, Y \in \mathcal{C}'$, we say that \mathcal{C}' is a **full subcategory** of \mathcal{C} .

We define the **product category** $\mathcal{C}_1 \times \mathcal{C}_2$ of two categories in the canonical way, using the pairs of objects and the pairs of morphisms.

B. Examples of Categories

(1) Taking all sets as the objects, all mappings as the morphisms, and the composition of mappings as the composition, we obtain a category called the **category of sets**, denoted by (Sets) (or (Ens) from the French *ensemble*). For the empty set \emptyset we make the convention that $\text{Hom}(\emptyset, Y)$ contains just one element for any Y and that $\text{Hom}(Y, \emptyset)$ is empty if $Y \neq \emptyset$.

(2) As we have seen, taking all groups as the objects and the homomorphisms as the morphisms, we get the **category of groups**, written (Gr) . If we limit the objects to \dagger Abelian groups, we get the **category of Abelian groups** (Ab) as a full subcategory of (Gr) .

(3) Fix a ring R . The left R -modules and their R -linear mappings define the **category of left R -modules**, which we denote by ${}_R\mathcal{M}$. The category of right R -modules, \mathcal{M}_R , is defined similarly. When R is \dagger unitary, we usually limit the objects of ${}_R\mathcal{M}$ and \mathcal{M}_R to \dagger unitary modules. If R is commutative we can identify ${}_R\mathcal{M}$ with \mathcal{M}_R . When $R = \mathbb{Z}$ (the ring of rational integers), ${}_R\mathcal{M}$ can be identified with (Ab) . When R is a field, ${}_R\mathcal{M}$ is also called the **category of linear spaces over R** .

(4) Taking rings as objects and homomorphisms of rings as morphisms, we obtain the **category of rings**. The subcategory consisting of unitary commutative rings and unitary homomorphisms is called the **category of commutative rings** and is denoted by (Rings) .

(5) If we take \dagger differentiable manifolds as objects and differentiable mappings as morphisms, we obtain the **category of differentiable manifolds**. Similarly, for \dagger analytic manifolds and analytic mappings we obtain the **category of analytic manifolds**.

(6) Taking topological spaces as objects and continuous mappings as morphisms, we get a category called the **category of topological spaces** and denoted by (Top) . On the other hand, if we take the \dagger homotopy classes of continuous mappings as morphisms and define their composition in the natural way,

we obtain another category, which is called the **homotopy category of topological spaces**.

(7) Fix a \dagger preordered set I . Taking the elements of I as the objects and the pairs (x, y) of elements of I with $x \leq y$ as the (unique) morphism from x to y , we get a category, in which we define the composite of the morphisms (x, y) and (y, z) to be (x, z) .

In examples (1) through (6), the totality of the objects $\text{Ob}(\mathcal{C})$ is not a set, but a \dagger class (\rightarrow 381 Sets G; for the logical foundation of category theory \rightarrow [3, 9]).

C. Diagrams

If a set of arrows $\{A_{\alpha}\}$ and a set of points $\{B_{\beta}\}$ are given in such a way that each arrow A_{α} has a unique initial point and a unique endpoint, then we say that $\{A_{\alpha}, B_{\beta}\}$ is a **diagram**. (Usually, we consider the case where each point B_{β} is the initial point or the endpoint of at least one A_{α} (Fig. 1).) Let \mathcal{C} be a category and $\{A_{\alpha}, B_{\beta}\}$ a diagram. If we associate a morphism f_{α} in \mathcal{C} with each arrow A_{α} and an object $Z_{\beta} \in \mathcal{C}$ with each point B_{β} so that $f_{\alpha} \in \text{Hom}(Z_{\beta}, Z_{\gamma})$ whenever A_{α} has the initial point B_{β} and the endpoint B_{γ} , then we say that $\{f_{\alpha}, Z_{\beta}\}$ is a **diagram in the category \mathcal{C}** (Fig. 2). Suppose, furthermore, that the following condition is satisfied: For any pair of points B_{β} and B_{γ} , and for any sequence of adjacent arrows $A_{\alpha_1}, \dots, A_{\alpha_m}$ starting at B_{β} and ending at B_{γ} (i.e., the initial point of A_{α_1} is B_{β} , the endpoint of A_{α_i} is the initial point of $A_{\alpha_{i+1}}$ and the endpoint of A_{α_m} is B_{γ}), the composite $f_{\alpha_m} \circ f_{\alpha_{m-1}} \circ \dots \circ f_{\alpha_1} (\in \text{Hom}(B_{\beta}, B_{\gamma}))$ depends only on B_{β} and B_{γ} . Then the diagram in \mathcal{C} is said to be a **commutative diagram**. For example, commutativity of Fig. 2 is equivalent to $f_3 \circ f_1 = f_4 \circ f_2 = f_5$.

Fig. 1

Fig. 2

D. Miscellaneous Definitions

A morphism $f: X \rightarrow Y$ in a category \mathcal{C} is called an **isomorphism** (or **equivalence**) if there exists a morphism $g: Y \rightarrow X$ such that $f \circ g = 1_Y$, $g \circ f = 1_X$. In this case, g is determined uniquely by f and is itself an isomorphism. We call g the **inverse morphism** of f . Then the inverse of g is f . An isomorphism is sometimes written $f: X \simeq Y$. Two objects X and Y are said to be **isomorphic** if there is an isomorphism $X \rightarrow Y$, and then we write $X \cong Y$. The composite of

isomorphisms is again an isomorphism. In particular, an isomorphism $X \rightarrow X$ is an invertible element of the semigroup $\text{Hom}(X, X)$, and is called an **automorphism** of X . Examples of isomorphisms are bijections in (Sets), group isomorphisms in (Gr), the R -isomorphisms in $R\mathcal{M}$, ring isomorphisms in the category of rings, \dagger diffeomorphisms in the category of differentiable manifolds, and homeomorphisms in (Top).

A morphism $f: X \rightarrow Y$ is called a **monomorphism** (or **injection**) if for any object Z and for any morphisms $u, v: Z \rightarrow X (u \neq v)$ we have $f \circ u \neq f \circ v$. Dually, $f: X \rightarrow Y$ is called an **epimorphism** (or **surjection**) if for any $u, v: Y \rightarrow Z (u \neq v)$ we have $u \circ f \neq v \circ f$. In the category of sets the monomorphisms and the epimorphisms coincide, respectively, with the injections and the surjections as mappings (\rightarrow 381 Sets). A monomorphism which is at the same time an epimorphism is called a **bijection**. An isomorphism is always a bijection, but the converse is false in some categories.

Two monomorphisms $f_1: X_1 \rightarrow X$ and $f_2: X_2 \rightarrow X$ (with the same X) are said to be equivalent if there exist $g_1: X_1 \rightarrow X_2$ and $g_2: X_2 \rightarrow X_1$ such that $f_1 = f_2 \circ g_1$ and $f_2 = f_1 \circ g_2$ (Fig. 3). An equivalence class with respect to this equivalence relation is called a **subobject** of X . Similarly, we define a **quotient object** of X as an equivalence class of epimorphisms $X \rightarrow X_i$.

Fig. 3

An object e of a category \mathcal{C} is called a **final object** of \mathcal{C} if for every object Y of \mathcal{C} , $\text{Hom}(Y, e)$ contains one and only one element. Dually, an object e' is called an **initial object** (or **cofinal object**) if $\text{Hom}(e', Y)$ contains one and only one element for every $Y \in \mathcal{C}$. If e_1 and e_2 are final objects, then there is a unique isomorphism $e_1 \simeq e_2$, and similarly for initial objects. A set with only one element is the final object in (Sets), and a space with only one point is the final object in (Top). In the category (Gr) (resp. (Ab)), the trivial group $\{1\}$ (or $\{0\}$) is the final object and the initial object at the same time. In the category of commutative rings, the zero ring $\{0\}$ is the final object and the ring of rational integers \mathbf{Z} is the initial object.

E. Product and Coproduct

Let X_1 and X_2 be objects of a category \mathcal{C} . We say that a triple (P, p_1, p_2) consisting of an

object P and morphisms $p_i: P \rightarrow X_i (i = 1, 2)$ is the **product** (or **direct product**) of X_1 and X_2 if for any pair of morphisms $f_i: X \rightarrow X_i (i = 1, 2)$, there exists a unique morphism $f: X \rightarrow P$ with $p_i \circ f = f_i (i = 1, 2)$ (Fig. 4). If (P', p'_1, p'_2) is another product of X_1 and X_2 , then by virtue of this definition there is a unique morphism $f: P \rightarrow P'$ such that $p'_i \circ f = p_i (i = 1, 2)$, and f is an isomorphism. The product is unique in this sense. The product (or any one of the products) of X_1 and X_2 is denoted by $X_1 \times X_2$ or by $X_1 \amalg X_2$.

Fig. 4

The product in the categories of sets, of groups, of rings, and of topological spaces coincides with the notion of \dagger direct product in the respective systems. In a general category, the product does not always exist. Suppose the product $X \times X$ exists for an object X ; then there is a unique morphism $\Delta_X: X \rightarrow X \times X$ such that $1_X = p_1 \circ \Delta_X = p_2 \circ \Delta_X$, which is called the **diagonal morphism** of X . Let $f_i: X \rightarrow X'_i (i = 1, 2)$ be morphisms and assume that the products $(X_1 \times X_2, p_1, p_2)$, $(X'_1 \times X'_2, p'_1, p'_2)$ exist. Then there is a unique morphism $f: X_1 \times X_2 \rightarrow X'_1 \times X'_2$ satisfying $p'_i \circ f = f_i \circ p_i (i = 1, 2)$. This f is denoted by $f_1 \times f_2$. On the other hand, if $g_i: X \rightarrow X_i (i = 1, 2)$ are given, the unique morphism $g: X \rightarrow X_1 \times X_2$ with $p_i \circ g = g_i (i = 1, 2)$ is denoted by (g_1, g_2) . We have $(g_1, g_2) = (g_1 \times g_2) \circ \Delta_X$ if $X \times X$ exists.

The dual notion of product is coproduct. We say that a triple (S, j_1, j_2) of an object S and morphisms $j_i: X_i \rightarrow S (i = 1, 2)$ is the **coproduct** (or **direct sum**) of X_1 and X_2 if for any morphisms $f_i: X_i \rightarrow X (i = 1, 2)$ there exists a unique morphism $f: S \rightarrow X$ with $f \circ j_i = f_i (i = 1, 2)$ (Fig. 5). The coproduct, like the product, is uniquely determined up to canonical isomorphisms. It is denoted by $X_1 + X_2$ or by $X_1 \amalg X_2$. The coproduct in (Gr) is the \dagger free product. In (Ab), or more generally in $R\mathcal{M}$, the product of two objects can be identified with the coproduct (= direct sum) (\rightarrow 277 Modules F). The coproduct in the category of commutative rings is the \dagger tensor product over \mathbf{Z} .

Fig. 5

Product and coproduct can also be defined for a family $\{X_i\}_{i \in I}$ of objects. Namely, the

product of $\{X_i\}_{i \in I}$ is an object P together with a family of morphisms $p_i: P \rightarrow X_i$ ($i \in I$) having the property that for any family of morphisms $f_i: X \rightarrow X_i$ ($i \in I$), there exists a unique morphism $f: X \rightarrow P$ such that $p_i \circ f = f_i$ ($i \in I$). The product is unique up to canonical isomorphisms, and similarly for the coproduct (\rightarrow Sections F, L).

F. Dual Category

In the theory of categories we often encounter the dual treatment of notions and propositions. To be precise, we may define the notion of the **dual category** \mathcal{C}° of a category \mathcal{C} as follows: The objects of \mathcal{C}° are those of \mathcal{C} , i.e., $\text{Ob}(\mathcal{C}^\circ) = \text{Ob}(\mathcal{C})$; for any objects X and Y we put $\text{Hom}_{\mathcal{C}^\circ}(X, Y) = \text{Hom}_{\mathcal{C}}(Y, X)$; if $f: X \rightarrow Y$ and $g: Y \rightarrow Z$ in \mathcal{C}° (i.e., $f: Y \rightarrow X$ and $g: Z \rightarrow Y$ in \mathcal{C}), then the composite $g \circ f$ in \mathcal{C}° is defined to be $f \circ g$ in \mathcal{C} . It is clear that \mathcal{C}° then satisfies the axioms of a category. Quite generally, given a proposition concerning objects and morphisms we can construct another proposition by reversing the directions of the morphisms, and we call the latter the dual proposition of the former. The dual proposition of a proposition in \mathcal{C} coincides with a proposition in \mathcal{C}° . For instance, a monomorphism (epimorphism) in \mathcal{C} is an epimorphism (monomorphism) in \mathcal{C}° , and the final (initial) object in \mathcal{C} is the initial (final) object in \mathcal{C}° . The product (coproduct) in \mathcal{C} is the coproduct (product) in \mathcal{C}° . Although the notion of the dual category is defined quite formally, it is useful in describing relations between specific categories. The dual category of (Ab) , for instance, is equivalent to the category of commutative compact topological groups ('Pontryagin's duality theorem').

G. Categories over an Object

Fix a category \mathcal{C} and an object $S \in \mathcal{C}$. A pair (X, f) of an object $X \in \mathcal{C}$ and a morphism $f: X \rightarrow S$ is called an object over S or an **S -object**, and f is called its **structure morphism**. We often omit f and simply say "an S -object X " if there is no danger of misunderstanding. If (X, f) and (Y, g) are S -objects, a morphism $h: X \rightarrow Y$ such that $f = g \circ h$ is called an **S -morphism** from (X, f) to (Y, g) . The category whose objects are the S -objects and whose morphisms are the S -morphisms is called the **category of S -objects** in \mathcal{C} , and is denoted by \mathcal{C}/S . It has $(S, 1_S)$ as the final object. The product of two S -objects X and Y , taken in \mathcal{C}/S , is called the **fiber product** of X and Y over S (in \mathcal{C}), and is denoted by $X \times_S Y$ or $X \amalg_S Y$. The dual notion of the fiber product is called **fiber sum** (or **amalgamated sum**). Thus for two

morphisms $f: S \rightarrow X$ and $g: S \rightarrow Y$, the fiber product of X and Y over S in \mathcal{C}°/S is the fiber sum of X and Y (with respect to S); it is denoted by $X \amalg_S Y$.

Let \mathcal{C} be the category of commutative rings and $K \in \mathcal{C}$. Then the family of K -objects in \mathcal{C}° is precisely the family of commutative K -algebras. The fiber product $A \times_K B$ in \mathcal{C}° , i.e., $A \amalg_K B$ in \mathcal{C} , is the tensor product $A \otimes_K B$ of algebras.

H. Functors

Let \mathcal{C} and \mathcal{C}' be categories. A **covariant functor** F from \mathcal{C} to \mathcal{C}' is a rule which associates (1) with each object X in \mathcal{C} , an object $F(X)$ in \mathcal{C}' , and (2) with each morphism $f: X \rightarrow Y$ in \mathcal{C} , a morphism $F(f): F(X) \rightarrow F(Y)$ such that $F(g \circ f) = F(g) \circ F(f)$, $F(1_X) = 1_{F(X)}$. A **contravariant functor** is defined dually, by modifying this definition to $F(f): F(Y) \rightarrow F(X)$, $F(g \circ f) = F(f) \circ F(g)$. Thus a contravariant functor from \mathcal{C} to \mathcal{C}' is the same as a covariant functor from the dual category \mathcal{C}° to \mathcal{C}' (or from \mathcal{C} to \mathcal{C}'°). **Functor** is a general term for both covariant functors and contravariant functors, but some authors use the word exclusively in the sense of a covariant functor. A functor in several variables is defined to be a functor from the product category of the categories in which the variables take their values.

A covariant functor $F: \mathcal{C} \rightarrow \mathcal{C}'$ is said to be **faithful (fully faithful)** if for any $X, Y \in \mathcal{C}$, the mapping $\text{Hom}(X, Y) \rightarrow \text{Hom}(F(X), F(Y))$ induced by F is injective (bijective), and similarly for contravariant functors. A faithful covariant functor $F: \mathcal{C} \rightarrow \mathcal{C}'$ which maps distinct objects of \mathcal{C} to distinct objects of \mathcal{C}' is called an **embedding**, and in this case \mathcal{C} can be identified with a subcategory of \mathcal{C}' by F . A fully faithful covariant functor $F: \mathcal{C} \rightarrow \mathcal{C}'$ is called an **equivalence** (between the categories) if it satisfies the condition that for any object X' of \mathcal{C}' , there exists an object X of \mathcal{C} such that $F(X) \cong X'$. In this case we can consider the two categories essentially the same. A contravariant functor from \mathcal{C} to \mathcal{C}' which defines an equivalence from \mathcal{C}° to \mathcal{C}' is called an **antiequivalence**.

I. Examples of Functors

(1) Let \mathcal{C} be the category of groups (or rings). For any $X \in \mathcal{C}$ let $F(X)$ be the underlying set of X (i.e., the set obtained from X by "forgetting" its structure as a group or ring), and for any homomorphism f put $F(f) = f$. Then we get a faithful covariant functor (often called the **forgetful functor**) $F: \mathcal{C} \rightarrow (\text{Sets})$.

(2) Let \mathcal{C} be any category and fix an object X of \mathcal{C} . Then we get a covariant functor $h_X: \mathcal{C} \rightarrow (\text{Sets})$ as follows: With each $Y \in \mathcal{C}$ we associate the set $\text{Hom}(X, Y)$, and with each morphism $f: Y \rightarrow Y'$ in \mathcal{C} the mapping $f \circ$ (where $f \circ: \text{Hom}(X, Y) \rightarrow \text{Hom}(X, Y')$ is defined by $(f \circ)(g) = f \circ g$). Similarly we define a contravariant functor $h^X: \mathcal{C} \rightarrow (\text{Sets})$ by $h^X(Y) = \text{Hom}(Y, X)$ and $h^X(f) = \circ f$.

(3) Let $\rho: A \rightarrow B$ be a homomorphism of rings. With each left A -module M associate the \dagger scalar extension $\rho^*(M) = B \otimes_A M$, and with each A -homomorphism f associate the B -homomorphism $\rho^*(f) = 1_B \otimes f$. Then we get a covariant functor $\rho^*: {}_A\mathcal{M} \rightarrow {}_B\mathcal{M}$.

(4) Let R be a ring. With each left R -module M associate its dual module $M^* = \text{Hom}_R(M, R)$, and to each R -linear mapping f associate its \dagger dual mapping $f^* = \circ f$. Then we get a contravariant functor ${}_R\mathcal{M} \rightarrow {}_R\mathcal{M}$, and similarly for ${}_R\mathcal{M} \rightarrow {}_R\mathcal{M}$.

(5) For each differentiable manifold X let $F(X)$ denote the commutative ring of the differentiable functions on X , and for each differentiable mapping $f: X \rightarrow Y$ let $F(f)$ be the ring homomorphism $\circ f: F(Y) \rightarrow F(X)$. Then F is a faithful contravariant functor.

(6) Fix an Abelian group A . By associating with each topological space X the cohomology group $H(X, A)$ and with each continuous mapping $f: X \rightarrow Y$ the homomorphism $H(Y, A) \rightarrow H(X, A)$ induced by f , we obtain a contravariant functor from (Top) to (Ab) .

(7) Fix a topological space X , and let $T(X)$ be the set of the open sets in X . Then $T(X)$ is ordered by inclusion, so it is a category (\rightarrow Section B, no. 7). The contravariant functors from $T(X)$ to (Ab) are precisely the \dagger pre-sheaves of Abelian groups over X . We can use any category instead of (Ab) to define a pre-sheaf over X (\rightarrow 383 Sheaves).

J. Natural Transformations

Let \mathcal{C} and \mathcal{C}' be categories, and denote by $\text{Hom}(\mathcal{C}, \mathcal{C}')$ the collection of all covariant functors $\mathcal{C} \rightarrow \mathcal{C}'$. Let $F, G \in \text{Hom}(\mathcal{C}, \mathcal{C}')$. A **natural transformation** (or **functorial morphism**) from F to G is a function which assigns to each object X of \mathcal{C} a morphism $\varphi(X): F(X) \rightarrow G(X)$ in \mathcal{C}' such that for any morphism $f: X \rightarrow Y$ in \mathcal{C} , the equation $G(f) \circ \varphi(X) = \varphi(Y) \circ F(f)$ holds; in other words, the accompanying diagram is commutative:

$$\begin{array}{ccccc} X & & F(X) & \xrightarrow{\varphi(X)} & G(X) \\ f \downarrow & F(f) \downarrow & & & \downarrow G(f) \\ Y & & F(Y) & \xrightarrow{\varphi(Y)} & G(Y) \end{array}$$

A natural transformation between contravariant functors is defined similarly. For instance, let A and B be Abelian groups and let $H^i(\cdot, A)$ and $H^i(\cdot, B)$ be the contravariant functors of \dagger cohomology viewed as functors $(\text{Top}) \rightarrow (\text{Sets})$. Then the natural transformations between them are the \dagger cohomology operations.

Let $\varphi: F \rightarrow G$ be a natural transformation, and suppose that $\varphi(X): F(X) \rightarrow G(X)$ is an isomorphism for every $X \in \mathcal{C}$. Then the inverse transformation $G \rightarrow F$ of φ exists, and φ is called a **natural equivalence** (**functorial isomorphism** or **isomorphism**) and is written $\varphi: F \simeq G$.

Suppose that $\text{Ob}(\mathcal{C})$ is a set. Then the collection $\text{Hom}(F, G)$ of all natural transformations $F \rightarrow G$ is also a set, and hence we can consider $\text{Hom}(\mathcal{C}, \mathcal{C}')$ a category in which the objects are the covariant functors $\mathcal{C} \rightarrow \mathcal{C}'$, the morphisms are the natural transformations, and the composition of morphisms is the natural one. Then $\text{Hom}(\mathcal{C}^\circ, \mathcal{C}')$ is the category of contravariant functors from \mathcal{C} to \mathcal{C}' . In particular, the category $\text{Hom}(\mathcal{C}^\circ, (\text{Sets}))$ is sometimes denoted by \mathcal{C} .

Given a category \mathcal{C} , a covariant (resp. contravariant) functor $F: \mathcal{C} \rightarrow (\text{Sets})$, and an object $X \in \mathcal{C}$, we can define a canonical bijection $\Phi_X: \text{Hom}(h_X, F) \simeq F(X)$ (resp. $\text{Hom}(h^X, F) \simeq F(X)$) by $\Phi_X(\varphi) = \varphi(X)1_X$. (The functors h_X and h^X were defined in Section I.) The inverse mapping of Φ_X assigns to $\xi \in F(X)$ the natural transformation $\varphi: h_X \rightarrow F$ defined by $\varphi(Y)u = F(u)\xi$ ($Y \in \mathcal{C}$). In particular, if we take $F = h_Y(h^Y)$, we obtain a canonical bijection $\text{Hom}(h_X, h_Y) \simeq \text{Hom}(Y, X)$ ($\text{Hom}(h^X, h^Y) \simeq \text{Hom}(X, Y)$). It follows that there is a fully faithful contravariant (covariant) functor $\mathcal{C} \rightarrow \text{Hom}(\mathcal{C}, (\text{Sets}))$ ($\mathcal{C} \rightarrow \text{Hom}(\mathcal{C}^\circ, (\text{Sets})) = \mathcal{C}$) which associates $h_X(h^X)$ with $X \in \mathcal{C}$.

K. Adjoint Functors

Let $F: \mathcal{C} \rightarrow \mathcal{C}'$ and $F': \mathcal{C}' \rightarrow \mathcal{C}$ be covariant functors. Suppose that there is a rule which assigns to each pair of objects $M \in \mathcal{C}$ and $M' \in \mathcal{C}'$ a bijective mapping $\theta_{M, M'}: \text{Hom}_{\mathcal{C}}(M, F'(M')) \simeq \text{Hom}_{\mathcal{C}'}(F(M), M')$ such that for any pair of morphisms $N \rightarrow M$ in \mathcal{C} and $M' \rightarrow N'$ in \mathcal{C}' , the following diagram induced by the morphisms is commutative:

$$\begin{array}{ccc} \text{Hom}_{\mathcal{C}}(M, F'(M')) & \xrightarrow{\theta_{M, M'}} & \text{Hom}_{\mathcal{C}'}(F(M), M') \\ \downarrow & & \downarrow \\ \text{Hom}_{\mathcal{C}}(N, F'(N')) & \xrightarrow{\theta_{N, N'}} & \text{Hom}_{\mathcal{C}'}(F(N), N') \end{array}$$

Then we say that F is a **left adjoint functor** of F' and that F' is a **right adjoint functor** of F . We can regard $\text{Hom}_{\mathcal{C}'}(F(M), M')$ as a functor from $\mathcal{C} \times \mathcal{C}'$ (contravariant in the variable

$M \in \mathcal{C}$, covariant in the variable $M' \in \mathcal{C}'$) to the category of sets, and similarly for $\text{Hom}_{\mathcal{C}}(M, F(M'))$. This commutativity of the diagram means that these two functors are isomorphic (\rightarrow Section J).

For instance, let A and B be rings and L a fixed B - A -bimodule. Let $F: {}_A\mathcal{M} \rightarrow {}_B\mathcal{M}$ and $F': {}_B\mathcal{M} \rightarrow {}_A\mathcal{M}$ be the functors defined by

$$F(M) = L \otimes_A M, \quad F'(M') = \text{Hom}_B(L, M'),$$

where the assignment for morphisms is defined in the natural way. Then F is the left adjoint of F' and F' is the right adjoint of F . In particular, let $\rho: A \rightarrow B$ be a homomorphism and consider the case $L = B$. Then F is the functor $\rho^*: {}_A\mathcal{M} \rightarrow {}_B\mathcal{M}$ and F' is the functor $\rho_*: {}_B\mathcal{M} \rightarrow {}_A\mathcal{M}$, so that ρ^* is the left adjoint of ρ_* (and ρ_* is the right adjoint of ρ^*) (\rightarrow 277 Modules, K, L; for more examples of adjoint functors \rightarrow [11]).

L. Representation of Functors

We begin by discussing an example. Let T be a set, and consider the following problem: Is it possible to find a group X and a mapping $\xi: T \rightarrow X$ such that, for any group Y and for any mapping $\eta: T \rightarrow Y$, there exists a unique homomorphism $u: X \rightarrow Y$ with $u \circ \xi = \eta$? The answer is yes; it is enough to take the free group X generated by T and the canonical injection $\xi: T \rightarrow X$ (Fig. 6). On the other hand, let $F(Y)$ be the set of all mappings $T \rightarrow Y$, and for each group homomorphism $f: Y \rightarrow Y'$ define the mapping $F(f): F(Y) \rightarrow F(Y')$ by $F(f)\eta = f \circ \eta$ ($\eta \in F(Y)$). Then we get a covariant functor from the category \mathcal{C} of groups to the category of sets, $F: \mathcal{C} \rightarrow (\text{Sets})$. We can now reformulate the condition on $X \in \mathcal{C}$ and $\xi \in F(X)$ as follows:

For any $Y \in \mathcal{C}$ and for any $\eta \in F(Y)$, there exists a unique homomorphism $u: X \rightarrow Y$ such that $F(u)\xi = \eta$.

Fig. 6

Proceeding to the general case, let \mathcal{C} be an arbitrary category and let $F: \mathcal{C} \rightarrow (\text{Sets})$ be a functor. If there exist an object X of \mathcal{C} and an element ξ of $F(X)$ satisfying the condition just stated (with the modification $u: Y \rightarrow X$ in the contravariant case), then we say that the pair (X, ξ) **represents** the functor F , or less specifically, that X represents F , and we call ξ the **canonical element** of $F(X)$. We also say that F is **representable**. The condition stated above is a formulation of the so-called **universal map-**

ping property. If (X', ξ') also represents F , the unique morphism $u: X \rightarrow X'$ (or $X' \rightarrow X$) with $F(u)\xi = \xi'$ is necessarily an isomorphism.

When (X, ξ) represents F , the natural transformation $\varphi: h_X \rightarrow F$ ($h_X \rightarrow F$ in the contravariant case) which corresponds to ξ by the canonical bijection $\Phi_X: \text{Hom}(h_X, F) \xrightarrow{\sim} F(X)$ is an isomorphism. Conversely, if there is a functorial isomorphism $\varphi: h_X \rightarrow F$ (or $h^X \rightarrow F$) for some $X \in \mathcal{C}$, then the object X represents F , with the canonical element of $F(X)$ the element which corresponds to φ by the canonical bijection Φ_X , i.e., $\xi = \varphi(X)1_X$.

We have already seen the example of a free group; here we list a few more examples. (1) Let $\{X_i\}_{i \in I}$ be a family of objects in a category \mathcal{C} . For each $Y \in \mathcal{C}$ we put $F(Y) = \prod_{i \in I} \text{Hom}(Y, X_i)$, and for each morphism $f: Y \rightarrow Y'$ we define the mapping $F(f): F(Y') \rightarrow F(Y)$ by $F(f)(f_i) = (f_i \circ f)$. Then we get a contravariant functor $F: \mathcal{C} \rightarrow (\text{Sets})$. A pair (X, ξ) which represents F (where $\xi \in F(X) = \prod_{i \in I} \text{Hom}(X, X_i)$) is the product of $\{X_i\}$. Thus representability of F is equivalent to the existence of the product of $\{X_i\}$, and similarly for the coproduct.

(2) Let R be a ring, M a right R -module, and N a left R -module. For each Abelian group Y let $F(Y)$ denote the set of the R -balanced mappings $M \times N \rightarrow Y$ (\rightarrow 277 Modules J). Since a homomorphism $f: Y \rightarrow Y'$ induces a natural mapping $F(f): F(Y) \rightarrow F(Y')$ by composition, we obtain a covariant functor $F: (\text{Ab}) \rightarrow (\text{Sets})$. This functor is representable: the pair consisting of the tensor product $M \otimes_R N$ and the canonical mapping $M \times N \rightarrow M \otimes_R N$ represents it.

(3) Let R be a commutative ring and S a subset of R . For each commutative ring Y , let $F(Y)$ denote the set of homomorphisms $R \rightarrow Y$ that map the elements of S to invertible elements of Y . As in the preceding example, we obtain a covariant functor $F: (\text{Rings}) \rightarrow (\text{Sets})$. This functor is represented by the ring of quotients $S^{-1}R$ and the canonical homomorphism $R \rightarrow S^{-1}R$.

M. Groups in a Category

Let \mathcal{C} be a category with a final object e , and assume that a finite product always exists in \mathcal{C} . If an object $G \in \mathcal{C}$ and morphisms $\alpha: G \times G \rightarrow G$, $\beta: G \rightarrow G$, $\varepsilon: e \rightarrow G$ are given such that the diagrams of Fig. 7 are commutative, then $(G, \alpha, \beta, \varepsilon)$ is called a **group in \mathcal{C}** (**group object** in \mathcal{C} or \mathcal{C} -**group**).

If \mathcal{C} is the category of sets, then α defines a law of composition in the set G , and the image of e by ε is the identity element and $\beta(x)$ is the inverse of x , so that G is an ordinary group. If \mathcal{C} is the category of topological spaces (analy-

tic manifolds, algebraic varieties, ^{*}schemes) then G is a ^{*}topological group (^{*}Lie group, ^{*}algebraic group, ^{*}group scheme).

We can also define the \mathcal{C} -group by lifting the group concept in (Sets) to the category \mathcal{C} by means of the functor h^X . Namely, let G be an object of \mathcal{C} , and suppose that for each $Y \in \mathcal{C}$ the set $h^G(Y) = \text{Hom}(Y, G)$ is equipped with a group structure and that for each morphism $f: Y \rightarrow Y'$ the induced mapping $h^G(Y') \rightarrow h^G(Y)$ is a group homomorphism. In other words, suppose that h^G is a contravariant functor from \mathcal{C} to the category of groups. Then the object G with the additional structure on h^G is called a \mathcal{C} -group. This definition is equivalent to the one given above.

$$\begin{array}{ccc} G \times G \times G & \xrightarrow{\alpha \times 1_G} & G \times G \\ \downarrow 1_G \times \alpha & & \downarrow \alpha \\ G \times G & \xrightarrow{\alpha} & G \end{array}$$

$$\begin{array}{ccc} G \times G & \xrightarrow{1_G \times \epsilon} & G \times G \\ \downarrow p_1 & \swarrow \alpha & \downarrow \alpha \\ G & & G \end{array} \quad \begin{array}{ccc} G & \xrightarrow{(1_G, \beta)} & G \times G \\ \downarrow e & & \downarrow \alpha \\ G & \xrightarrow{\epsilon} & G \end{array}$$

Fig. 7

N. Additive Categories

A category \mathcal{C} is called an **additive category** if for each pair $X, Y \in \mathcal{C}$, the set of morphisms $\text{Hom}(X, Y)$ has the structure of an additive group such that (1) the composition of morphisms is distributive in both ways: $h \circ (f + g) = h \circ f + h \circ g$, $(f + g) \circ h = f \circ h + g \circ h$; (2) there exists an object $0'$ with $\text{Hom}(0', 0') = \{0\}$; (3) the product (or the coproduct) of any two objects exists. Then the object $0'$ in (2) is a final and initial object, and is called the **zero object**. Both the product and the coproduct of any two objects exist and can be identified. The dual category of an additive category is also an additive category. A functor F from an additive category to another is called an **additive functor** if $F(f + g) = F(f) + F(g)$ holds for morphisms. In an additive category \mathcal{C} , $\text{Hom}(X, Y)$ is an additive functor from \mathcal{C} to (Ab) in each variable.

For any ring R , the category of left (or right) R -modules is an additive category. The following definitions are generalizations of the corresponding concepts in the theory of modules. The **kernel** of a morphism $f: A \rightarrow B$ is a pair consisting of an object A' and a monomorphism $i: A' \rightarrow A$ with $f \circ i = 0$, such that any morphism $u: X \rightarrow A$ with $f \circ u = 0$ is divisible by i (that is, $u = i \circ v$ for some $v: X \rightarrow A'$). Dually, the **cokernel** of f is a pair consisting of an object B' and an epimorphism $j: B \rightarrow B'$ with $j \circ f = 0$ which divides any morphism $u: B \rightarrow X$ with $u \circ f = 0$. We write $A' = \text{Ker } f$, $B' =$

$\text{Coker } f$. The kernel of $j: B \rightarrow \text{Coker } f$ is called the **image** of f and is denoted by $\text{Im } f$; the cokernel of $i: \text{Ker } f \rightarrow A$ is called the **coimage** of f and is denoted by $\text{Coim } f$. If all these exist, it follows from the definitions that there is a unique morphism $\text{Coim } f \rightarrow \text{Im } f$ such that the composite of $A \rightarrow \text{Coim } f \rightarrow \text{Im } f \rightarrow B$ is equal to f .

An additive category \mathcal{C} is called an **Abelian category** if it satisfies the following conditions: (1) every morphism has a kernel and a cokernel, (2) for every morphism f , the morphism $\text{Coim } f \rightarrow \text{Im } f$ just mentioned is an isomorphism. The dual category of an Abelian category is also Abelian. The categories of Abelian groups, of R -modules, and of sheaves of \mathcal{O} -modules on a ^{*}ringed space (X, \mathcal{O}) are important examples of Abelian categories. Many propositions which are valid in (Ab) remain valid in any Abelian category. In particular, the notion of an ^{*}exact sequence is defined in an Abelian category in the same way as in (Ab), and the fiber product and fiber sum of a finite number of objects always exist in an Abelian category. A functor between Abelian categories which carries exact sequences into exact sequences is called an **exact functor**; (such a functor is automatically additive). If \mathcal{C} is a category of which $\text{Ob}(\mathcal{C})$ is a set and if \mathcal{C}' is an Abelian category, then $\text{Hom}(\mathcal{C}, \mathcal{C}')$ is an Abelian category. Given an Abelian category \mathcal{C} and a subcategory \mathcal{C}' which satisfies certain conditions, one can construct an Abelian category \mathcal{C}/\mathcal{C}' which is called the **quotient category** (Serre's theory of classes of Abelian groups; → [8]).

If \mathcal{C} is an Abelian category of which $\text{Ob}(\mathcal{C})$ is a set, there is an embedding of \mathcal{C} into the category ${}_R\mathcal{M}$ of modules over some ring R by a fully faithful flat exact covariant functor (**full embedding theorem**, B. Mitchell, *Amer. J. Math.*, 86 (1964)). This remarkable theorem enables us to extend results obtained for modules to the case of Abelian categories.

The notions of category and functor were introduced in [7] and were applied first in topology and then in homological algebra and algebraic geometry (→ 200 Homological Algebra).

53 (XXI.17) Cauchy, Augustin Louis

The French mathematician Augustin Louis Cauchy (August 21, 1789–May 25, 1857) graduated from the Ecole Polytechnique in 1807 and from the Ecole des Ponts et Chaussées in 1810, to become a civil engineer. In 1816, his mathematical works were recognized, and he was appointed a member of the Académie des Sciences while a professor at the Ecole Polytechnique. After the July revolution in 1830, he refused to pledge loyalty to Louis-Philippe and fled to Turin; he later moved to Prague. He returned to France after the revolution of 1848 and became a professor at the University of Paris, where he remained until his death. He was a Catholic and a Royalist all his life.

His scientific contributions were numerous and covered many fields. In algebra, he did pioneering work in \dagger determinants and in the theory of \dagger groups. He also made notable achievements in theoretical physics, optics, and the theory of elasticity. His main field was analysis. He was interested in making analysis rigorous by giving calculus a solid foundation in such works as *Cours d'analyse de l'Ecole Polytechnique* (1821). In his paper “Memoire sur les intégrales définies prises entre les limites imaginaires” (1825), he proved the main theorem of the theory of functions of a complex variable. Another important work is his proof of the existence theorem for the solutions of \dagger differential equations in the cases of real and complex variables

54 (III.21) Cayley Algebras

Let Q be a \dagger quaternion algebra over a field K of characteristic zero. A **general Cayley algebra** \mathcal{C} is a 2-dimensional Q - \dagger module $Q + Qe$ with the multiplication $(q + re)(s + te) = (qs + \gamma \bar{t}r) + (tq + r\bar{s})e$, where $q, r, s, t \in Q$, γ is a given element in K , and \bar{t}, \bar{s} are the \dagger conjugate quaternions of t, s , respectively. The elements of \mathcal{C} are called **Cayley numbers**; \mathcal{C} is a nonassociative, \dagger alternative algebra of dimension 8 over K (\rightarrow 231 Jordan Algebras). The map $a = q + re \rightarrow \bar{a} = \bar{q} - re$ is an \dagger antiautomorphism of \mathcal{C} . Define two maps $\mathcal{C} \rightarrow K$ by $N(a) = a\bar{a} = \bar{a}a$ (**norm** of a) and $T(a) = a + \bar{a}$ (**trace** of a). Then every a in \mathcal{C} satisfies the equation $x^2 - T(a)x + N(a) = 0$. Furthermore, $N(ab) = N(a)N(b)$ for a, b in \mathcal{C} . The \dagger quadratic form $N(x) = T(x\bar{x})/2$ characterizes \mathcal{C} . In particular, any two (non-associative) general Cayley algebras over the same field K which are not \dagger alternative fields are isomorphic.

In order for \mathcal{C} to be an alternative field, either of the following two conditions is necessary and sufficient: (i) $N(a) = 0$ implies $a = 0$; (ii) Q is a noncommutative division algebra and γ cannot be expressed in the form $\sigma^2 - \lambda\xi^2 - \mu\eta^2 + \lambda\mu\zeta^2$ ($\sigma, \xi, \eta, \zeta \in K$). (For the meaning of λ, μ with respect to $Q \rightarrow$ 29 Associative Algebras D.) Every alternative field of finite dimension is a general Cayley algebra.

In particular, when Q is the \dagger quaternion field over the real number field with $\lambda = \mu = -1$, the general Cayley algebra over Q with $\gamma = -1$ is called the **Cayley algebra**. When K is an \dagger algebraic number field of finite degree, there are only a finite number of nonisomorphic general Cayley algebras over K .

The Lie algebra $\mathfrak{D}(\mathcal{C})$ of all \dagger derivations of a general Cayley algebra \mathcal{C} is a \dagger simple Lie algebra of type G_2 . If K is the real number field, the identity component of the group of all \dagger automorphisms of the Cayley algebra \mathcal{C} is a compact simply connected \dagger simple Lie group of type G_2 . The Cayley algebra \mathcal{C} is the unique alternative field over the real number field K . This last fact is important because of the following proposition: In the theory of \dagger non-

Desarguesian projective planes, the field which gives rise to the coordinates is an alternative field. Let \mathcal{P}_2 be the set of all 3×3 [†]Hermitian matrices A over the Cayley algebra \mathcal{C} such that $\text{tr } A = 1$, $A^2 = A$. Then we can define a structure of a projective plane on \mathcal{P}_2 , which with this structure is called the **Cayley projective plane**. Furthermore, let \mathfrak{J} be the set of all 3×3 [†]Hermitian matrices over \mathcal{C} , with a multiplication in \mathfrak{J} defined by $A \cdot B = (1/2)(BA + AB)$. The identity component G of the group of all automorphisms of \mathfrak{J} is a compact simply connected simple Lie group of type F_4 . This group G acts on \mathcal{P}_2 transitively, and $\mathcal{P}_2 = G/\text{Spin}(9)$ (\rightarrow 249 Lie Groups; Appendix A, Table 5.III).

55 (XX.6) Celestial Mechanics

A. General Remarks

The motions of planets, comets, the moon, and satellites in our solar system are the main topics in **celestial mechanics** (\rightarrow 392 Spherical Astronomy). However, studies in this subject can also include motions of fixed and binary stars in our galaxy, equilibrium figures of celestial bodies, and rotational motions of the earth and the moon.

Celestial mechanics is usually based on [†]Newtonian mechanics, with the effects of [†]general relativity sometimes taken into account to determine corrections to the orbits of celestial bodies. Therefore the main task of celestial mechanics is to solve differential equations of motion based on Newtonian mechanics. However, since the equations for the problem of $n > 2$ bodies cannot be solved rigorously (\rightarrow 420 Three-Body Problem), appropriate methods have been devised where by we may obtain approximate solutions of the equations with accuracy comparable to that of observations.

The **two-body problem**, which concerns the behavior of two celestial bodies regarded as

points exerting mutual interactions, can be reduced to a one-body problem with reference to a central force, since integrals of motion of the center of gravity for the system exist. The [†]Hamilton-Jacobi equation for the one-body problem is of [†]separable type and can be solved completely. The orbit for the two-body problem is a [†]conic with one of its [†]foci at the center of gravity. The majority of celestial bodies in the solar system actually perform **elliptic motions**. [†]Kepler's orbital elements for elliptic motion are functions of the integration constants in the solution of the Hamilton-Jacobi equation and are determined by the initial conditions.

B. Perturbations

In studying the [†] n -body problem, we first solve certain two-body problems and then apply the method of [†]perturbations, i.e., the **method of variation of constants**, in order to obtain solutions developed as [†]power series of small parameters. The parameters are ratios of the masses of planets to that of the sun for planetary motions and the ratio of the geocentric lunar distance to the solar distance for lunar motion.

Electronic computers have made it possible to compute planetary coordinates for long intervals of time by solving numerically differential equations of motion including all possible interactions. However, in discussing the stability of the solar system, analytic methods are more effective, particularly the method of obtaining **secular perturbations** by eliminating short-periodic terms by canonical transformations. This is one of the averaging methods of solving differential equations.

However, as the solutions obtained by means of perturbation methods are not always convergent, most important problems related to the stability of motion have not yet been solved rigorously. Secular perturbations for planetary motions can be derived by solving differential equations that are linearized by neglecting cubic powers of orbital eccentricities and inclinations to the ecliptic (\rightarrow 309 Orbit Determination), which are small quantities. The [†]eigenvalues of these linear differential equations correspond to mean angular velocities of the perihelion and the ascending node. The equations for the eigenvalues are called **secular equations**.

C. Artificial Satellites

To discuss motions of artificial satellites close to the earth, the latter cannot be regarded as a

point or as a sphere but must be assumed to be an oblate spheroid, i.e., an ℓ ellipsoid of revolution. The effects of oblateness on the motion of satellites can be derived as perturbations of the theoretical elliptic motions obtained as the solutions of this two-body problem under the assumption that the earth is spherical. Also, by utilizing a special potential very close to the geopotential, we can find a Hamilton-Jacobi equation of separable type which is solvable. This special potential appears in the problem of two fixed centers with equal masses situated on an imaginary axis. When the geopotential is assumed to be axially symmetric, the equations of motion for the satellites have two degrees of freedom; therefore there appear two fundamental frequencies related to the special potential. When these two frequencies are equal, the problem is called a **critical inclination problem** and is important from the mathematical point of view. Theories for satellites can be applied to the motions of fixed stars in the galaxy.

D. Equilibrium Figures

There is a large literature concerning **equilibrium figures** and the stabilities of celestial bodies assumed to consist of spinning fluids. The two-body problem with tidal interactions is particularly important; problems concerning the evolution of the earth-moon system are special cases of such a problem.

The theory of rotation of the earth as it is affected by \dagger precession, \dagger nutation, and latitude variations is also a part of celestial mechanics; for this theory, elastic theory and geophysics are applied.

For the n -body problem \rightarrow 420 Three-Body Problem.

56 (IX.14) Characteristic Classes

A. General Remarks

The theory of characteristic classes arose from the problem of whether or not there exists a \dagger tangent r -frame field on a \dagger differentiable manifold (E. Stiefel [5]) (\rightarrow 105 Differentiable Manifolds). The importance of the characteristic class as a fundamental invariant of \dagger vector bundle structure is now fully recognized (\rightarrow 114 Differential Topology, 147 Fiber Bundles, 427 Topology of Lie Groups and Homogeneous Spaces).

B. Stiefel-Whitney Classes

Let $\xi = (E, B, \mathbf{R}^n)$ be an n -dimensional real \dagger vector bundle (called an \mathbf{R}^n -bundle) with \dagger paracompact Hausdorff \dagger base space B , fiber \mathbf{R}^n , and \dagger orthogonal group $O(n)$ as the \dagger structure group. Then the element $w_i(\xi)$ of the i -dimensional \dagger cohomology group $H^i(B; \mathbf{Z}_2)$ ($i = 1, 2, \dots, n$) of the base space B with coefficient in $\mathbf{Z}_2 = \mathbf{Z}/2\mathbf{Z}$, called the i -dimensional (or i th) **Stiefel-Whitney class**, and the element $w(\xi) = 1 + w_1(\xi) + \dots + w_n(\xi)$ of the \dagger cohomology ring $H^*(B; \mathbf{Z}_2)$, called the **total Stiefel-Whitney class**, are defined as follows. First, we deal with the case $n = 1$. We call the **infinite-dimensional real projective space** the \dagger inductive limit $\mathbf{P}^\infty(\mathbf{R}) = \varinjlim \mathbf{P}^n(\mathbf{R})$ of the finite-dimensional real \dagger projective space $\mathbf{P}^n(\mathbf{R})$. The nontrivial \dagger line bundle γ_1 over the infinite-dimensional real projective space $\mathbf{P}^\infty(\mathbf{R})$ is a universal \mathbf{R}^1 -bundle (\dagger universal bundle for the orthogonal group $O(1)$); therefore any \mathbf{R}^1 -bundle $\xi = (E, B, \mathbf{R}^1)$ is equivalent to an \dagger induced bundle from the universal bundle γ_1 by a \dagger classifying mapping $f_\xi: B \rightarrow \mathbf{P}^\infty(\mathbf{R})$: $\xi \equiv f_\xi^* \gamma_1$. We define the 1-dimensional universal Stiefel-Whitney class $w_1(\gamma_1)$ to be the generator of $H^1(\mathbf{P}^\infty(\mathbf{R}); \mathbf{Z}_2)$ and set $w_1(\xi) =$

$f_{\xi}^* w_1(\gamma_1)$. For general n , we consider the principal $O(n)$ -bundle $(P, B, O(n))$ \dagger associated with the given \mathbf{R}^n -bundle $\xi = (E, B, \mathbf{R}^n)$. Let Q_n be the subgroup of $O(n)$ consisting of all diagonal matrices. Then the orbit space $Y = P/Q_n$ is the base space of the \dagger principal Q_n -bundle $\eta = (P, P/Q_n, Q_n)$. Let $\rho: Y \rightarrow B = P/O(n)$ be the natural projection. Then the \mathbf{R}^n -bundle $\rho^* \xi$ over Y induced by ρ is associated with η and is equivalent to the \dagger Whitney sum of n line bundles (F. Hirzebruch [4]), $\rho^* \xi \equiv \xi_1 \oplus \dots \oplus \xi_n$. Moreover, the homomorphism $\rho^*: H^*(B; \mathbf{Z}_2) \rightarrow H^*(Y, \mathbf{Z}_2)$ is injective (A. Borel [1]). Therefore we can uniquely define the total Stiefel-Whitney class $w(\xi)$ of the \mathbf{R}^n -bundle by the relation $\rho^* w(\xi) = w(\xi_1) \dots w(\xi_n)$. The Stiefel-Whitney classes defined above are compatible with bundle mappings $f: w(f^* \xi) = f^* w(\xi)$ (\rightarrow 147 Fiber Bundles M). The Stiefel-Whitney class $w_i(\gamma_n) \in H^i(B_{O(n)}; \mathbf{Z}_2)$ ($1 \leq i \leq n$) of the universal \mathbf{R}^n -bundle γ_n over the \dagger classifying space $B_{O(n)}$ is called the i -dimensional **universal Stiefel-Whitney class**. For the Whitney sum of vector bundles, we have $w(\xi \oplus \eta) = w(\xi)w(\eta)$.

In order for an \mathbf{R}^n -bundle ξ to be \dagger orientable, namely, for ξ to have an $SO(n)$ -structure, it is necessary and sufficient that $w_1(\xi) = 0$. For an oriented \mathbf{R}^n -bundle ξ , the **Euler-Poincaré class** $X_n(\xi)$ is defined to be the \dagger primary obstruction $X_n(\xi) \in H^n(B; \mathbf{Z})$ for constructing a \dagger cross section of the \dagger associated $(n-1)$ -sphere bundle. In particular, the Euler-Poincaré class of the universal bundle for $SO(n)$ is called the **universal Euler-Poincaré class**. $X_n(\xi) \bmod 2$ is equal to $w_n(\xi)$. If n is odd, we have $2X_n(\xi) = 0$.

C. Chern Classes

We consider an n -dimensional complex vector bundle $\omega = (E, B, \mathbf{C}^n)$ (called \mathbf{C}^n -bundle in the following) with a paracompact Hausdorff base space B , fiber \mathbf{C}^n , and unitary group $U(n)$ as the structure group. The cohomology class $c_i(\omega) \in H^{2i}(B; \mathbf{Z})$ ($i = 1, 2, \dots, n$), called the $2i$ -dimensional (or i th) **Chern class**, and the **total Chern class** $c(\omega) = 1 + c_1(\omega) + \dots + c_n(\omega) \in H^*(B; \mathbf{Z})$ are defined as follows. In the case $n = 1$, let $\mathbf{C}^\infty = \varinjlim \mathbf{C}^n$ (the inductive limit of the \dagger complex Euclidean spaces \mathbf{C}^n), S^∞ be its unit sphere, and $\mathbf{P}^\infty(\mathbf{C})$ be the **infinite-dimensional complex projective space** consisting of all complex lines through the origin O of \mathbf{C}^∞ . Then the natural mapping $S^\infty \rightarrow \mathbf{P}^\infty(\mathbf{C})$ defines a universal principal $U(1)$ -bundle $(S^\infty, \mathbf{P}^\infty(\mathbf{C}), U(1))$. Let γ_1 be its associated universal \mathbf{C}^1 -bundle. Then we define the 1-dimensional universal Chern class $c_1(\gamma_1) \in H^2(\mathbf{P}^\infty(\mathbf{C}); \mathbf{Z})$ to be the cohomology class that takes the value -1 on the cycle $S^2 (\approx \mathbf{P}^1(\mathbf{C})) \subset$

$\mathbf{P}^\infty(\mathbf{C})$ with the natural orientation. Since a general \mathbf{C}^1 -bundle $\xi = (E, B, \mathbf{C}^1)$ is induced from γ_1 by a classifying mapping $f_\xi: B \rightarrow \mathbf{P}^\infty(\mathbf{C})$, we set $c_1(\xi) = f_\xi^* c_1(\gamma_1)$. When $n > 1$, let $(P, B, U(n))$ be the principal $U(n)$ -bundle associated with the given \mathbf{C}^n -bundle $\xi = (E, B, \mathbf{C}^n)$. Let T_n be the subgroup of $U(n)$ consisting of all diagonal matrices (which is a \dagger maximal torus of $U(n)$). Then the quotient space $Y = P/T_n$ is the base space of the principal T_n -bundle $\eta = (P, P/T_n, T_n)$. Let $\rho: Y \rightarrow B = P/U(n)$ be the natural projection. Then the \mathbf{C}^n -bundle $\rho^* \xi$ over Y is associated with η and is equivalent to the \dagger Whitney sum of n complex line bundles: $\rho^* \xi \equiv \xi_1 \oplus \dots \oplus \xi_n$. Moreover, $\rho^*: H^*(B; \mathbf{Z}) \rightarrow H^*(Y; \mathbf{Z})$ is a monomorphism (Borel [1], Hirzebruch [4]). Therefore we can uniquely define the total Chern class $c(\xi)$ of the \mathbf{C}^n -bundle ξ by the relation $\rho^* c(\xi) = c(\xi_1) \dots c(\xi_n)$. The Chern classes, as defined above, are compatible with bundle mappings f (i.e., $c(f^* \xi) = f^* c(\xi)$) (\rightarrow 147 Fiber Bundles N). The Chern class $c_i(\gamma_n) \in H^{2i}(B_{U(n)}; \mathbf{Z})$ ($1 \leq i \leq n$) of the universal \mathbf{C}^n -bundle γ_n over $B_{U(n)}$ is called the $2i$ -dimensional **universal Chern class**. Let ξ, η be complex vector bundles over B . Then we have $c(\xi \oplus \eta) = c(\xi)c(\eta)$. By the natural inclusion $U(n) \subset SO(2n)$, we can identify a \mathbf{C}^n -bundle ω with an oriented \mathbf{R}^{2n} -bundle $\omega_{\mathbf{R}}$. Then we have $c_i(\omega) \bmod 2 = w_{2i}(\omega_{\mathbf{R}})$, $w_{2i+1}(\omega_{\mathbf{R}}) = 0$ ($i = 0, 1, \dots, n$), $c_n(\omega) = X_{2n}(\omega_{\mathbf{R}})$.

Examples. Let $(S^{2n+1}, \mathbf{P}^n(\mathbf{C}), U(1))$ be the \dagger Hopf bundle, and let γ_1^n be the associated complex line bundle. Then the classifying mapping of γ_1^n is the natural inclusion $\mathbf{P}^n(\mathbf{C}) \rightarrow BU(1) = \mathbf{P}^\infty(\mathbf{C})$, and $c(\gamma_1^n) = 1 - g_n$, where $g_n \in H^2(\mathbf{P}^n(\mathbf{C}); \mathbf{Z})$ is the cohomology class dual to the homology class represented by the hyperplane $\mathbf{P}^{n-1}(\mathbf{C})$. On the other hand, for the complex line bundle $\xi_1^n = \{\mathbf{P}^{n-1}(\mathbf{C})\}$ determined by the \dagger divisor (\rightarrow 72 Complex Manifolds) $\mathbf{P}^{n-1}(\mathbf{C}) \subset \mathbf{P}^n(\mathbf{C})$, we have $c(\xi_1^n) = 1 + g_n$, and ξ_1^n, γ_1^n are dual to each other. ξ_1^n is called the **canonical line bundle** over the complex projective space. Moreover, the Whitney sum $\tau \oplus \varepsilon_1$ of the tangent bundle $\tau(\mathbf{P}^n(\mathbf{C}))$ of the n -dimensional complex projective space $\mathbf{P}^n(\mathbf{C})$ and the trivial \mathbf{C}^1 -bundle ε_1 is equivalent to the Whitney sum of $(n+1)$ copies of ξ_1^n . Therefore we have $c(\tau(\mathbf{P}^n(\mathbf{C}))) = c(\xi_1^n \oplus \xi_1^n \oplus \dots \oplus \xi_1^n) = (1 + g_n)^{n+1}$.

D. Pontryagin Classes

Utilizing the inclusion mapping $O(n) \subset U(n)$ of structure groups, we can associate a \mathbf{C}^n -bundle $\xi_{\mathbf{C}} = \xi \oplus \sqrt{-1} \xi$ with an \mathbf{R}^n -bundle ξ . We define the $4i$ -dimensional (or i th) **Pontryagin class** of the \mathbf{R}^n -bundle ξ by $p_i(\xi) = (-1)^i c_{2i}(\xi_{\mathbf{C}})$ ($\in H^{4i}(B; \mathbf{Z})$) ($i = 1, 2, \dots, [n/2]$) (Hirzebruch

[4]). In particular, the Pontryagin classes of the universal bundle for $O(n)$ are called the **universal Pontryagin classes**. We also define the **total Pontryagin classes** $p(\xi) = 1 + p_1(\xi) + \dots + p_{[n/2]}(\xi)$. We have $2c_{2i+1}(\xi_C) = 0$. For \mathbf{R}^n -bundles ξ and η , $p(\xi \oplus \eta) = p(\xi)p(\eta)$ modulo 2-torsion elements. We have $p_i(\xi) \pmod{2} = (w_{2i}(\xi))^2$ and $p_n(\xi) = (X_{2n}(\xi))^2$ for the oriented \mathbf{R}^{2n} -bundle ξ . Moreover, for a complex vector bundle ω , we have (Wu [8])

$$(-1)^k p_k(\omega_{\mathbf{R}}) = \sum_{i=0}^{2k} (-1)^i c_i(\omega) c_{2k-i}(\omega),$$

where we put $c_0(\omega) = 1$.

All such classes as defined in Sections B–D are called **characteristic classes**.

E. Other Definitions of Characteristic Classes

Axiomatic Definition. (1) For a \mathbf{C}^n -bundle ξ over a paracompact Hausdorff base space B , Chern classes $c_i(\xi) \in H^{2i}(B; \mathbf{Z})$ ($i \geq 0$) are defined, and we have $c_0(\xi) = 1$, $c_i(\xi) = 0$ ($i > n$). (2) For the total Chern class $c(\xi) = \sum_{i=0}^{\infty} c_i(\xi)$, we have $c(f^* \xi) = f^* c(\xi)$ for each bundle mapping f . (3) For the Whitney sum, we have $c(\xi \oplus \eta) = c(\xi) \cdot c(\eta)$. (4) Normalization condition: For the canonical line bundle ξ_1^n , we have $c(\xi_1^n) = 1 + g_n$ (\rightarrow Section C). We can verify the existence and uniqueness of $c_i(\xi)$ satisfying these four conditions, so Chern classes can be defined axiomatically by these conditions (Hirzebruch [4]). We can similarly define Stiefel-Whitney classes axiomatically.

Definition in Terms of Obstruction Classes.

When the base space is a \dagger CW complex, we can define the Chern class of a \mathbf{C}^n -bundle ξ over B as follows: Let $V_{n,n-q+1}(\mathbf{C}) = U(n)/I_{n-q+1} \times U(q-1)$ be the \dagger complex Stiefel manifold of all orthonormal $(n-q+1)$ -frames in \mathbf{C}^n with Hermitian metric. Then $V_{n,n-q+1}(\mathbf{C})$ is $\dagger(2q-2)$ -connected, and its $(2q-1)$ -dimensional \dagger homotopy group $\pi_{2q-1}(V_{n,n-q+1}(\mathbf{C})) = \mathbf{Z}$. Let ξ' be the \dagger associated bundle of ξ with fiber $V_{n,n-q+1}(\mathbf{C})$. Then the \dagger primary obstruction ($\in H^{2q}(B; \mathbf{Z})$) to constructing a \dagger cross section of ξ' coincides with the Chern class $c_q(\xi)$. Analogously, we can interpret $w_q(\xi)$ for an \mathbf{R}^n -bundle ξ as an obstruction class (\rightarrow 147 Fiber Bundles).

Definition in Terms of Schubert Varieties.

We denote by \mathbf{C}^k the subspace defined by $z_{k+1} = z_{k+2} = \dots = z_{n+N} = 0$ of the space $\mathbf{C}^{n+N} = \{(z_1, \dots, z_{n+N}) \mid z_i \in \mathbf{C}, i = 1, \dots, n+N\}$, and fix the sequence of subspaces $\mathbf{C}^1 \subset \mathbf{C}^2 \subset \dots \subset \mathbf{C}^{n+N}$. The set of all complex n -planes X through the origin O in \mathbf{C}^{n+N} forms the \dagger complex Grassmann manifold $M_{n+N,n}(\mathbf{C})$. We denote

by $E(\gamma_n^N)$ the set of all pairs (X, v) , where $X \in M_{n+N,n}(\mathbf{C})$ and v is a vector in X . Then we can define a $2N$ -universal complex n -dimensional vector bundle γ_n^N with base space $M_{n+N,n}(\mathbf{C})$, with total space $E(\gamma_n^N)$ and projection $(X, v) \rightarrow X$. Let $\omega = (\omega(1), \dots, \omega(n))$ be a sequence of integers satisfying the condition $0 \leq \omega(1) \leq \dots \leq \omega(n) \leq N$. Then the set e_ω of all n -planes $X \subset \mathbf{C}^{n+N}$ through the origin O satisfying $\dim(X \cap \mathbf{C}^{i+\omega(i)}) = i$, $\dim(X \cap \mathbf{C}^{i+\omega(i)-1}) = i-1$, $i = 1, 2, \dots, n$, forms a real $(2 \sum_{i=1}^n \omega(i))$ -dimensional open \dagger cell. The set of all these open cells e_ω gives a \dagger cellular subdivision of $M_{n+N,n}(\mathbf{C})$ as a CW complex. The closure \bar{e}_ω of e_ω is a cellular subcomplex of $M_{n+N,n}(\mathbf{C})$, called a **Schubert variety**. This is a \dagger pseudo-manifold with canonical orientation and represents a $(2 \sum_{i=1}^n \omega(i))$ -dimensional integral cycle, called a **Schubert cycle**. We denote \bar{e}_ω by $(\omega(1), \dots, \omega(n))$. All these homology classes form the basis of the homology group $H_*(M_{n+N,n}(\mathbf{C}); \mathbf{Z})$. The cocycle dual to the cycle $(\underbrace{0, \dots, 0}_{n-q}, \underbrace{1, \dots, 1}_q)$ represents the Chern class $c_q(\gamma_n^N) \in H^{2q}(M_{n+N,n}(\mathbf{C}); \mathbf{Z})$. For the real Grassmann manifold $M_{n+N,n}(\mathbf{R})$, we can analogously define the universal Stiefel-Whitney classes.

Thom's Definition. Let ξ be an \mathbf{R}^n -bundle over B , B_ξ be its \dagger Thom space, and $U \in H^n(B_\xi; \mathbf{Z}_2)$ be the \dagger fundamental class of B_ξ . Let $j: B \rightarrow B_\xi$ be the inclusion induced from the zero cross section and $\varphi: H^k(B; \mathbf{Z}_2) \cong H^{k+n}(B_\xi; \mathbf{Z}_2)$ be the \dagger Thom-Gysin isomorphism. Then we have $j^* U = w_n(\xi)$, $\varphi^{-1}(Sq^i U) = w_i(\xi)$ ($0 \leq i \leq n$), where Sq^i is the \dagger Steenrod square (R. Thom [6]).

Definition in Terms of Differential Forms.

Let B be a \dagger differentiable manifold and $\xi = (P_\xi, B, U(n))$ be a differentiable principal $U(n)$ -bundle over B . Let $\Omega = (\Omega_{ij})$ be the \dagger curvature form corresponding to the \dagger connection form $\omega = (\omega_{ij})$, $i, j = 1, \dots, n$, on P_ξ . Then Ω_{ij} is a complex-valued 2-form, and $\bar{\Omega}_{ij} = -\Omega_{ji}$. For the matrix Ω , we consider the differential form

$$\psi = \sum_q \psi_q = \det[I + (2\pi\sqrt{-1})^{-1} \Omega],$$

where I is the unit matrix, the multiplication in the determinant is the \dagger exterior product, and ψ_q is the part of degree $2q$ in ψ . Then ψ is defined as a real form independent of the connection ω . We have $d\psi_q = 0$, and the cohomology class of $(-1)^q \psi_q$ in $H^{2q}(B; \mathbf{R})$ is the Chern class $c_q(\xi)$ with real coefficients (Borel and Hirzebruch [2], S. S. Chern [3]).

Definition in Terms of Symmetric Polynomials.

(\rightarrow 427 Topology of Lie Groups and Homogeneous Spaces.)

F. Characteristic Classes of Manifolds

For a differentiable (complex or almost complex) manifold M , the characteristic classes of its tangent bundle are called **characteristic classes of the manifold** M . We shall denote **Stiefel-Whitney classes**, **Pontryagin classes**, **Euler-Poincaré classes**, and **Chern classes** of M by $w_i(M)$, $p_i(M)$, $X_n(M)$, and $c_i(M)$, respectively. These are invariants of differentiable structures, orientations, or (almost) complex structures of a manifold M if M is a differentiable, oriented differential, or (almost) complex manifold. By the **Stiefel-Whitney numbers** of an n -dimensional manifold M , we mean the values of n -dimensional monomials of Stiefel-Whitney classes of M on the fundamental homology class $((w_1(M)^{r_1} w_2(M)^{r_2} \dots w_n(M)^{r_n})[M] \in \mathbb{Z}_2$, where $r_1 + 2r_2 + \dots + nr_n = n$, $r_i \geq 0$). We can define integer-valued **Pontryagin numbers** and **Chern numbers** similarly. These numbers are called generally **characteristic numbers** of the given manifold. In particular, $X_n(M)[M] = \chi(M)$ is the \dagger Euler-Poincaré characteristic.

In the case of topological manifolds, we can define characteristic classes in the following sense. Let M be a closed n -dimensional topological manifold and X^n the generator of $H^n(M; \mathbb{Z}_2)$. By defining $X^i(Y^{n-i}) = (X^i Y^{n-i})[M] \in \mathbb{Z}_2$ for $X^i \in H^i(M; \mathbb{Z}_2)$, $Y^{n-i} \in H^{n-i}(M; \mathbb{Z}_2)$, we have an isomorphism $H^i(M; \mathbb{Z}_2) \cong \text{Hom}(H^{n-i}(M, \mathbb{Z}_2); \mathbb{Z}_2)$. The element $u_i \in H^i(M; \mathbb{Z}_2)$, corresponding to the homomorphism $Y^{n-i} \rightarrow Sq^i Y^{n-i}[M]$ under this isomorphism is called the **Wu class** of M , where Sq^i is the \dagger Steenrod square. Moreover, we call $w_j = \sum_{i=0}^j Sq^{j-i} u_i \in H^j(M; \mathbb{Z}_2)$ the **Stiefel-Whitney class** of the topological manifold M . Then for any \dagger differentiable structure \mathcal{D} , we have $w_j(M, \mathcal{D}) = w_j$. Therefore Stiefel-Whitney classes of differentiable manifolds are topological invariants (more precisely homotopy type invariants) (Thom [6], W. T. Wu [8]). J. W. Milnor [9] proved that Pontryagin classes of differentiable manifolds are not topological invariants. The image of $p_i(M)$ by the homomorphism $H^{4i}(M; \mathbb{Z}) \rightarrow H^{4i}(M; \mathbb{Q})$ induced by the inclusion $\mathbb{Z} \subset \mathbb{Q}$ (the rational number field) is called the **rational Pontryagin class**. In 1966, S. P. Novikov [10] proved the topological invariance of the rational Pontryagin class (\rightarrow Section H).

G. Index Theorem for Differentiable Manifolds

Let M be an oriented closed manifold of dimension $4k$. Putting $f(x, y) = x \cdot y[M]$ for elements x, y of the $2k$ -dimensional real coho-

mology group $H^{2k}(M; \mathbb{R})$, we obtain a bilinear form on $H^{2k}(M; \mathbb{R})$. The \dagger signature of the quadratic form $f(x, x)$ (namely, (number of positive terms) – (number of negative terms) in its canonical form) is a topological invariant (homotopy type invariant) of the manifold M . We call it the **index** or the **signature** of the manifold M and denote it by $\tau(M)$. If the dimension of M is not divisible by 4, we define $\tau(M) = 0$. For the product of manifolds we have $\tau(M \times N) = \tau(M) \cdot \tau(N)$. Also $\tau(M)$ is an invariant of the \dagger cobordism class of M (Thom [6]).

The index τ of a differentiable manifold gives a homomorphism of the \dagger cobordism ring Ω into the ring \mathbb{Z} of integers. Hirzebruch investigated the multiplicative property of τ and gave its expression by means of Pontryagin numbers. Let P_i be the i th \dagger elementary symmetric function of indeterminates β_1, \dots, β_n . Then a homogeneous part of the formal power series

$$\prod_{i=1}^n \frac{\sqrt{\beta_i}}{\tanh \sqrt{\beta_i}}$$

of β_1, \dots, β_n is a symmetric polynomial of β_1, \dots, β_n , and therefore a polynomial of P_i with rational coefficients. For $k \leq n$, we denote the homogeneous part of degree k by $L_k(P_1, \dots, P_k)$. Specifically, if P_i are the Pontryagin classes $p_i(M^{4k})$ of a $4k$ -dimensional closed differentiable manifold M^{4k} , then $L_k(P_1, \dots, P_k)$ is a $4k$ -dimensional cohomology class of M^{4k} . Then we have the formula

$$\tau(M^{4k}) = L_k(P_1, \dots, P_k)[M^{4k}],$$

called the **index theorem** of differentiable manifolds (or **Hirzebruch index theorem**). For example, $L_1 = (1/3)P_1$, $L_2 = (1/45)(7P_2 - P_1^2)$, and $L_3 = (1/945)(62P_3 - 13P_2P_1 + 2P_1^3)$, \dots (\rightarrow 114 Differential Topology). Later this index theorem was generalized to the \dagger Atiyah-Singer index theorem (\rightarrow 237 K-Theory).

H. Combinatorial Pontryagin Classes

Let K be an oriented n -dimensional compact \dagger homology manifold, and let Σ^r be the boundary of an oriented $(r+1)$ -simplex, namely, the combinatorial r -sphere. Let $f: K \rightarrow \Sigma^{n-4i}$ be a \dagger piecewise linear mapping. Then for almost all points y of Σ^{n-4i} , $f^{-1}(y)$ is an oriented $4i$ -dimensional compact homology manifold, and its index $\tau(f^{-1}(y))$ is independent of y . We denote this by $\tau(f)$. The $\tau(f)$ is an invariant of the homotopy class of f . Let σ be the fundamental class of $H^{n-4i}(\Sigma^{n-4i}; \mathbb{Z})$. Then for $n \geq 8i + 2$, there exists a unique cohomology class $l_i = l_i(K) \in H^{4i}(K; \mathbb{Q})$ such that for any piecewise linear mapping $f: K \rightarrow \Sigma^{n-4i}$, we have

$(l_i \cdot f^* \sigma)[K] = \tau(f)$. We can remove the restriction $n \geq 8i + 2$ if we take $K \times \Sigma^m$ for K and define $l_i(K)$ to be $l_i(K \times \Sigma^m)$ for sufficiently large m . If K is a $\dagger C^1$ -triangulation of a differentiable manifold M , $l_i(K)$ coincides with the class $L_i(P_1, \dots, P_j)$ defined by Hirzebruch (R. Thom [7]; V. Rokhlin and A. Shvarts), where $P_j = p_j(M)$ is the Pontryagin class of M . Since the variable P_i can be expressed as a polynomial with rational coefficients of $L_j(P_1, \dots, P_j)$, $j \leq i$, we define the **combinatorial Pontryagin class** $p_i(K)$ of a homology manifold K as the polynomial of $l_j(K)$ with rational coefficients. Therefore, if K is a C^1 -triangulation of a differentiable manifold M , we have $p_i(K) = p_i(M)$ (modulo torsion elements). The class $l_i(K)$ and consequently $p_i(K)$ are important combinatorial invariants of K . These classes are topological invariants [10].

57 (XXI.6) Chinese Mathematics

A. Mathematics in the Chao, Han, and Tang Dynasties (3rd Century B.C.–10th Century A.D.)

In ancient China, the art of divination, called *yi*, was used in government administration. This was a kind of calculation that used pieces called *tse*. The book embodying it, called the *I-Ching*, is still popularly used. It shows that “numbers” or mathematics was seriously utilized in China at that time. The multiplication table for numbers up to nine (called the Pythagorean table in the West) was known in China from the legendary period. However, mathematics in the Greek sense, that is, mathematics as a logically systematized science, was unknown in ancient China.

Suanching-Shihshu, or the Ten Books on Arithmetic—namely, *Choupi-Suanching*, *Chiuchang-Suanshu*, *Haitao-Suanching* (edited by Liu Hui), *Suntzu-Suanching*, *Wutsao-Suanching*, *Hsiahouyang-Suanching*, *Changchiu-Suanching*, *Wuching-Suanshu*, *Chiku-Suanching* (edited by Wang Hsiao-Tong), and *Shushu-Chiyi* (edited by Hsu Yue)—came into being between the 2nd century B.C. and the 6th century A.D., from the Chao to the Han eras, with the exception of the *Chiku-Suanching* compiled in the Tang era. These are the only mathematical texts from this early period whose authors and times of publication are known. They were used in the civil service examination for selecting administrators up to the beginning of the Sung era (960 A.D.). The most important among them is *Chinchang-Suanshu*, or the Book of Arithmetic, which contains nine chapters. It treats positive and negative fractions with laws of operations on signed numbers, equations, and the elementary mathematical knowledge of daily life. The *Chiku-Suanching* contains a number of problems reducible to equations of the 3rd and 4th degrees.

There were also two works called *San Tung Shu* (edited by Tong Chuan) and *Chui Shu* (edited by Tsu Chung-Chih), but no copies of them are extant. Later works, one from the Sui era (published in 636) and another from the Tang era, tell us that the latter contained the result $3.1415927 > \pi > 3.1415926$ and the approximate values $355/113$ and $22/7$ for π .

In the 1st century A.D. Buddhism was introduced from India, and paper was invented.

However, despite the communication with India, neither the Indian numeration system, written calculation, nor the abacus was at that time widely used in China. The extraction of square or cube roots was done with calculating rods.

B. Mathematics in the Sung and Yuan Dynasties (10th–14th Centuries)

In the Sung and Yuan periods contact was made with the Arab world. In the 13th century, a mechanical algebra utilizing calculating rods made remarkable progress; this can be attributed to Arab influence. Toward the end of the Sung era appeared the *Shushu-Chiuchang* by Ch'in Chiu-Shao and the *Yiku-Yentan* by Li Chih. The former gives a method like Horner's for approximate solution of equations, and the latter gives the principle of *tiennyuan-shu*, i.e. the mechanical algebra of this period. The principle of *tiennyuan-shu* was further expounded in the *Suanhsueh Chimeng* (1295) and the *Suyuan Yuchien* (1303) by Shih Shih-Chieh, the *Yanghui Suanfa* by Yang Hui, and other works. These were introduced into Japan and they influenced the *wasan* (Japanese mathematics) of early times. Until recently, no further original mathematical ideas appeared in China.

C. Mathematics after the Ming Era (15th Century)

In this epoch, European renaissance civilization began to influence the Orient. In 1607, Matteo Ricci (1552–1610) translated Books I–IV of Euclid's *Elements* into Chinese with the aid of Hsu Kuang-Chi. In 1592 *Suanfa Tangtsung* by Ch'êng Ta-Wei appeared, which dealt with the use of the abacus. This book had great influence upon *wasan*.

No development was seen in the indigenous mathematics of the Ching era, that is, after the 17th century, but science and technology were imported by Christian missionaries. This brought about calendar reform from the lunar to the solar method. On the other hand, new editions of classical works such as the Ten Books on Arithmetic began to appear in this period. Emperor Kang Hsi-Ti (1655–1722), who was in correspondence with Leibniz, asked Ferdinand Verbiest (renamed Nan Huai Jen in Chinese) to compile *Shuli-Chingwen* (Advanced mathematics), whose 53 chapters were completed in 1723. This book dealt with European-style algebra and trigonometry. In the latter half of the 19th century, Alexander Wylie translated a number of Western mathe-

matical books into Chinese, including Books VII–XIII of Euclid's *Elements* and some works on calculus. Many current Chinese and Japanese mathematical terms originated with this translation.

58 (X.9) C^∞ -Functions and Quasi-Analytic Functions

A. General Remarks

An example of a ${}^*C^\infty$ -function is a * real analytic function, which is defined to be a function that can be expressed as a power series that converges in a neighborhood of each point of the domain where the function is defined. Many examples, however, show that real analytic functions form a rather small subset of the C^∞ -functions. Sometimes C^∞ -functions (not real analytic functions) play essential roles in the development of theories of analysis (\rightarrow 105 Differentiable Manifolds S). On the other hand, there is a subfamily of C^∞ -functions having some remarkable properties in common with the family of real analytic functions. This family is called the **family of quasi-analytic functions**. It has been an important object of study since the beginning of the 20th century. On the other hand, the Gevrey class functions, which are no longer quasi-analytic in general, also constitute an important subset of C^∞ -functions. The first part of this article deals with C^∞ -functions, the second part with quasi-analytic functions, and the third part with Gevrey class functions.

B. C^∞ -Functions

Let Ω be an open set of the n -dimensional real Euclidean space \mathbf{R}^n . A real-valued function $f(x_1, \dots, x_n)$ defined on Ω is called a **function of class C^∞** on Ω (or C^∞ -function on Ω) if $f(x_1, \dots, x_n)$ is continuously differentiable up to any order. The totality of C^∞ -functions defined on Ω is denoted by $C^\infty(\Omega)$. It is an * associative algebra over the real number field \mathbf{R} . A continuous function f defined on some closed set F

of \mathbf{R}^n is called a C^∞ -function on F if there exist an open neighborhood U of F and a function $g \in C^\infty(U)$ such that $f = g|_F$. This definition is equivalent to the following (H. Whitney [6]): For any multi-index $\alpha = (\alpha_1, \dots, \alpha_n)$, we can find a continuous function $f^\alpha(x_1, \dots, x_n)$ on F such that (i) $f^0(x_1, \dots, x_n) = f(x_1, \dots, x_n)$ and (ii) for any positive integer r and for every multi-index α with $|\alpha| \leq r$,

$$\lim_{y \rightarrow x} \left[\frac{1}{\|y - x\|^{r-|\alpha|}} \left| f^\alpha(x) - \sum_{|\alpha+\beta| \leq r} f^{\alpha+\beta}(x) \frac{(x-y)^\beta}{\beta!} \right| \right] = 0,$$

where $\| \cdot \|$ denotes the Euclidean norm of \mathbf{R}^n .

C. Local Theory of C^∞ -Functions

We shall now introduce an equivalence relation \sim in $C^\infty(\mathbf{R}^n)$, defined as follows: $f \sim g \Leftrightarrow f|U = g|U$ for some open neighborhood U of the origin. Let \mathcal{E}_n denote the quotient set $C^\infty(\mathbf{R}^n)/\sim$, which naturally inherits the structure of an associative algebra from $C^\infty(\mathbf{R}^n)$. An element of \mathcal{E}_n is called a **germ of a C^∞ -function at the origin**. We denote the germ of $f \in C^\infty(\mathbf{R}^n)$ by \tilde{f} . To $\tilde{f} \in \mathcal{E}_n$, we assign the **formal Taylor expansion** $\sum (D^\alpha f(0)/\alpha!) x^\alpha$ around 0, where $D^\alpha f$ means $(\partial^{r_1} + \dots + \partial^{r_n})f / (\partial^{r_1} x_1 \dots \partial^{r_n} x_n)$ for $\alpha = (r_1, \dots, r_n)$. This assignment induces a homomorphism τ from \mathcal{E}_n to the ring of formal power series $\mathbf{R}[[x_1, \dots, x_n]]$ of n variables. The homomorphism τ is surjective but not injective. Put $\Lambda_n = \tau^{-1}(0) \subset \mathcal{E}_n$. A function f whose germ \tilde{f} belongs to Λ_n is called a **flat function**. The function $\varphi(x)$ defined by $\varphi(x) = \exp(-1/x^2)$ when $x \neq 0$ and $\varphi(0) = 0$ is an example of a flat function on \mathbf{R}^1 . A close study of the relationship between \mathcal{E}_n and $\mathbf{R}[[x_1, \dots, x_n]]$ leads to the **preparation theorem for C^∞ -functions**, which can be stated as follows: Let $\tilde{F}(x_1, \dots, x_n) \in \mathcal{E}_n$ satisfy $\tilde{F}(0, \dots, 0, x_n) = x_n^p \tilde{g}(x_n)$ ($\tilde{g} \in \mathcal{E}_1, g(0) \neq 0$). Then any $\tilde{f} \in \mathcal{E}_n$ can be expressed as $\tilde{f} = \tilde{F} \tilde{Q} + \tilde{R}$, where $\tilde{Q} \in \mathcal{E}_n$ and $\tilde{R} = \sum_{i=0}^{p-1} r_i(x_1, \dots, x_{n-1}) x_n^i$ with $r_i \in \mathcal{E}_{n-1}$ (B. Malgrange [3]).

Let $f(x_1, \dots, x_n)$ be a symmetric function in (x_1, \dots, x_n) of class C^∞ . Then there exists a germ $\tilde{g} \in \mathcal{E}_1$ such that $\tilde{f}(x_1, \dots, x_n) = \tilde{g}(\sigma_1, \dots, \sigma_n)$, where $\sigma_1, \dots, \sigma_n$ denote elementary symmetric functions with respect to x_1, \dots, x_n (G. Glaeser, Malgrange). Let $\tilde{f} \in \mathcal{E}_1$ satisfy $f(x) = f(-x)$. Then there exists a germ $\tilde{g} \in \mathcal{E}_1$ such that $\tilde{f}(x) = \tilde{g}(x^2)$ (H. Whitney).

D. Global Results

Case of n Variables. $C^\infty(\Omega)$ becomes a * Fréchet space when it is endowed with the topology of

uniform convergence on compact sets for all partial derivatives. Let J and J_1 be two closed * ideals of $C^\infty(\Omega)$. Then we have $J = J_1$ if and only if $\tau_x(J) = \tau_x(J_1)$ for each $x \in \Omega$, where τ_x is the mapping from $C^\infty(\Omega)$ to the ring of the formal power series that assigns the formal Taylor series of f around x (Whitney).

Case of One Variable. In the case of one variable, further information can be obtained from various points of view. In the following, f denotes a C^∞ -function defined on the unit interval $I = [0, 1]$. If f satisfies $f(1) = 1, f'(0) = \dots = f^{(r-1)}(0) = 0$, then we have

$$\frac{1}{m_1} + \frac{1}{\sqrt{m_2}} + \dots + \frac{1}{\sqrt[r]{m_r}} < k,$$

where $m_i = \sup\{|f^{(i)}(x)| \mid x \in I\}$ and where k is some constant independent of the choice of f and r (E. Borel). Similar kinds of inequalities were obtained by A. N. Kolmogorov, A. Gorny, and H. Cartan. Let A be an arbitrary countable set of real numbers. If for any $x \in I$ we can find an integer $r(x)$ such that $f^{(r(x))}(x) \in A$, then such a function f is necessarily a polynomial. The interval I can be divided into three disjoint subsets: $S_1^{(f)}, S_2^{(f)}$, and $S_3^{(f)}$. These are characterized as follows: For $x \in S_1^{(f)}$ the formal Taylor series $\tau_x(f)$ of f around x converges to f in some neighborhood of x . For $x \in S_2^{(f)}$, $\tau_x(f)$ diverges. And for $x \in S_3^{(f)}$, $\tau_x(f)$ converges in some neighborhood of x but does not tend to f . Then $S_1^{(f)}$ is an open set and $S_2^{(f)}$ is a G_δ -set, while $S_3^{(f)}$ is an F_σ -set of the first category. Conversely, let $I = S_1 + S_2 + S_3$ be any partition of I into an open set S_1 , a G_δ -set S_2 , and an F_σ -set S_3 of the first category. Then there is some $f \in C^\infty(I)$ with $S_i = S_i^{(f)}$ ($i = 1, 2, 3$) [5].

E. Relations between C^∞ -Functions and Real Analytic Functions

Let $C^\omega(I)$ be the set of real analytic functions on I . Then $C^\omega(I)$ is a subalgebra of $C^\infty(I)$. Applying the above result in the case of $S_1 = \emptyset$, we find a function $f \in C^\infty(I)$ that admits no real analytic function coinciding with f in a subinterval of I . Actually, functions with such a property are distributed densely in $C^\infty(I)$. A necessary and sufficient condition for a function $f \in C^\infty(I)$ to belong to $C^\omega(I)$ is that for suitable constants A and k , $|f^{(n)}(x)| \leq Ak^n n!$, $x \in I, n = 0, 1, 2, \dots$, be valid (**Pringsheim's theorem**). If $f^{(n)}(x) \geq 0$ for all $x \in I$ and $n = 0, 1, 2, \dots$, then $f \in C^\omega(I)$ (S. N. Bernstein). For any open set $\Omega (\subset \mathbf{R}^n)$, the set $C^\omega(\Omega)$ of real analytic functions on Ω is dense in $C^\infty(\Omega)$ (**polynomial approximation theorem**). This result is true even when the topology of $C^\infty(\Omega)$

is replaced by a stronger one (Whitney [6]). Let $f \in C^\infty(\Omega)$ and $\varphi \in C^\infty(\Omega)$. Then we can find $g \in C^\infty(\Omega)$ satisfying $f = g\varphi$ if and only if for any $x \in \Omega$, $\tau_x(f)$ is divisible by $\tau_x(\varphi)$ in the ring of formal power series (S. Łojasiewicz, Malgrange [3]).

F. Quasi-Analytic Functions

The investigation of quasi-analytic functions began with the attempt to obtain an intrinsic characterization of analytic functions. Borel defined monogenic functions as functions differentiable on their domains of definition, which can be any subset of the complex plane, not necessarily assumed to be open (\rightarrow 198 Holomorphic Functions Q). Similar to complex analytic functions, monogenic functions are uniquely determined by their values on any curve. While quasi-analyticity can be defined by such properties, it is customary to approach quasi-analytic functions from another aspect, that is, the behavior of higher derivatives of C^∞ -functions.

Generally, a subset B of $C^\infty(I)$ is called a **set of quasi-analytic functions** if the mapping $\tau_x: B \rightarrow \mathbb{R}[[x]]$ defined in Section D is injective at each point $x \in I$. The functions belonging to B are called **quasi-analytic** (with respect to B). Here, an important problem is to characterize a set of quasi-analytic functions B by specializing the image of $\tau_x(B)$.

Now let $\{M_n\}$ be a sequence of positive numbers. Let $C(M_n)$ be the subset of $C^\infty(I)$ consisting of f such that

$$|f^{(n)}(x)| \leq A k^n M_n, \quad x \in I, \quad n = 0, 1, 2, \dots,$$

where $A = A(f)$ and $k = k(f)$ are constant. Then Pringsheim's theorem simply asserts that $C(n!) = C^\omega(I)$.

In 1912, J. Hadamard raised the problem of determining the condition that the sequence $\{M_n\}$ should satisfy so that $C(M_n)$ becomes a set of quasi-analytic functions [9]. A. Denjoy showed that if

$$M_n = (n \log^1 n \log^2 n \dots \log^p n)^n,$$

where

$$\log^1 n = \log n, \quad \log^p n = \log(\log^{p-1} n),$$

$$p = 2, 3, \dots,$$

then $C(M_n)$ is a set of quasi-analytic functions [10]. Later he derived an improved result that the condition $\sum M_n^{-1/n} = \infty$ is sufficient. T. Carleman first gave a necessary and sufficient condition for $C(M_n)$ to be a set of quasi-analytic functions, and later A. Ostrowski and T. Bang gave another version of the same condition [11–13]. The condition states essen-

tially the following: A necessary and sufficient condition for $C(M_n)$ to be a family of quasi-analytic functions in the interval (a, b) is given by either (i) $\sum \beta_n^{-1} = +\infty$, where $\beta_n = \inf_{k \geq n} M_k^{1/k}$ (Carleman), or (ii) $\int^\infty (\log T(r))/(r^2) dr = \infty$, where $T(r) = \sup_{n \geq 1} (r^n/M_n)$ (Ostrowski, Bang). S. Mandelbrojt and T. Bang also gave another condition [13, 14]. (The simplest proof of these results is found in [13] or [15], where the proof follows Bang's idea.)

Related to the above theorem, we also have the following: Let $\{M_n\}$ be a sequence of positive numbers with $\sum (M_n/M_{n+1}) < \infty$. For $\alpha > 0$ we can find $f \in C(M_n)$ defined on $(-\infty, \infty)$ such that $f(0) > 0$, $f^{(n)}(\pm\alpha) = 0$. Moreover, for $0 < \alpha < \beta$ there exists $f \in C(M_n)$ such that $f(0) > 0$, $f^{(n)} = 0$ ($\alpha \leq x \leq \beta$, $n = 0, 1, 2, \dots$) [16].

Suppose that we are given an interval I and increasing sequences $\{v_n\}$ and $\{M_n\}$ of positive numbers. Then we have the problem of finding suitable conditions on $\{v_n\}$ and $\{M_n\}$ under which the mapping $f \rightarrow \{f^{(v_n)}(x_0)\}$ gives an injective mapping from $C(M_n)$ to the sequences above. When $\{v_n\}$ and $\{M_n\}$ satisfy the above conditions, then a function belonging to $C(M_n)$ is called **quasi-analytic (v_n) in the generalized sense**. The study of the inclusion relation between two families $C(M_n)$ and $C(M'_n)$ also deserves attention. In [15] the relation between $C(M_n)$ and $C(n!) = C^\omega(I)$ is discussed in detail. There are many open problems concerning the relationship between $C(M_n)$ and $C(M'_n)$ in general.

Quasi-analytic functions are closely related to problems in various branches of analysis, in particular the theories of complex analytic functions, Fourier series, Fourier integrals, Dirichlet series, and asymptotic expansions [8, 15, 17].

G. Gevrey Class Functions

This class of functions has its origin in the study of \dagger parabolic equations. A C^∞ -function $f(x)$ defined in a domain of \mathbb{R}^n is called of **Gevrey class s** ($1 \leq s < \infty$) if for every compact set K in that domain there exist positive constants A_K and C_K such that

$$\max_K |D^\alpha f(x)| \leq A_K C_K^{|\alpha|} \alpha!^s$$

for all multi-indices α ($|\alpha| = \alpha_1 + \dots + \alpha_n$, $\alpha! = \alpha_1! \alpha_2! \dots \alpha_n!$). A typical example is

$$f(x) = \begin{cases} \exp(-1/x) & \text{for } x > 0, \\ 0 & \text{for } x \leq 0, \end{cases}$$

which is of Gevrey class 2. Let us denote the function space of a Gevrey class s by $\gamma^{(s)}$. Evidently $\gamma^{(s)} \subset \gamma^{(s')}$ if $s < s'$. Let $f(x) \in \gamma^{(s)}$ and $F(y) \in \gamma^{(s)}$; then $x \mapsto F(f(x)) \in \gamma^{(s)}$. In particular,

the sum and the product of two functions in $\gamma^{(s)}$ belong also to $\gamma^{(s)}$. Furthermore, the simplicity theorem holds in this class. Unlike the class of analytic functions, we can use this class of functions of class s (> 1) for a \dagger partition of unity, and several problems in partial differential equations can be treated within this function space. Gevrey class functions are discussed in a complete form in [20] (\rightarrow also [19]).

Class Field Theory

A. History

The notion of a class field was first introduced by D. Hilbert (1898). Let k be an \dagger algebraic number field and K a \dagger Galois extension of k . Hilbert called such a field K a class field over k (or K/k was called a class field) when the following property was satisfied: A \dagger prime ideal \mathfrak{p} of k of absolute degree 1 (i.e., a prime ideal whose \dagger absolute norm is a prime number) is decomposed in K as the product of prime ideals of K of absolute degree 1 if and only if \mathfrak{p} is a \dagger principal ideal. (Such a field K is now said to be an **absolute class field** over k in order to distinguish it from a class field defined later more generally by T. Takagi as explained below.) Hilbert conjectured the following theorems (1)–(4) together with the principal ideal theorem (\rightarrow Section D), and proved them in some special cases. (1) For any algebraic number field k there exists one and only one class field K/k . (2) A class field K/k is an \dagger Abelian extension whose \dagger Galois group is isomorphic to the \dagger ideal class group of k . Hence the degree $n = [K:k]$ is equal to the \dagger class number h of k . (3) The \dagger relative different of a class field K/k is the principal order; thus K/k is an \dagger unramified extension. (4) Let \mathfrak{p} be a prime ideal of k , and let f be the smallest positive integer such that \mathfrak{p}^f is a principal ideal. Then \mathfrak{p} is decomposed in the class field K/k as $\mathfrak{p} = \mathfrak{P}_1 \mathfrak{P}_2 \dots \mathfrak{P}_g$, $N_{K/k}(\mathfrak{P}_i) = \mathfrak{p}^f$, $fg = n$.

Hilbert was led to these conjectures by the analog to the theory of \dagger algebraic functions in one variable. Theorems (1)–(4) were proved by P. Furtwängler (*Math. Ann.*, 63 (1907)), but these results were subsumed under the class field theory of Takagi, who generalized the notion of class field and proved that every Abelian extension of k is a class field over k (*J. Coll. Sci. Imp. Univ. Tokyo*, (9) 41 (1920)). Since

then, the arithmetic of Abelian extensions of k has developed through this theory. In Takagi's paper, L. Kronecker's problem concerning Abelian extensions of an imaginary quadratic field (\rightarrow 73 Complex Multiplication) was solved simultaneously; this had been an open problem since the 19th century. Later, E. Artin proved the general law of reciprocity (*Abh. Math. Sem. Univ. Hamburg*, 5 (1927)) which put class field theory into its complete form. The original proof by Takagi was rather complicated, and H. Hasse, Artin, J. Herbrand, C. Chevalley, and others tried to simplify it. In particular, Chevalley introduced the notion of \dagger ideles and gave a purely arithmetic proof. On the other hand, attempts are also being made to generalize this theory to non-Abelian extensions. We mention here the results of G. Shimura [15] and Y. Ihara [16]. Today, class field theory is considered one of the most beautiful theories in mathematics.

B. Definition of a Class Field

Let k be an algebraic number field. For the definition of a general class field over k , we need a generalization of the ideal class group of k (\rightarrow 14 Algebraic Number Fields H). Let \mathfrak{m} be an \dagger integral divisor of k , and let $\mathfrak{I}(\mathfrak{m})$ be the multiplicative group of all \dagger fractional ideals of k which are \dagger relatively prime to \mathfrak{m} . For the rest of this article, we mean by an ideal of k a fractional ideal of k . Denote by $S(\mathfrak{m})$ the \dagger ray modulo \mathfrak{m} . Let $H(\mathfrak{m})$ be an \dagger ideal group modulo \mathfrak{m} , that is, a subgroup of $\mathfrak{I}(\mathfrak{m})$ containing $S(\mathfrak{m})$. A Galois extension K of k is said to be a **class field** over k for the ideal group $H(\mathfrak{m})$ if the following property is satisfied: A prime ideal \mathfrak{p} of k of absolute degree 1 which is relatively prime to \mathfrak{m} is decomposed in K as the product of prime ideals of K of absolute degree 1 if and only if \mathfrak{p} belongs to $H(\mathfrak{m})$. The absolute class field of Hilbert is the case where $\mathfrak{m}=(1)$ and $H(\mathfrak{m})$ is the group of all principal ideals of k .

A class field K/k for an ideal group H is uniquely determined by H (**uniqueness theorem**). The \dagger conductor \mathfrak{f} of H is said to be the **conductor** of the class field for H . The ideal group H corresponding to the class field K/k is determined by K as follows: $H(\mathfrak{f})/S(\mathfrak{f})$ is the union of all cosets C of $\mathfrak{I}(\mathfrak{f})$ modulo $S(\mathfrak{f})$ such that C contains a \dagger relative norm $N_{K/k}(\mathfrak{A})$ of some ideal \mathfrak{A} of K which is relatively prime to \mathfrak{f} . In general, let K/k be a Galois extension and \mathfrak{m} be an integral divisor of k . Let $H(\mathfrak{m})$ be the union of all cosets C of $\mathfrak{I}(\mathfrak{m})$ modulo $S(\mathfrak{m})$ such that C contains a relative norm $N_{K/k}(\mathfrak{A})$ of some ideal \mathfrak{A} of K which is relatively prime to

\mathfrak{m} . Then $H(\mathfrak{m})$ is a multiplicative subgroup of $\mathfrak{I}(\mathfrak{m})$, and the index $h=(\mathfrak{I}(\mathfrak{m}):H(\mathfrak{m}))$ is not greater than the degree $n=[K:k]$. We have $h=n$ if and only if K/k is the class field for H . Hence a class field K/k can be defined as a Galois extension of k such that $h=n$ for a suitable integral divisor \mathfrak{m} of k .

C. Fundamental Theorems in Class Field Theory

(1) **Main theorem**: Any Abelian extension K/k is a class field over k for a suitable ideal group H .

(2) **Existence theorem**: For any ideal group $H(\mathfrak{m})$ there exists one and only one class field for $H(\mathfrak{m})$.

(3) **Composition theorem**: Let K_1 and K_2 be class fields for H_1 and H_2 , respectively. Then the composite field $K_1 K_2$ is the class field over k for $H_1 \cap H_2$. Consequently, $K_1 \supset K_2$ if and only if $H_1 \subset H_2$.

(4) **Isomorphism theorem**: The Galois group of a class field K/k for $H(\mathfrak{m})$ is isomorphic to $\mathfrak{I}(\mathfrak{m})/H(\mathfrak{m})$. In particular, every class field K/k is an Abelian extension of k .

(5) **Decomposition theorem**: Let \mathfrak{f} be the conductor of the class field for H . If \mathfrak{p} is a prime ideal of k relatively prime to \mathfrak{f} and f is the smallest positive integer with $\mathfrak{p}^f \in H$, then \mathfrak{p} is decomposed in K/k as $\mathfrak{p} = \mathfrak{P}_1 \mathfrak{P}_2 \dots \mathfrak{P}_g$, $N_{K/k}(\mathfrak{P}_i) = \mathfrak{p}^f$, $fg = n$.

(6) **Conductor-ramification theorem**: Let \mathfrak{f} be the conductor of a class field K/k . Then \mathfrak{f} is not divisible by any prime divisor that is unramified for K/k , and \mathfrak{f} is divisible by every prime divisor that ramifies for K/k . Let $\mathfrak{f} = \prod \mathfrak{f}_p$, $\mathfrak{f}_p = \mathfrak{p}^c$. Then \mathfrak{f}_p coincides with the \dagger \mathfrak{p} -conductor of K/k , and the exponent c can be explicitly expressed by the order of the \dagger ramification groups and the \dagger ramification numbers of \mathfrak{p} for K/k (\rightarrow 14 Algebraic Number Fields P).

(7) Let \mathfrak{p} be a prime ideal of k that ramifies for K/k . Let H_p be the ideal group of k such that (i) the conductor of H_p is relatively prime to \mathfrak{p} and (ii) H_p is the minimal ideal group of k containing H with property (i). Let $n=[K:k]$, $e=(H_p:H)$, and $\mathfrak{p}^f \in H_p$, where $\mathfrak{p}^d (d < f) \notin H_p$. Then \mathfrak{p} is decomposed in K/k as $\mathfrak{p} = (\mathfrak{P}_1 \mathfrak{P}_2 \dots \mathfrak{P}_g)^e$, $N_{K/k}(\mathfrak{P}_i) = \mathfrak{p}^f$, $n = efg$.

(8) **Translation theorem**: Let K/k be the class field for an ideal group $H(\mathfrak{m})$, and let Ω be an arbitrary finite extension of k . Then $K\Omega/\Omega$ is the class field for H^* , where H^* is the ideal group of Ω consisting of all ideals \mathfrak{b} of Ω with $N_{\Omega/k}(\mathfrak{b}) \in H(\mathfrak{m})$. In particular, the conductor of $K\Omega/\Omega$ is a divisor of the conductor of K/k .

(9) **Artin's general law of reciprocity**: Let K/k be the class field for an ideal group H with the

conductor \mathfrak{f} . We denote the * Artin symbol of an ideal \mathfrak{a} of k that is relatively prime to \mathfrak{f} by

$$(K/\mathfrak{a}) = \left(\frac{K/k}{\mathfrak{a}} \right).$$

Let a mapping Φ from $\mathfrak{I}(\mathfrak{f})$ to the Galois group G of K/k be defined by $\Phi(\mathfrak{a}) = (K/\mathfrak{a})$ for $\mathfrak{a} \in \mathfrak{I}(\mathfrak{f})$. Then Φ induces the isomorphism $\mathfrak{I}(\mathfrak{f})/H(\mathfrak{f}) \cong G$. Namely, the isomorphism mentioned in (4) is explicitly given by the Artin symbol. Also, the ideal group $H(\mathfrak{f})$ is characterized as the set of all ideals \mathfrak{a} such that $\mathfrak{a} \in \mathfrak{I}(\mathfrak{f})$ and $(K/\mathfrak{a}) = 1$. From this theorem we can prove all the known laws of reciprocity for power-residue and norm-residue symbols (\rightarrow 14 Algebraic Number Fields O, Q, R).

From the general results of class field theory we can systematically derive all the known theorems concerning the arithmetic of quadratic fields, cyclotomic fields, and Kummer extensions.

D. Principal Ideal Theorem

Let K/k be an absolute class field. Then the extension of any ideal of k to K is a principal ideal of K . This theorem is called the **principal ideal theorem**. It was conjectured by Hilbert, formulated by Artin as a theorem of group theory, and proved by Furtwängler (*Abh. Math. Sem. Univ. Hamburg*, 7 (1930)). Later a simple proof was given by S. Iyanaga (*Abh. Math. Sem. Univ. Hamburg*, 10 (1934)). This theorem was also generalized to the following general principal ideal theorem (Iyanaga, *Japan. J. Math.*, 7 (1930)): Let K/k be the class field for the ray $S(\mathfrak{f})$, and let $\mathfrak{f} = \mathfrak{f}\mathfrak{D}$, where \mathfrak{D} is the relative different of K/k . Then the extension to K of any ideal of k that is relatively prime to \mathfrak{f} belongs to $S(\mathfrak{f})$. Put $\mathfrak{F} = \prod \mathfrak{P}^v$. Then v is equal to the ramification number $v_r + 1$ (\rightarrow 14 Algebraic Number Fields K). For an absolute class field K/k , let the extension of an ideal \mathfrak{a} to K be $(\Theta(\mathfrak{a}))$. Then we can choose $\Theta(\mathfrak{a}) \in K$ such that $\Theta(\mathfrak{a})\Theta(\mathfrak{b})^{\sigma(\mathfrak{a})}\Theta(\mathfrak{a}\mathfrak{b})^{-1} \in k$, where $\sigma(\mathfrak{a}) = (K/\mathfrak{a})$ is the Artin symbol for \mathfrak{a} (T. Tannaka, *Ann. Math.*, 67 (1958)). This result can also be generalized for the class field for $S(\mathfrak{f})$.

E. Theory of Genera

Let K/k be a Galois extension and let $H(\mathfrak{m})$ be an ideal group of k . The set of all ideals \mathfrak{A} of K relatively prime to \mathfrak{m} such that $N_{K/k}(\mathfrak{A})$ belongs to $H(\mathfrak{m})$ forms an ideal group of K . This ideal group is said to be the **principal genus** for H . Each coset of $\mathfrak{I}(\mathfrak{m})$ modulo the principal genus for H is said to be a **genus** for H . In

particular, let K/k be a cyclic extension with the conductor \mathfrak{f} , and let $H(\mathfrak{f})$ be the ideal group of k generated by $N_{K/k}(A)$ ($A \in K$) and $S(\mathfrak{f})$. Then the principal genus for $H(\mathfrak{f})$ is the ideal group formed by the ideal classes of K of the form $C^{1-\sigma}$, where σ is a generator of the Galois group of K/k (\rightarrow 347 Quadratic Fields F). In general, let K/k be an Abelian extension, and let \mathfrak{f} be the conductor of K/k . Then for the ideal $\mathfrak{F} = \prod \mathfrak{P}^v$ of K defined in Section D, $N_{K/k}(S(\mathfrak{m}\mathfrak{F})) = S(\mathfrak{m}\mathfrak{f})$ for an arbitrary integral ideal \mathfrak{m} of k . In particular, let K/k be a cyclic extension, and let $H = S(\mathfrak{m}\mathfrak{f})$. Then the principal genus for H is the ideal group consisting of all cosets of $\mathfrak{I}(\mathfrak{m}\mathfrak{F})$ modulo $S(\mathfrak{m}\mathfrak{F})$ of the form $B^{1-\sigma}$ (Herbrand; Iyanaga, *J. Reine Angew. Math.*, 171 (1934)).

F. Class Field Tower Problem and Construction Problem

Furtwängler considered the following problem: Let k be a given algebraic number field, $k = k_0 \subset k_1 \subset k_2 \dots$ be the sequence of fields such that k_i is the absolute class field over k_{i-1} , and K_∞ be the union of all the k_i . Is K_∞ a finite extension of k ? The answer is yes if and only if k_n is of class number 1 for some n . This problem is called the **class field tower problem**. Artin remarked that if for every algebraic number field F of degree n we have the inequality $|D_F| > (\pi/4)^{2r_2} (n^n/n!)^2 > (\pi e^2/4)^n / (2\pi n e^{1/6n})$ for the * discriminant D_F , then K_∞/k is always finite [1, p. 46]. E. S. Golod and I. R. Shafarevich (1964) solved the class field tower problem negatively; they proved that K_∞/k is infinite if k_i ($i = 1, 2, \dots$) is the maximal unramified Abelian p -extension of k_{i-1} for a fixed prime number p and if the inequality $\gamma \geq 3 + 2\sqrt{\rho + 2}$ holds, where γ is the minimal number of generators of the p -component of the ideal class group of k and ρ is the rank of the unit group of k . (We call an extension K/k a **p -extension** if the degree $[K:k]$ is a power of a prime number p .) For example, the class field tower K_∞/k is actually infinite if k is an imaginary quadratic field ($\rho = 1$) and $\gamma \geq 7$ for $p = 2$, for example, $k = Q(\sqrt{-3 \cdot 5 \cdot 7 \cdot 11 \cdot 13 \cdot 17 \cdot 19})$.

Construction problem. Let k be a given algebraic number field and G a finite group. The construction problem asks us whether there exists a Galois extension K/k such that its Galois group $\text{Gal}(K/k)$ is isomorphic to G . If G is Abelian the problem can be solved affirmatively by using class field theory. This problem was also solved affirmatively for p -groups by A. Scholtz and H. Reinhardt in 1937, and for general solvable groups by Shafarevich in 1954 (*Izv. Akad. Nauk SSSR*, ser. mat. 18).

G. Class Field Theory for Algebraic Function Fields and Local Class Field Theory

F. K. Schmidt developed an analog of class field theory for Abelian extensions over an algebraic function field in one variable with finite coefficient field (1930; → [8]). An arithmetic proof was given by M. Moriya (1938). An analog of class field theory for local fields with finite residue-class fields, called **local class field theory** (→ 257 Local Fields) was first developed by Hasse, and later Chevalley gave an algebraic derivation (1933).

H. Cohomology of Groups and Class Field Theory

For the purpose of simplifying the proof of the main theorems in class field theory, the theory of \dagger Galois cohomology was developed by T. Nakayama, G. Hochschild, A. Weil, Artin, J. Tate, and others. In particular, Artin and Tate [9] constructed class field theory on the basis of the cohomology theory of finite groups as follows: Let G be a finite group, A a $\dagger G$ -module (or a multiplicative commutative group with the operator domain G), and $\hat{H}^n(G, A)$ the n th \dagger cohomology group ($n=0, \pm 1, \pm 2, \dots$) of G with coefficients in A (→ 200 Homological Algebra N). Then we have $\hat{H}^0(G, A) \cong A^G/N_G(A)$, where A^G is the set of all G -invariant elements in A and $N_G(A)$ is the set of all elements of the form $N_G(a) = \sum_{\sigma \in G} \sigma a$ ($a \in A$). We can consider \mathbf{Z} a G -module by defining $\sigma n = n$ ($n \in \mathbf{Z}, \sigma \in G$). Let A, B, C be G -modules such that a G -bilinear mapping $(A, B) \rightarrow C$ is defined. Then we can define the \dagger cup product $(\alpha, \beta) \rightarrow \alpha \smile \beta$ ($\alpha \in \hat{H}^r(G, A), \beta \in \hat{H}^s(G, B), \alpha \smile \beta \in \hat{H}^{r+s}(G, C)$) for $r, s \in \mathbf{Z}$ with the usual properties. Let A be a G -module and H a subgroup of G . Then the \dagger restriction homomorphism $R_{G/H}: \hat{H}^n(G, A) \rightarrow \hat{H}^n(H, A)$ and the \dagger injection homomorphism $\text{Inj}_{H/G}: \hat{H}^n(H, A) \rightarrow \hat{H}^n(G, A)$ are defined for $n \in \mathbf{Z}$. If H is a normal subgroup of G , then the \dagger inflation homomorphism $\text{Inf}_{(G/H)/G}: \hat{H}^n(G/H, A^H) \rightarrow \hat{H}^n(G, A)$ can be defined for $n \geq 1$ (→ 200 Homological Algebra M).

Let k be an algebraic number field, and let K be a Galois extension of k of degree n with the Galois group $G = G(K/k)$. The multiplicative group $K^\times = K - \{0\}$, the \dagger idele group J_K of K , and the idele class group C_K of K are multiplicative commutative groups with G as their operator domain. The fundamental formulas in Galois cohomology for class field theory are

$$\hat{H}^1(G, C_K) = 0, \quad (1)$$

$$\hat{H}^2(G, C_K) \cong \mathbf{Z}/n\mathbf{Z}. \quad (2)$$

It is possible to realize the isomorphism of (2) by the **invariant** $\text{inv}_{K/k}: \hat{H}^2(G, C_K) \xrightarrow{\sim} \{(r/n) \pmod{\mathbf{Z}} \mid r=0, 1, \dots, n-1\}$ in such a way that the following properties hold, where the **canonical cohomology class** for K/k is the element $\xi_{K/k}$ of $\hat{H}^2(G, C_K)$ such that $\text{inv}_{K/k} \xi_{K/k} = (1/n) \pmod{\mathbf{Z}}$: (i) for $k \subset l \subset K, G = G(K/k), H = G(K/l)$, the relation $\text{Res}_{G/H} \xi_{K/k} = \xi_{K/l}$ holds; (ii) if l/k is also a Galois extension with $F = G(l/k)$, then we have $\text{Inf}_{F/G} \xi_{l/k} = \xi_{K/k}^m$ ($m = [K:l]$); (iii) for a cyclic extension K/k we have $\text{inv}_{K/k} \xi_{K/k} = \sum_{\mathfrak{p}} \text{inv}_{\mathfrak{p}}(\xi_{K/k})_{\mathfrak{p}} \pmod{\mathbf{Z}}$, where \mathfrak{p} runs over all prime divisors of k and $\text{inv}_{\mathfrak{p}}$ is the invariant in the local theory (→ 257 Local Fields E). By these properties, the canonical cohomology class $\xi_{K/k}$ is uniquely determined. After these preliminaries we can state Tate's theorem, from which the fundamental theorems in class field theory follow.

Tate's theorem. Let K/k be a Galois extension with the Galois group G . Then we have the isomorphism $\Phi_n: \hat{H}^{n-2}(G, \mathbf{Z}) \cong \hat{H}^n(G, C_K)$ ($n = 0, \pm 1, \pm 2, \dots$) that is given explicitly by $\Phi_n(\alpha) = \xi_{K/k} \smile \alpha$, where $\xi_{K/k} \in \hat{H}^2(G, C_K)$ is the canonical cohomology class for K/k (*Ann. Math.*, (2) 56 (1952)).

Corollary 1. Since $\hat{H}^{-2}(G, \mathbf{Z}) \cong G/[G, G]$ and $\hat{H}^0(G, C_K) \cong C_k/N_{K/k}(C_K)$, we have the isomorphism $\Phi_0: G/[G, G] \cong C_k/N_{K/k}(C_K)$. Let $f(\tau, \sigma)$ ($\tau, \sigma \in G$) be a 2- \dagger cocycle belonging to $\xi_{K/k}$. Then by the explicit expression for the cup product we obtain the isomorphism

$$\Phi_0: \sigma \pmod{[G, G]} \rightarrow \prod_{\tau \in G} f(\tau, \sigma)^{-1} \pmod{N_{K/k}(C_K)}.$$

This is an analog of the result in local theory that was proved earlier by T. Nakayama and Y. Akizuki (*Math. Ann.*, 112 (1936)).

Corollary 2. For an Abelian extension K/k we have the isomorphism $\Phi_0: G \cong C_k/N_{K/k}(C_K)$. Φ_0^{-1} has the property of being the norm-residue symbol for C_k , and from this isomorphism we can prove immediately Artin's law of reciprocity. Thus we can prove the main theorems in class field theory by cohomology-theoretic methods [9].

We can also see, by generalizing this isomorphism to infinite Abelian extensions, that the Galois group of the maximal Abelian extension of k over the ground field k with \dagger Krull topology is algebraically and topologically isomorphic to C_k/D_k , where D_k is the connected component of the unit element in C_k . The structures of D_k and C_k/D_k were explicitly determined by Artin and T. Kubota, respectively (→ 6 Adeles and Ideles D).

If we assume the fundamental formulas (1) and (2) stated above and several other simple assumptions as axioms for an infinite ex-

tension of a fixed ground field, we can develop the results stated in this section purely cohomology-theoretically. Such a system is called a **class formation** (Artin; \rightarrow [9]). In addition to the cases of algebraic number fields, algebraic function fields in one variable with finite coefficient fields, and local fields with finite residue-class fields, which we have mentioned already, we also know several other cases for which analogies of class field theory are valid. These analogies can be explained systematically by using class formation theory (Y. Kawada, *Duke Math. J.*, 22 (1955)). Examples are (1) the theory of unramified Abelian extensions of an algebraic function field in one variable with algebraically closed constant field of characteristic 0 (Tate and Kawada, *Amer. J. Math.*, 77 (1955)); (2) the theory of Kummer extensions over a field k such that (i) the characteristic of k is 0, (ii) k contains all the roots of unity, and (iii) for any Galois extension K/k , $N_{K/k}(K) = k$; (3) the theory of Abelian p -extensions of a field of characteristic p (E. Witt, *J. Reine Angew. Math.*, 176 (1963); I. Satake and Kawada, *J. Fac. Sci. Univ. Tokyo*, 7 (1955)); (4) the theory of unramified Abelian p -extensions of an algebraic function field in one variable with algebraically closed constant field of characteristic p (Hasse and Witt, *Monatsh. Math.*, 43 (1936), H. L. Schmid, I. R. Shafarevich, Kawada, T. Tamagawa); and (5) the theory of Abelian extensions of a local field with algebraically closed residue-class fields (J.-P. Serre, *Bull. Soc. Math. France*, 89 (1961)).

An analogy of class field theory for infinite Abelian extensions was considered by Herbrand, Moriya, M. Mori, and Kawada.

60 (IV.5) Classical Groups

A. Introduction

The general linear groups, unitary groups, orthogonal groups, symplectic groups, etc., that are described below are all called **classical groups** (\rightarrow 13 Algebraic Groups, 151 Finite Groups, 248 Lie Algebras, 249 Lie Groups).

B. General Linear Groups

Let V be a \dagger linear space of dimension n over a \dagger field K , and let $GL(V)$ denote the set of all \dagger linear mappings of V onto V (hence they are

all bijections). Then $GL(V)$ is a group under the composition of mappings. This group is called the **general linear group** (or **full linear group**) on V . Let e_1, \dots, e_n be a basis of V over K , and let (α_j^i) be the matrix associated with an element A of $GL(V)$: $Ae_i = \sum_j \alpha_j^i e_j$. Then the mapping $A \rightarrow (\alpha_j^i)$ is an isomorphism of $GL(V)$ onto the multiplicative group $GL(n, K)$ of all $n \times n$ invertible matrices over K . We can thus identify the group $GL(V)$ with $GL(n, K)$. $GL(n, K)$ is called the **general linear group of degree n over K** . Consider the homomorphism $A \rightarrow |A|$ ($|A|$ is the determinant of A) of $GL(V)$ onto the multiplicative group $K^* = K - \{0\}$. Its kernel $SL(V)$ is a normal subgroup of $GL(V)$ and is called the **special linear group** (or **unimodular group**) on V . The subgroup $SL(n, K) = \{A \mid A \in GL(n, K), |A| = 1\}$ of $GL(n, K)$ corresponds to $SL(V)$ under the above isomorphism $GL(V) \cong GL(n, K)$. $SL(n, K)$ is called the **special linear group of degree n over K** . Unless $n = 2$ and K is the finite field $F_2 = GF(2)$, $SL(n, K)$ is the commutator subgroup of $GL(n, K)$. The center \mathfrak{z} of $GL(n, K)$ coincides with the set of all scalar matrices αI ($\alpha \in K^*$), and the center \mathfrak{z}_0 of $SL(n, K)$ is a finite group given by $\mathfrak{z} \cap SL(n, K) = \{\alpha I \mid \alpha \in K, \alpha^n = 1\}$.

Now let $P(V)$ be the projective space of dimension $n - 1$ obtained from a linear space V of dimension n . Namely, $P(V)$ is the set of all linear subspaces of dimension 1. Then there exists a natural homomorphism ϕ of $GL(V)$ into the group of all projective transformations of $P(V)$, and the kernel of ϕ coincides with the center \mathfrak{z} of $GL(V)$. Hence $\phi(GL(V)) \cong GL(V)/\mathfrak{z}$. This group is written as $PGL(V)$ and is called the **projective general linear group** on $P(V)$. Similarly, $PGL(n, K) = GL(n, K)/\mathfrak{z}$ is called the **projective general linear group of degree n over K** . The quotient group $SL(n, K)/\mathfrak{z}_0$ of $SL(n, K)$ by the center \mathfrak{z}_0 is called the **projective special linear group** and is written as $PSL(n, K)$ or $LF(n, K)$ (**linear fractional group**).

The groups $GL(n, K)$, $SL(n, K)$, etc., are also written as $GL_n(K)$, $SL_n(K)$, etc. In particular, when K is the finite field F_q , these groups are denoted by $GL(n, q)$, $SL(n, q)$, $PGL(n, q)$, $PSL(n, q)$, $LF(n, q)$.

Simplicity of $PSL(n, k)$. When $n = 2$ and $K = F_2$, $PSL(2, 2) \cong \mathfrak{S}_3$ (the symmetric group of degree 3). When $n = 2$ and $K = F_3$, $PSL(2, 3) \cong \mathfrak{A}_4$ (the alternating group of degree 4). Except for these cases, the group $PSL(n, K)$ ($n \geq 2$) is a noncommutative simple group (\rightarrow 151 Finite Groups I).

Suppose that K is the finite field F_q , and let $\alpha(n, q)$, $\beta(n, q)$, $\gamma(n, q)$, $\delta(n, q)$ denote the orders of $GL(n, q)$, $SL(n, q)$, $PGL(n, q)$, $PSL(n, q)$, res-

pectively. Then we have

$$\alpha(n, q) = (q^n - 1)(q^n - q) \dots (q^n - q^{n-1}),$$

$$\beta(n, q) = \gamma(n, q) = \alpha(n, q)/(q - 1),$$

$$\delta(n, q) = \gamma(n, q)/d,$$

where $d = (n, q - 1)$ (the greatest common divisor of n and $q - 1$).

C. Properties as Lie Groups

If the ground field K is the field \mathbf{R} of real numbers (the field \mathbf{C} of complex numbers), the above groups are all Lie groups (complex Lie groups). In particular, $SL(n, \mathbf{C})$ is a simply connected, simple, and semisimple complex Lie group of type A_{n-1} , and $PSL(n, \mathbf{C})$ is the adjoint group of the complex simple Lie algebra of type A_{n-1} .

D. Determination of the Rational Representations of $GL(V)$

In Sections D and E, the field K is assumed to be of characteristic 0. Let ρ be a homomorphism of $GL(V) = GL(n, K)$ into $GL(m, K)$ ($\rho: A = (\alpha_j^i) \rightarrow B = (\beta_j^i)$). Then if each β_j^i is a rational function (or polynomial or analytic function) in $(\alpha_1^1, \alpha_2^1, \dots, \alpha_n^n)$ over K , ρ is called a **rational representation** (or **polynomial** or **analytic representation**) of degree m of $GL(V)$. (We suppose that K is \mathbf{R} or \mathbf{C} when we consider analytic functions.) For example, every rational representation of degree 1 can be expressed as $A \rightarrow |A|^e$ (e is an integer). In particular, if K is the field \mathbf{C} of complex numbers, every analytic representation of $GL(n, \mathbf{C})$ is a rational representation. Since $GL(n, \mathbf{C})$ is the complexification of the unitary group $U(n)$, there exists a one-to-one correspondence between the complex analytic representations of $GL(n, \mathbf{C})$ and the continuous representations of $U(n)$; this correspondence preserves equivalence, irreducibility, tensor product, and direct sum of the representations (\rightarrow 249 Lie Groups). Hence, determining the rational representations of $GL(n, \mathbf{C})$ is equivalent to determining the continuous representations of $U(n)$. In the general case, the rational representations of $GL(V) = GL(n, K)$ are all completely reducible. For any rational representation ρ of $GL(V)$, there exists a natural number e such that the representation $\rho': A \rightarrow |A|^e \rho(A)$ is a polynomial representation. Hence in order to determine the rational representations of $GL(V)$, it is sufficient to determine the irreducible polynomial representations of $GL(V)$, which, as described below, can be obtained by decomposing the representations on the tensor space

$V^m = V \otimes \dots \otimes V$ of degree m (m copies of V) ($m = 1, 2, \dots$). For $A \in GL(V)$, define $D_m(A) \in GL(V^m)$ as the tensor product

$$D_m(A) = A \otimes \dots \otimes A \text{ (} m \text{ copies of } A \text{)}.$$

Namely, for $v_1, \dots, v_m \in V$, we have

$$D_m(A)(v_1 \otimes \dots \otimes v_m) = Av_1 \otimes \dots \otimes Av_m.$$

The mapping $GL(V) \ni A \rightarrow D_m(A) \in GL(V^m)$ is a polynomial representation of degree n^m of $GL(V)$. Now let $\mathfrak{Q}(V^m)$ be the \dagger associative algebra of all linear mappings of V^m into V^m (\dagger total matrix algebra), and let \mathfrak{A} be the subalgebra of $\mathfrak{Q}(V^m)$ generated by $\{D_m(A) \mid A \in GL(V)\}$. Next, for an element σ of the symmetric group \mathfrak{S}_m of degree m , define $B_\sigma \in GL(V^m)$ by $B_\sigma(v_1 \otimes \dots \otimes v_m) = v_{\sigma^{-1}(1)} \otimes \dots \otimes v_{\sigma^{-1}(m)}$. Then the mapping $\sigma \rightarrow B_\sigma$ is a representation of \mathfrak{S}_m on V^m . Thus we obtain a representation τ of the \dagger group ring $K[\mathfrak{S}_m]$ of \mathfrak{S}_m over K on $V^m: K[\mathfrak{S}_m] \rightarrow \mathfrak{Q}(V^m)$. Set $\tau(K[\mathfrak{S}_m]) = \mathfrak{B}$. Then \mathfrak{A} and \mathfrak{B} are \dagger commutators of each other in $\mathfrak{Q}(V^m)$, i.e., $\mathfrak{A} = \{X \in \mathfrak{Q}(V^m) \mid XB = BX \text{ (for all } B \in \mathfrak{B})\}$, $\mathfrak{B} = \{X \in \mathfrak{Q}(V^m) \mid AX = XA \text{ (for all } A \in \mathfrak{A})\}$.

Now for a right ideal \mathfrak{r} of \mathfrak{B} , let $\mathfrak{r}(V^m)$ be the subspace of V^m composed of all the finite sums of the form $\sum Bx$ ($B \in \mathfrak{r}, x \in V^m$). Then the following statements hold:

(1) $\mathfrak{r}(V^m)$ is invariant under \mathfrak{A} ; hence it is a subspace of V^m invariant under $GL(V)$. Conversely, for any subspace U of V^m invariant under $GL(V)$, there exists a unique right ideal \mathfrak{r} of \mathfrak{B} such that $U = \mathfrak{r}(V^m)$.

(2) Let $\mathfrak{r}_1, \mathfrak{r}_2$ be right ideals of \mathfrak{B} , and put $U_1 = \mathfrak{r}_1(V^m)$, $U_2 = \mathfrak{r}_2(V^m)$. Then $\mathfrak{r}_1 \cong \mathfrak{r}_2$ (as right \mathfrak{S}_m -modules) if and only if $U_1 \cong U_2$ (as representation spaces of $GL(V)$).

(3) The mapping $\mathfrak{r} \rightarrow \mathfrak{r}(V^m)$ is a lattice isomorphism of the \dagger lattice of right ideals of \mathfrak{B} onto the lattice of $GL(V)$ -invariant subspaces of V^m . Hence if $\mathfrak{r} = \mathfrak{r}_1 + \mathfrak{r}_2$ (direct sum), then $U = U_1 + U_2$ (direct sum). Also, $\mathfrak{r}(V^m)$ gives an irreducible representation of $GL(V)$ if and only if \mathfrak{r} is a minimal right ideal of \mathfrak{B} .

Since the algebra $K[\mathfrak{S}_m]$ is a \dagger semisimple algebra, \mathfrak{B} can be considered as a two-sided ideal of $K[\mathfrak{S}_m]$. Hence a minimal right ideal \mathfrak{r} of \mathfrak{B} is also a minimal right ideal of $K[\mathfrak{S}_m]$, and the \dagger idempotent element ε which generates \mathfrak{r} is a \dagger primitive idempotent of $K[\mathfrak{S}_m]$. From the theory of symmetric groups (\rightarrow 362 Representations H) the primitive idempotents of $K[\mathfrak{S}_m]$ are all given (up to isomorphism) by \dagger Young's diagrams $T(f_1, \dots, f_k)$ ($f_1 \geq f_2 \geq \dots \geq f_k > 0$, $m = f_1 + \dots + f_k$). In this setting, we have

(4) Let $\varepsilon = \varepsilon(f_1, \dots, f_k)$ be the primitive idempotent determined by Young's diagram $T(f_1, \dots, f_k)$. Then $\varepsilon K[\mathfrak{S}_m] \subset \mathfrak{B}$ if and only if $k \leq n$. In this case, put $\varepsilon K[\mathfrak{S}_m] = \mathfrak{r}$, $\mathfrak{r}(V^m) =$

$\varepsilon(V^m) = V^m(T(f_1, \dots, f_k))$ and denote the irreducible representation of $GL(V)$ on $V^m(T(f_1, \dots, f_k))$ by $A \rightarrow D(A; f_1, \dots, f_k)$. We call (f_1, \dots, f_k) the **signature** of this irreducible representation.

(5) The representation $D(A; f_1, \dots, f_k)$ is an irreducible polynomial representation of $GL(V)$. Furthermore, for any irreducible polynomial representation ρ of $GL(V)$, there exists a unique $D(A; f_1, \dots, f_k)$ equivalent to ρ . For example, if $k = 1$, then $f_1 = m$, $\varepsilon = (m!)^{-1} \sum_{\sigma \in \mathfrak{S}_m} \sigma$, and $V^m(T(m))$ is the space of \dagger symmetric tensors of degree m . If $f_1 = \dots = f_k = 1$, then $k = m$, $\varepsilon = (m!)^{-1} \sum_{\sigma \in \mathfrak{S}_m} (\text{sgn } \sigma) \sigma$, and $V^m(T(1, \dots, 1))$ is the space of \dagger alternating tensors of degree m .

(6) Let $\chi(A; f_1, \dots, f_k)$ be the \dagger character of the irreducible representation $D(A; f_1, \dots, f_k)$. Then

$$\chi(A; f_1, \dots, f_k) = \begin{vmatrix} \varepsilon_1^{l_1} & \varepsilon_1^{l_2} & \dots & \varepsilon_1^{l_n} \\ \dots & \dots & \dots & \dots \\ \varepsilon_n^{l_1} & \varepsilon_n^{l_2} & \dots & \varepsilon_n^{l_n} \end{vmatrix} \div \begin{vmatrix} \varepsilon_1^{n-1} & \varepsilon_1^{n-2} & \dots & \varepsilon_1 & 1 \\ \dots & \dots & \dots & \dots & \dots \\ \varepsilon_n^{n-1} & \varepsilon_n^{n-2} & \dots & \varepsilon_n & 1 \end{vmatrix},$$

where $\varepsilon_1, \dots, \varepsilon_n$ are the \dagger eigenvalues of A and $l_1 = f_1 + (n-1)$, $l_2 = f_2 + (n-2)$, \dots , $l_n = f_n$ (set $f_{k+1} = \dots = f_n = 0$). Hence the degree d of $D(A; f_1, \dots, f_k)$ is expressed as

$$d = D(l_1, \dots, l_n) / D(n-1, \dots, 1, 0),$$

where $D(x_1, \dots, x_n) = \prod_{i < j} (x_i - x_j)$.

(7) In particular, denote the character of $D(A; m)$ by $p_m = p_m(A)$. Then they satisfy $|I - zA|^{-1} = p_0 + p_1 z + p_2 z^2 + \dots$ and

$$\chi(A; f_1, \dots, f_k) = \begin{vmatrix} p_{f_1} & p_{f_1+1} & \dots & p_{f_1+(n-1)} \\ p_{f_2-1} & p_{f_2} & \dots & p_{f_2+(n-2)} \\ \dots & \dots & \dots & \dots \\ p_{f_n-(n-1)} & p_{f_n-(n-2)} & \dots & p_{f_n} \end{vmatrix},$$

where we put $f_{k+1} = f_{k+2} = \dots = f_n = 0$, $p_{-1} = p_{-2} = \dots = 0$. This matrix is simply written as $|p_{l_i - (n-1)}, \dots, p_{l_i}|$, with the convention that in each row, we set $l_1 = f_1 + (n-1)$, \dots , $l_{n-1} = f_{n-1} + 1$, $l_n = f_n$.

E. Determination of the Rational Representations of $SL(V)$

The rational representations of $SL(V)$ are completely reducible. By restricting any irreducible representation $D(A; f_1, \dots, f_n)$ ($f_1 \geq f_2 \geq \dots \geq f_n \geq 0$) of $GL(V)$ to $SL(V)$, we get an irreducible rational representation $\tilde{D}(A; f_1, \dots, f_n)$ of $SL(V)$. Furthermore, any irreducible rational representation of $SL(V)$

can be obtained in this way. $\tilde{D}(A; f_1, \dots, f_n)$ and $\tilde{D}(A; f'_1, \dots, f'_n)$ are equivalent representations of $SL(V)$ if and only if $f_i - f_{i+1} = f'_i - f'_{i+1}$ ($i = 1, \dots, n-1$).

F. Unitary Groups

The set $U(n)$ of all $n \times n$ \dagger unitary matrices with complex elements is a group under multiplication (\rightarrow 269 Matrices). This group $U(n)$ is called the **unitary group** (or **unitary transformation group**) of degree n . The subset of $U(n)$ consisting of all matrices of determinant 1 is a normal subgroup of $U(n)$. This group is called the **special unitary group** and is denoted by $SU(n)$.

$U(n)$ and $SU(n)$ are subgroups of $GL(n, \mathbb{C})$ and $SL(n, \mathbb{C})$, respectively, and can be obtained from these groups through the \dagger unitary restriction. Hence they are both compact, connected Lie groups; in particular, $SU(1)$ is composed only of the identity and $U(1)$ is the multiplicative group of all complex numbers of absolute value 1. The center \mathfrak{z} of $U(n)$ is the set of all diagonal matrices λI ($\lambda \in \mathbb{C}, |\lambda| = 1$), and we have

$$\mathfrak{z} \cong U(1), \quad \mathfrak{z} \cdot SU(n) = U(n),$$

$$U(n)/SU(n) \cong U(1).$$

Moreover, for $n \geq 2$, $SU(n)$ is a simple, semi-simple, and simply connected Lie group, which gives one of four infinite series of simple compact Lie groups.

$U(n)/\mathfrak{z}$ is denoted by $PU(n)$ and is called the **projective unitary group**. We have the relations $PU(n) \cong SU(n)/\mathfrak{z} \cap SU(n)$, $\mathfrak{z} \cap SU(n) \cong \mathbb{Z}/n\mathbb{Z}$. Hence $PU(n)$ is locally isomorphic to $SU(n)$.

G. Irreducible Representations of $U(n)$

Restricting the irreducible representation $D(A; f_1, \dots, f_k)$ of $GL(n, \mathbb{C})$ on $SU(n)$, we obtain a continuous irreducible representation of $SU(n)$, and conversely, all continuous irreducible representations of $SU(n)$ are obtained in this manner. Similarly, any continuous irreducible representations of $U(n)$ are given by $A \rightarrow |A|^e D(A; f_1, \dots, f_k)$, where e is an integer. Since both $U(n)$ and $SU(n)$ are compact, any continuous representation of these groups can be decomposed into a direct sum of the irreducible representations mentioned above (\rightarrow 69 Compact Groups).

The representation theory of $U(n)$ and $SU(n)$ is important as the most typical and concrete example of the representation theory of general compact Lie groups (\rightarrow 69 Compact Groups, 248 Lie Algebras, 249 Lie Groups).

H. Unitary Groups over General Fields

A unitary matrix and the unitary group can also be defined over some fields other than the field \mathbb{C} of complex numbers. Namely, let P be a field and K a quadratic extension field of P ; for an element ξ of K , let $\bar{\xi}$ be the \dagger conjugate of ξ over P . Then a matrix of degree n with entries in K is called a unitary matrix of K (relative to P) if it leaves invariant the \dagger Hermitian form $\xi_1 \bar{\xi}_1 + \xi_2 \bar{\xi}_2 + \dots + \xi_n \bar{\xi}_n$. The multiplicative group consisting of all unitary matrices is called the **unitary group over K** (relative to P) and is denoted by $U(n, K, P)$; its subgroup consisting of all unitary matrices of determinant 1 is called the **special unitary group over K** and is denoted by $SU(n, K, P)$. The quotient group of $SU(n, K, P)$ by its subgroup consisting of all λI ($\lambda^n = 1, |\lambda| = 1$) is called the **projective special unitary group over K** and is denoted by $PSU(n, K, P)$. In particular, when K and P are the finite fields \mathbb{F}_{q^2} and \mathbb{F}_q ($q = p^m$), $U(n, K, P)$, $SU(n, K, P)$, $PSU(n, K, P)$ are written simply as $U(n, q)$, $SU(n, q)$, $PSU(n, q)$. Then for $n \geq 3$, each $PSU(n, q)$ is a noncommutative simple group, except for $PSU(3, 2)$ (\rightarrow 151 Finite Groups I).

I. Orthogonal Groups

The set of all \dagger orthogonal matrices of degree n (with real entries) forms a group under multiplication. This group $O(n)$ is called the **orthogonal group** (or **orthogonal transformation group**) of degree n . The subset of $O(n)$ consisting of all orthogonal matrices of determinant 1 forms a normal subgroup of $O(n)$ of index 2. This group $SO(n)$ (also denoted by O_n^+) is called the **rotation group** (**special orthogonal group** or **proper orthogonal group**) of degree n . Geometrically, $O(n)$ is the set of all orthogonal transformations leaving a point in Euclidean space of dimension n fixed, and $SO(n)$ is composed of all rotations around the point.

Both $O(n)$ and $SO(n)$ are compact Lie groups, and $SO(n)$ coincides with the connected component of $O(n)$ which contains the identity. For $n = 3$ or $n \geq 5$, each $SO(n)$ is a simple and semisimple Lie group. Following the theory of Lie algebras, we divide the set of all $SO(n)$ ($n \geq 3$ but $n \neq 4$) into two classes according as n is even or odd, and we thus get two of the four infinite series of simple and semisimple compact Lie groups (for $SO(4)$, for example, see [1]).

Although $SO(n)$ ($n \geq 3$) is a connected Lie group, it is not simply connected. The simply connected Lie group which is locally isomorphic to $SO(n)$ is called the **spinor group** and is denoted by $Spin(n)$. $SO(n)$ is isomorphic to the

quotient group of $Spin(n)$ by a normal subgroup of order 2. Let z be the center of $Spin(n)$. Then $z \cong \mathbb{Z}/2\mathbb{Z}$ for odd n , $z \cong \mathbb{Z}/4\mathbb{Z}$ for $n \equiv 2 \pmod{4}$, and $z \cong (\mathbb{Z}/2\mathbb{Z}) \oplus (\mathbb{Z}/2\mathbb{Z})$ for $n \equiv 0 \pmod{4}$ (\rightarrow 61 Clifford Algebras).

The group $O(n, \mathbb{C})$ of all \dagger complex orthogonal matrices is called the **complex orthogonal group**, and the group $SO(n, \mathbb{C})$ of all matrices in $O(n, \mathbb{C})$ of determinant 1 is called the **complex special orthogonal group**. $SO(n, \mathbb{C})$ ($n \geq 3, n \neq 4$) is a simple and semisimple complex Lie group.

J. Irreducible Representations of Orthogonal Groups

In the same way as for $GL(n, K)$, the irreducible representations of $O(n)$ can be obtained by decomposing the tensor product $D_m(A) = A \otimes \dots \otimes A$ of m copies of an orthogonal matrix A using Young's diagram. Namely, consider the Young's diagram $T(f_1, f_2, \dots, f_k)$ such that the sum of the lengths of the first column and of the second column is not greater than n , and call it an $O(n)$ diagram. Then to any $O(n)$ diagram $T = T(f_1, \dots, f_k)$, there corresponds an absolutely irreducible representation $D^0(A; f_1, f_2, \dots, f_k)$, and the representations $D^0(A; f_1, f_2, \dots, f_k)$ corresponding to two distinct $O(n)$ diagrams are mutually inequivalent. $D_m(A)$ can be decomposed into the direct sum of those representations $D^0(A; f_1, f_2, \dots, f_k)$ such that $f = f_1 + \dots + f_k$ takes the values $m, m-2, m-4, \dots$. Furthermore, any continuous irreducible representation of $O(n)$ is equivalent to a $D^0(A; f_1, f_2, \dots, f_k)$ obtained from some $O(n)$ diagram $T = T(f_1, f_2, \dots, f_k)$.

In general, two $O(n)$ diagrams T and T' are called **mutually associated diagrams** if the sum of the lengths of their first columns is equal to n and if the lengths of each column other than the first one coincide. In particular, if $T = T(f_1, f_2, \dots, f_k)$ and $2k = n$, then T is said to be self-associated. The set of all $O(n)$ diagrams can be divided into pairs of mutually associated T, T' (and self-associated $T = T'$). Suppose that we are given mutually associated diagrams T and T' and that the length k of the first column of $T = T(f_1, f_2, \dots, f_k)$ is not greater than $n/2$. Then the character $\chi_T(A)$ of $D^0(A; f_1, f_2, \dots, f_k)$ corresponding to T and the character $\chi_{T'}(A)$ of the irreducible representation corresponding to T' are given by

$$\chi_T(A) = |p_{l-(v-1)} - p_{l-(v+1)}|,$$

$$p_{l-(v-2)} - p_{l-(v+2)}, \dots, p_l - p_{l-2v},$$

$$\chi_{T'}(A) = |A| \chi_T(A), \quad v = [n/2],$$

where p_i and $|p_{l-(v-1)} - p_{l-(v+1)}, \dots|$ have the same meaning as in the formula for the char-

acters of irreducible representations of $GL(n, K)$.

The irreducible representations of $SO(n)$ can be obtained immediately from those of $O(n)$. Namely, if $T = T(f_1, f_2, \dots, f_k)$ is not self-associated, $D^0(A; f_1, f_2, \dots, f_k)$ is irreducible as a representation of $SO(n)$, and the representations of $SO(n)$ derived from T and the associated T' coincide. If T is self-associated, $D^0(A; f_1, f_2, \dots, f_k)$ can be decomposed into two irreducible representations of $SO(n)$ of the same degree over the field of complex numbers. Furthermore, the irreducible representations of $SO(n)$ obtained in this way from different pairs of associated diagrams are mutually inequivalent, while any continuous irreducible representation of $SO(n)$ is equivalent to one of these representations. For the representations of $SO(3)$ (the rotation group of degree 3) \rightarrow 353 Racah Algebra.

Since $SO(n)$ is isomorphic to the quotient group of $Spin(n)$ by a normal subgroup N of order 2, a continuous representation of $Spin(n)$ which is not the identity representation on N can be considered as a double-valued representation of $SO(n)$. This representation is called the **spin representation** and is important in the field of applied mathematics.

The orthogonal group $O(n)$ consists of all $n \times n$ real matrices which leave invariant the quadratic form $\xi_1^2 + \dots + \xi_n^2$, while the group of all $n \times n$ real matrices which leave invariant the quadratic form $\xi_1^2 + \dots + \xi_r^2 - \xi_{r+1}^2 - \dots - \xi_n^2$ of \dagger signature $(r, n-r)$ is called the **Lorentz group** of signature $(r, n-r)$. The case for $n=4$ and $r=3$ is used in special relativity (\rightarrow 359 Relativity). Let G_0 be the connected component of the identity of the Lorentz group of signature $(3, 1)$. Then G_0 is called the **proper Lorentz group**. For $\sigma = (g_{ij}) \in G$, we have $|\sigma| = \pm 1$ and $g_{44} \geq 1$ or $g_{44} \leq -1$. Moreover, we have $G_0 = \{\sigma \mid |\sigma| = 1, g_{44} \geq 1\}$, $G/G_0 \cong (\mathbb{Z}/2\mathbb{Z}) \oplus (\mathbb{Z}/2\mathbb{Z})$ (\dagger four group), and $G_0 \cong SL(2, \mathbb{C})/\{\pm I\}$.

K. Orthogonal Groups over General Fields

Orthogonal groups can also be defined over other general fields than the field of real numbers as follows: Fix a \dagger quadratic form $Q(\xi, \xi) = \sum_{i,j=1}^n \alpha_{ij} \xi_i \xi_j$ ($|\alpha_{ij}| \neq 0$) over a field K . Then a linear transformation of ξ_i ($i=1, 2, \dots, n$) over K which leaves Q invariant is called an **orthogonal transformation** with respect to Q . The set of all orthogonal transformations forms a group. This group is denoted by $O(n, K, Q)$ or simply $O(Q)$ and is called the **orthogonal (transformation) group over K with respect to Q** . In particular, the normal subgroup of all transformations in $O(n, K, Q)$ of determinant 1 is called the **special orthogonal group over K with**

respect to Q and is denoted by $SO(n, K, Q)$ (or simply $SO(Q)$). $O(n)$ and $SO(n)$ are special cases of $O(n, K, Q)$ and $SO(n, K, Q)$, where K is the field \mathbf{R} of real numbers and $Q(\xi, \xi)$ is the unit quadratic form $\xi_1^2 + \xi_2^2 + \dots + \xi_n^2$.

Let $\Omega(n, K, Q)$ be the \dagger commutator subgroup of $O(n, K, Q)$. Then this subgroup coincides with the commutator subgroup of $SO(n, K, Q)$. If K is of characteristic $\neq 2$, and if $n \geq 5$ and the \dagger index v of $Q \geq 1$, then $\Omega(n, K, Q)/3$ (3 is the center of $\Omega(n, K, Q)$) is a simple group, where $3 = \{I\}$ or $3 = \{\pm I\}$ (L. Dickson, J. Dieudonné). Suppose that K is a finite field F_q (of characteristic $\neq 2$). Then we have $v = m$ if $n = 2m + 1$, and $v = m$ or $m - 1$ if $n = 2m$. Hence $v \geq 2$ if $n \geq 5$. If $v = 0$ and $K = \mathbf{R}$, we have $\Omega(n, \mathbf{R}, Q) = SO(n)$ and, as mentioned before, $SO(n)/3$ is simple for $n \geq 5$. The same proposition also holds when K is an \dagger algebraic number field (M. Kneser, 1956). If K is of characteristic 2, then $O(n, K, Q) = SO(n, K, Q)$, $3 = \{I\}$, and $\Omega(n, K, Q)$ is a simple group in many cases (Dieudonné [5]). For the case where K is a finite field (Dickson) \rightarrow 151 Finite Groups I.

L. Symplectic Groups

Let $\xi_1, \xi_2, \dots, \xi_{2n}$ and $\eta_1, \eta_2, \dots, \eta_{2n}$ be two sets of variables, and suppose that the same linear transformation A over a field K acts on them (from the left). If A leaves the \dagger bilinear form $\sum_{i=1}^n (\xi_{2i-1}\eta_{2i} - \xi_{2i}\eta_{2i-1})$ invariant, this linear transformation (or the corresponding matrix) A is called a **symplectic transformation (symplectic matrix)** of degree $2n$. The set of all symplectic transformations (or matrices) of degree $2n$ over K forms a group denoted by $Sp(n, K)$ and called the **symplectic group (symplectic transformation group, complex group, or Abelian linear group) over K** .

Any matrix in $Sp(n, K)$ is always of determinant 1, and the center 3 of $Sp(n, K)$ consists of I and $-I$. The quotient group $PSp(n, K)$ of $Sp(n, K)$ by 3 is called the **projective symplectic group over K** . Except for the three cases $n = 1$, $K = F_2$; $n = 1$, $K = F_3$; and $n = 2$, $K = F_2$, the group $PSp(n, K)$ ($n \geq 1$) is always simple.

Properties of Symplectic Groups as Lie Groups.

When K is the field \mathbf{C} of complex numbers or the field \mathbf{R} of real numbers, $Sp(n, K)$ is a Lie group. The intersection of the **complex symplectic group** $Sp(n, \mathbf{C})$ and the unitary group $U(2n)$, namely, the unitary restriction of $Sp(n, \mathbf{C})$, is denoted by $Sp(n)$ and is called the **unitary symplectic group** (or simply **symplectic group**). $Sp(n, \mathbf{C})$ is a simple and semisimple complex Lie group, and both $Sp(n, \mathbf{R})$ and $Sp(n)$ are simple and semisimple Lie groups. Moreover, $Sp(n)$ is compact and simply con-

nected and gives one of the four series of simple, semisimple and compact Lie groups (\rightarrow 249 Lie Groups).

Let \mathbf{H}^n be the linear space of dimension n over the \dagger quaternion field \mathbf{H} . Define the inner product of two elements $x = (x_1, \dots, x_n)$ and $y = (y_1, \dots, y_n)$ in \mathbf{H}^n by $(x, y) = x_1 \bar{y}_1 + \dots + x_n \bar{y}_n$ (\bar{y}_i is the \dagger conjugate quaternion of y_i), and consider the group of all linear transformations which leave this inner product invariant. Then this group is isomorphic to $Sp(n)$. $Sp(n)$ is thus compared with the orthogonal group $O(n)$, which leaves invariant the inner product of a linear space over the field \mathbf{R} of real numbers and with the unitary group $U(n)$, which has the same property over the field \mathbf{C} of complex numbers (C. Chevalley [4, ch. 1]).

M. Irreducible Representations of Symplectic Groups

In the same way as for $GL(n, K)$, the representation $D_m(A) = A \otimes \dots \otimes A$ (tensor product of m copies of A) of $Sp(n, \mathbf{C})$ can be decomposed into irreducible components using Young's diagram. Namely, for any Young's diagram $T = T(f_1, f_2, \dots, f_k)$ ($k \leq n$) such that the number k of rows is not greater than n , an irreducible representation $D^s(A; f_1, \dots, f_k)$ of $Sp(n, \mathbf{C})$ is determined. These $D^s(A; f_1, \dots, f_k)$ are mutually inequivalent, and $D_m(A)$ can be decomposed into the direct sum of representations $D^s(A; f_1, f_2, \dots, f_k)$ such that $f = f_1 + \dots + f_k$ is equal to any of the values $m, m-2, m-4, \dots$. The character of $D^s(A; f_1, f_2, \dots, f_k)$ is given by

$$\chi_T(A) = |p_{l-n+1}, p_{l-n+2}, p_{l-n}, \dots, p_l + p_{l-2n+2}|,$$

where p_i and $|p_{l-n+1}, p_{l-n+2}, p_{l-n}, \dots|$ have the same meaning as in the formula for the characters of the irreducible representations of $GL(n, K)$.

For the matrices A in $Sp(n)$, $D^s(A; f_1, f_2, \dots, f_k)$ gives rise to a continuous irreducible representation of $Sp(n)$. Furthermore, any continuous irreducible representation of $Sp(n)$ is equivalent to a representation $D^s(A; f_1, f_2, \dots, f_k)$ corresponding to some diagram T .

N. Relations among Various Classical Groups

There are some isomorphisms (homomorphisms) among the classical groups mentioned above. For general fields $K \rightarrow$ [1, 5]. For finite fields $K \rightarrow$ 151 Finite Groups I. For $K = \mathbf{R}$ or \mathbf{C} , the following isomorphisms hold: $SO(3) \cong SU(2)/\{\pm I\}$, $SU(2) \cong Sp(1)$, $SO(5) \cong Sp(2)/\{\pm I\}$, $SO(6) \cong SO(4)/\{\pm I\}$ (\rightarrow 248 Lie Algebras, 249 Lie Groups).

O. Classical Groups over Noncommutative Fields

Let V be a right linear space over a noncommutative field K . Then the set of all linear transformations of V forms a group under the multiplication defined by the composition of mappings. This group $GL(V)$ is called the **general linear group** on V . It is isomorphic to the multiplicative group of all $n \times n$ invertible matrices with entries in K . The commutator subgroups $SL(V)$ and $SL(n, K)$ of $GL(V)$ and $GL(n, K)$, respectively, are called the **special linear group** of degree n on V and over K , respectively. Now, suppose that an element A of $GL(V)$ leaves each element of a subspace U of dimension $n-1$ of V fixed. Choose an element x of V which does not belong to U , and set $Ax \equiv x\alpha \pmod{U}$; $\alpha \in K$ depends not only on A but also on the choice of x . However, the conjugate class $\dot{\alpha} = \{\lambda\alpha\lambda^{-1} \mid \lambda \in K^*\}$ of α in the multiplicative group K^* of K is determined only by A . In particular, if $\dot{\alpha} = \{1\}$ and $A \neq I$, then A is called a **transvection**. For a \dagger matrix unit E_{ij} , $B_{ij}(\alpha) = I + \alpha E_{ij}$ is a transvection if $i \neq j$ and $\alpha \neq 0$. $SL(V)$ coincides with the subgroup of $GL(V)$ generated by all transvections. This fact also holds when K is a commutative field, except when $n=2$ and $K = \mathbb{F}_2$. In this case, transvections generate the whole $GL(2, 2)$, which is isomorphic to the symmetric group \mathfrak{S}_3 of degree 3 and does not coincide with the commutator subgroup. The center \mathfrak{z} of $GL(n, K)$ consists of all scalar matrices corresponding to nonzero elements in the center of K . Let C be the commutator subgroup of the multiplicative group K^* of K . Then for $n \geq 2$, $GL(n, K)/SL(n, K)$ is isomorphic to K^*/C . This isomorphism can be obtained by appropriately defining, for $A \in GL(n, K)$, an element $\det A$ of K^*/C which is called the **determinant** of A [6, 9]. The center \mathfrak{z}_0 of $SL(n, K)$ is $\{\alpha I \mid \alpha^n \in C\}$. The quotient group $PSL(n, K) = SL(n, K)/\mathfrak{z}_0$ is called the **projective special linear group** of degree n over K . If K is a noncommutative field, then $PSL(n, K)$ ($n \geq 2$) is always a simple group [5, 8].

Next, let K be any field (commutative or noncommutative), and let V be a right linear space of dimension n over K . Consider a Hermitian form $f(x, y)$ (\rightarrow 256 Linear Spaces) on V relative to an \dagger involution J of K . If for a fixed element ε in the center of K we have $f(x, y) = \varepsilon f(y, x)$, then f is called an **ε -Hermitian form**. For the rest of this article, f is assumed to be an ε -Hermitian form on V . Let W be a subspace of V . If $f(x, y) = 0$ for any $x, y \in W$, then W is called a **totally isotropic subspace**. The largest dimension m of the totally isotropic subspaces of V is called the **index** of f . We always have $2m \leq n$. If $f(Ax, Ay) = f(x, y)$

for any $x, y \in V$, then A is called a **unitary transformation** relative to f .

The set $U(n, K, f)$ of all unitary transformations relative to f forms a subgroup of $GL(V)$. This group is called the **unitary group** relative to f . Also, the group $SU(n, K, f) = U(n, K, f) \cap SL(n, K)$ is called the **special unitary group**. When $J = 1$ and $\varepsilon = 1$, a unitary transformation (unitary group) is called an **orthogonal transformation (orthogonal group)**, and $U(n, K, f)$ is written as $O(n, K, f)$. Also, when $J = 1$ and $\varepsilon = -1$, a unitary transformation (unitary group) is called a **symplectic transformation (symplectic group)**, and $U(n, K, f)$ is written as $Sp(n, K)$. In fact, in these cases, for arbitrary choice of f , the corresponding groups are mutually isomorphic.

An ε -Hermitian form f is called an **ε -trace form** if for any $x \in V$, there exists an $\alpha \in K$ which satisfies $f(x, x) = \alpha + \varepsilon\alpha^J$. If $J = 1$, $\varepsilon = -1$ (hence K is commutative) or $\varepsilon = 1$ and K is of characteristic $\neq 2$, then any ε -Hermitian form is an ε -trace form. If f is an ε -trace form, a linear mapping B of any subspace W of V into V such that for any $x, y \in W$, $f(Bx, By) = f(x, y)$ can be extended to an element A of the unitary group $U(n, K, f)$ relative to f (**Witt's theorem**). In particular, $U(n, K, f)$ acts transitively on the maximal totally isotropic subspaces, and their dimensions are equal to the index m of f . Now, let P be a **Pythagorean ordered field** (an ordered field which contains square roots of any positive element). If $K = P$ and $J = 1$, or if $K = P(\sqrt{-1})$, or if the noncommutative field K is a \dagger quaternion algebra over P and J is the operation of \dagger conjugation of K , then for two Hermitian forms f, f' , their unitary groups $U(n, K, f)$ and $U(n', K, f')$ are isomorphic if and only if $n = n'$, and the indices of f and f' are equal. In this case, $U(n, K, f)$ can be written as $U(n, m, K)$, where m is the index of f . If the field K is a \dagger quaternion algebra over P and f is an \dagger anti-Hermitian form, there exists an orthogonal basis (e_i) of V such that $f(e_i, e_i) = j$ (quaternion unit), $1 \leq i \leq n$. Hence, in this case, the unitary group $U(n, K, f)$ relative to f is determined only by n and K .

Suppose that we are given an ε -trace form f over a general field K whose index m is not equal to 0. We exclude the case where $J = 1$ and $\varepsilon = 1$. Then the unitary group $U(n, K, f)$ contains transvections. Let $T(n, K, f)$ denote the subgroup of $U(n, K, f)$ generated by transvections which are unitary transformations. If $m \geq 2$, then $T(n, K, f)$ is the commutator subgroup of $U(n, K, f)$. The center W_n of $T(n, K, f)$ coincides with the intersection of $T(n, K, f)$, and the center \mathfrak{z} of $GL(n, K)$. If $n \geq 3$ and K contains more than 25 elements, then the quotient group $T(n, K, f)/W_n$ is a simple group [6]. Also, if K is commutative and $n \geq 2$, $m \geq 1$,

$J \neq 1$, then $T(n, K, f) = SU(n, K, f)$, except for the case where $n = 3$, $K = \mathbf{F}_4$.

If K is the field \mathbf{R} of real numbers, the field \mathbf{C} of complex numbers, or the quaternion field \mathbf{H} , then $GL(n, K)$, $SL(n, K)$, and $U(n, K, f)$ are all Lie groups. In particular, $SL(n, K)$ and $U(n, K, f)$ are simple Lie groups except in the following three cases: (1) $n = 1$, $K = \mathbf{R}$ or \mathbf{C} ; (2) $n = 2$, $K = \mathbf{R}$, $J = 1$, $\varepsilon = 1$; (3) $n = 4$, $K = \mathbf{R}$ or \mathbf{C} , $J = 1$, $\varepsilon = 1$, $m = 2$. In cases (1) and (2) they are commutative groups, and in case (3) they are locally direct sums of two noncommutative simple groups.

Suppose that $K = \mathbf{H}$. Since \mathbf{H} contains \mathbf{C} as a subfield, a vector space V of dimension n over \mathbf{H} has the structure of a vector space of dimension $2n$ over \mathbf{C} . From this fact, $GL(n, \mathbf{H})$ can be considered as a subgroup of $GL(2n, \mathbf{C})$ in a natural way.

Each of the complex classical simple groups $G = SL(n, \mathbf{C})$, $SO(n, \mathbf{C})$, $Sp(n, \mathbf{C})$ has the structure of an \dagger algebraic group defined over \mathbf{R} (\rightarrow 13 Algebraic Groups). The **real forms** of G , i.e., the algebraic subgroups of G whose scalar extension to \mathbf{C} is G , can be realized as $SL(n, K)$, $U(n, K, f)$ corresponding to $K = \mathbf{R}, \mathbf{C}, \mathbf{H}$. Namely, a real form of a complex classical group G is conjugate in G to one of the following groups: (i) The real forms of $SL(n, \mathbf{C})$: $SL(n, \mathbf{R})$ (type AI); $SL(k, \mathbf{H})$ only for $n = 2k$ (type AII); and the special unitary group $SU(n, m, \mathbf{C})$, $0 \leq m \leq [n/2]$, relative to a Hermitian form f of index m (type AIII). (ii) The real forms of $SO(2n+1, \mathbf{C})$: the proper orthogonal group $SO(2n+1, m, \mathbf{R})$, $0 \leq m \leq n$, relative to a quadratic form of index m on a space of dimension $2n+1$ (type BI and BII). (iii) The real forms of $SO(2n, \mathbf{C})$: $SO(2n, m, \mathbf{R})$, $0 \leq m \leq n$ (type DI and DII); and $U(n, H, f)$ relative to an anti-Hermitian form f on \mathbf{H} (type DIII). (iv) The real forms of $Sp(n, \mathbf{C})$: $Sp(n, \mathbf{R})$ (type CI); the unitary group $U(2n, m, \mathbf{H})$, $0 \leq m \leq n$, relative to a Hermitian form f of index m on \mathbf{H} (type CII); and $Sp(n)$ corresponds to the special case $m = 0$. The quotient groups of these real forms by their centers can all be realized as the groups of automorphisms of semisimple algebras with involutions J which commute with J (A. Weil [10]).

61 (III.16) Clifford Algebras

A. Definitions and Basic Properties

Let V be an n -dimensional \dagger linear space over a field K , and let Q be a \dagger quadratic form on V . Denote the \dagger tensor algebra over V by $T(V)$, the tensor multiplication by \otimes . Let $I(Q)$ be the two-sided ideal of $T(V)$ generated by the elements $x \otimes x - Q(x) \cdot 1$ ($x \in V$). The resulting \dagger quotient associative algebra $T(V)/I(Q)$ is then denoted by $C(Q)$ and is called the **Clifford algebra** of the quadratic form Q . The elements of $C(Q)$ are called **Clifford numbers**.

The composite of two canonical mappings $\tau: V \rightarrow T(V)$, $\sigma: T(V) \rightarrow C(Q)$ is a linear injection $\sigma \circ \tau: V \rightarrow C(Q)$. Hence we can regard V as a linear subspace of $C(Q)$ via $\sigma \circ \tau$. Then $C(Q)$ is an associative algebra over K generated by 1 and V . Furthermore, $x^2 = Q(x) \cdot 1$ for every x in V .

Indeed, $C(Q)$ is the universal associative algebra with these properties. That is, let A be any associative algebra with a unity element, and let $f: V \rightarrow A$ be a linear mapping such that $f(x)^2 = Q(x) \cdot 1$ for every x in V . Then f can be extended uniquely to an algebra homomorphism $\tilde{f}: C(Q) \rightarrow A$ with $\tilde{f}(1) = 1$. Furthermore, let Φ be the \dagger symmetric bilinear form associated with Q : $\Phi(x, y) = Q(x+y) - Q(x) - Q(y)$, $x, y \in V$. Then $xy + yx = \Phi(x, y) \cdot 1$ for every x, y in V . $C(Q)$ is of dimension 2^n over K . If e_1, \dots, e_n is a basis of V , then

$$1, e_i, e_i e_j (i < j), \dots, e_1 e_2 \dots e_n$$

form a basis of $C(Q)$. In particular, if $\{e_i\}$ is an orthogonal basis relative to Q , we have

$$e_i e_j = -e_j e_i, \quad e_i^2 = Q(e_i) \cdot 1;$$

$$i, j = 1, \dots, n, \quad i \neq j. \quad (1)$$

In this case, $C(Q)$ can be defined as an associative algebra (with a unity element) generated by the $\{e_i\}$ together with the defining relations (1). In particular, for $Q=0$, $C(Q)$ is the exterior algebra (\dagger Grassmann algebra) over V .

B. The Principal Automorphism and the Principal Antiautomorphism of $C(Q)$

There exists a unique automorphism α of the algebra $C(Q)$ such that $\alpha(x) = -x$ for every x in V . This automorphism α is called the **principal automorphism** of $C(Q)$, and we have $\alpha^2 = 1$.

Also, there exists a unique antiautomorphism β of the algebra $C(Q)$ such that $\beta(x) = x$ for every x in V . This antiautomorphism β is called the **principal antiautomorphism** of $C(Q)$, and we have $\beta^2 = 1$.

For the rest of this article we assume that the \dagger discriminant of Q is $\neq 0$. We also assume for the sake of simplicity that the characteristic of K is $\neq 2$. Let $C^+ = C^+(Q) = K \cdot 1 + V^2 + V^4 + \dots$, and $C^- = C^-(Q) = V + V^3 + V^5 + \dots$. Then $C(Q)$ is the direct sum of the linear subspaces $C^+(Q)$ and $C^-(Q)$. Furthermore, $C^+C^+ \subset C^+$, $C^+C^- \subset C^-$, $C^-C^+ \subset C^-$, and $C^-C^- \subset C^+$. Thus $C(Q) = C^+ + C^-$ has the structure of a \dagger graded algebra with the index group $\{\pm 1\}$, and C^+ is a subalgebra of $C(Q)$. The elements of $C^+(Q)$, $C^-(Q)$ are called **even elements** and **odd elements**, respectively. We have $\dim C^+(Q) = \dim C^-(Q) = 2^{n-1}$.

C. The Structure of $C(Q)$ and $C^+(Q)$

$C(Q)$ and $C^+(Q)$ are both \dagger separable, \dagger semi-simple associative algebras over K . Suppose n is even: $n = 2r$. Then $C(Q)$ is a \dagger simple algebra with K as its center; the center Z of $C^+(Q)$ is 2-dimensional over K . Let e_1, \dots, e_n be an orthogonal basis of V . Then 1 and $z = 2^r e_1 \dots e_n$ form a basis of Z , and we have

$$z^2 = 2^{2r}(-1)^r Q(e_1) \dots Q(e_n) = (-1)^r D,$$

where D is the \dagger discriminant of Φ relative to the basis $\{e_i\}$. Thus if $(-1)^r D$ has a square root in K , $Z \cong K \oplus K$ (direct sum), and so $C^+(Q)$ is decomposed into the direct sum of two simple algebras. If $(-1)^r D$ does not have a square root in K , then Z is a field and $C^+(Q)$ is a simple algebra. In particular, if the \dagger index of Q (i.e., the dimension of a maximal \dagger totally singular subspace of V (\rightarrow 348 Quadratic Forms)) is r , $C(Q)$ is isomorphic to the \dagger total matrix algebra of degree 2^r over K , and $C^+(Q)$ is isomorphic to the direct sum of two copies of the total matrix algebra of degree 2^{r-1} over K .

Now suppose that n is odd: $n = 2r + 1$. Then

$C^+(Q)$ is a simple algebra with K as its center. (In particular, if Q is of index r , then $C^+(Q)$ is isomorphic to the total matrix algebra of degree 2^r over K .) The center Z of $C(Q)$ is 2-dimensional over K , and we have $C(Q) \cong Z \otimes_K C^+(Q)$. If e_1, \dots, e_n is an orthogonal basis of V , then 1 and $z = e_1 \dots e_n$ form a basis of Z . Putting $z' = 2^{r+1} z$, we have $z'^2 = 2(-1)^r D$, where D is the discriminant of Φ relative to $\{e_i\}$. Thus if $2(-1)^r D$ has a square root in K , $C(Q)$ is the direct sum of two 2^{2r} -dimensional simple algebras. If $2(-1)^r D$ has no square root in K , then $C(Q)$ is a simple algebra.

D. The Clifford Group

Let G be the set of all invertible elements s in $C(Q)$ such that $sVs^{-1} = V$. Then G forms a group relative to the multiplication of $C(Q)$. This group G is called the **Clifford group** of the quadratic form Q . The subgroup $G^+ = G \cap C^+(Q)$ is called the **special Clifford group**. The linear transformation $\varphi(s): x \rightarrow sxs^{-1}$ of V induced by $s \in G$ belongs to the \dagger orthogonal group $O(Q)$ of V relative to Q . Moreover, the mapping $s \rightarrow \varphi(s)$ is a homomorphism from G into $O(Q)$. Thus φ is a \dagger representation of G on V . This representation φ is called the **vector representation** of G . The \dagger kernel of φ consists of invertible elements in the center Z of $C(Q)$. If $x \in G \cap V$, then $Q(x) \neq 0$ and $-\varphi(x)$ is the reflection mapping of V relative to the hyperplane orthogonal to x . If $n = \dim V$ is odd, $\varphi(G) = \varphi(G^+) = SO(Q)$. If n is even, $\varphi(G) = O(Q)$, $\varphi(G^+) = SO(Q)$.

Exploiting the principal antiautomorphism β of $C(Q)$, we obtain a homomorphism $N: G^+ \rightarrow K^*$ (the multiplicative group of K) defined by $N(s) = \beta(s)s$ ($s \in G^+$), and $N(s)$ is called the **spinorial norm** of $s \in G^+$. The normal subgroup of G^+ defined as the kernel of N is denoted by G_0^+ and is called the **reduced Clifford group** (of Q). The subgroup $\varphi(G_0^+)$ of $SO(Q)$ is denoted by $O_0^+(Q)$ and is called the **reduced orthogonal group**.

In particular, when the ground field K is the real number field \mathbf{R} , $O_0^+(Q)$ coincides with the \dagger identity component of the \dagger Lorentz group $O(Q)$. Furthermore, if Q is definite, $O_0^+(Q) \cong SO(n)$, so that the identity component $Spin(n)$ of G_0^+ is a \dagger simply connected \dagger covering group of $SO(n)$ via the covering homomorphism φ (with each point in $SO(n)$ covered twice). The group $Spin(n)$ is called the **spinor group** of degree n .

E. Spin Representations

In this section we assume that the ground field K is the complex number field \mathbf{C} and that n

$= \dim V \geq 3$. Then we have $O_0^+(Q) \cong SO(n, \mathbb{C})$, so G_0^+ is a simply connected covering group of $SO(n, \mathbb{C})$ via the covering homomorphism φ . In this section we denote G_0^+ by $Spin(n, \mathbb{C})$ and call it the **complex spinor group** of degree n . $Spin(n, \mathbb{C})$ is the \dagger complexification (\rightarrow 249 Lie Groups) of the compact Lie group $Spin(n)$ and is a complex analytic subgroup of the \dagger complex Lie group $C(Q)^*$ consisting of all invertible elements of $C(Q)$. With the bracket operation $[x, y] = xy - yx$, $C(Q)$ becomes the \dagger Lie algebra of $C(Q)^*$. Furthermore, the Lie subalgebra of $C(Q)$ associated with the complex analytic subgroup $Spin(n, \mathbb{C})$ is given by $\sum_{i < j} \mathbb{C} e_i e_j$, where e_1, \dots, e_n is an orthogonal basis of V . The spin representations of the group $Spin(n, \mathbb{C})$ are defined as follows:

(1) When n is odd: $n = 2r + 1$. Since $C^+(Q)$ is isomorphic to a total matrix algebra of degree 2^r over \mathbb{C} , $C^+(Q)$ has a unique (up to equivalence) \dagger irreducible representation $\tilde{\rho}$, which is of degree 2^r . The restriction of $\tilde{\rho}$ on $Spin(n, \mathbb{C})$ (on $Spin(n)$) defines an irreducible representation ρ of degree 2^r of $Spin(n, \mathbb{C})$ (of $Spin(n)$); ρ is called the **spin representation** of the group $Spin(n, \mathbb{C})$ (of $Spin(n)$). The elements in the representation space of ρ are called **spinors**. Thus we can say that a spinor is a quantity with 2^r components which obey the transformation law according to the spin representation (\rightarrow 258 Lorentz Group). This representation ρ defines a representation of the Lie algebra $\mathfrak{so}(n, \mathbb{C})$ of $Spin(n, \mathbb{C})$ (note that $\mathfrak{so}(n, \mathbb{C})$ is a \dagger complex simple Lie algebra of type B_r). This representation of $\mathfrak{so}(n, \mathbb{C})$ is also called the spin representation of $\mathfrak{so}(n, \mathbb{C})$. Note that ρ is not well defined on $SO(n, \mathbb{C})$ or on $SO(n)$; ρ is of valence 2 on $SO(n, \mathbb{C})$ or on $SO(n)$.

(2) When n is even: $n = 2r$. Since $C(Q)$ is isomorphic to a total matrix algebra of degree 2^r over \mathbb{C} , $C(Q)$ has a unique (up to equivalence) irreducible representation $\tilde{\rho}$, which is of degree 2^r . The restriction of $\tilde{\rho}$ on $Spin(n, \mathbb{C})$ (on $Spin(n)$) defines a representation ρ of degree 2^r of $Spin(n, \mathbb{C})$ (of $Spin(n)$); ρ is called the spin representation of the group $Spin(n, \mathbb{C})$ (of $Spin(n)$). This representation ρ is, however, not irreducible; ρ is decomposed into the direct sum of two irreducible representations ρ_+ and ρ_- . They are not equivalent to each other, and both are of degree 2^{r-1} . By taking a suitable minimal left ideal L of $C(Q)$ as the representation space of the representation $\tilde{\rho}$, we obtain the representation spaces L^+, L^- of ρ_+, ρ_- , respectively, by putting $L^+ = L \cap C^+(Q)$ and $L^- = L \cap C^-(Q)$. The representation ρ^+ (or ρ^-) is called the **half-spin representation** of the group $Spin(n, \mathbb{C})$ or of the group $Spin(n)$. The elements in the representation space of ρ^+ (or ρ^-) are called **half-spinors**. Again, ρ^+ and ρ^- are not well defined on $SO(n, \mathbb{C})$ or on $SO(n)$.

They are of valence 2 on these groups. The representations of the Lie algebra of the Lie group $SO(n, \mathbb{C})$ (note that this Lie algebra is a \dagger complex simple Lie algebra of type D_r) associated with ρ^+, ρ^- are also called **half-spin representations** of this Lie algebra.

62 (XI.9) Cluster Sets

A. Cluster Sets of Functions Meromorphic in an Arbitrary Domain

Let D be an arbitrary \dagger domain in the complex z -plane, Γ its boundary, and E a \dagger totally disconnected closed set contained in Γ . Let $w = f(z)$ be a single-valued \dagger meromorphic function defined in D . Then for each point z_0 in Γ , we can define the following sets related to the mapping $w = f(z)$ in the complex w -plane (or on the complex w -sphere $\hat{\mathbb{C}}$).

The Cluster Set. A value α is called a **cluster value** of $f(z)$ at z_0 if there exists a sequence of points $\{z_n\}$ such that

$$z_n \in D, \quad z_n \rightarrow z_0, \quad f(z_n) \rightarrow \alpha.$$

The totality $C_D(f, z_0)$ of all the cluster values of $f(z)$ at z_0 is called the **cluster set** of $f(z)$ at z_0 or, more precisely, the **interior cluster set**. It is a nonempty, closed, but not necessarily connected set.

The Boundary Cluster Set. The set of all values α such that there exist a sequence of points $\{\zeta_n\}$ of $\Gamma - \{z_0\}$ (resp. $\Gamma - \{z_0\} - E$) and a sequence of points $\{w_n\}$ in the complex w -plane satisfying

$$\zeta_n \rightarrow z_0, \quad w_n \in C_D(f, \zeta_n), \quad w_n \rightarrow \alpha$$

is called the **boundary cluster set** of $f(z)$ at z_0 and is denoted by $C_\Gamma(f, z_0)$ (resp. $C_{\Gamma-E}(f, z_0)$). These are closed sets, and

$$C_{\Gamma-E}(f, z_0) \subset C_\Gamma(f, z_0) \subset C_D(f, z_0).$$

If $z_0 \in \Gamma - E$ or z_0 is an isolated point of E , then $C_{\Gamma-E}(f, z_0) = C_\Gamma(f, z_0)$. Furthermore, $C_\Gamma(f, z_0)$

(resp. $C_{\Gamma-E}(f, z_0)$) is empty if and only if z_0 is an isolated boundary point (resp. z_0 is an exterior point of $\Gamma - E$).

Range of Values. The set of values α such that

$$z_n \in D, \quad z_n \rightarrow z_0, \quad f(z_n) = \alpha$$

is called the **range of values** of $f(z)$ at z_0 and is denoted by $R_D(f, z_0)$. In other words, $R_D(f, z_0)$ is the set of values α assumed by $f(z)$ infinitely often in any neighborhood of z_0 and is a $\dagger G_\delta$ -set.

The Asymptotic Set. Let z_0 be an \dagger accessible boundary point of D . If $f(z)$ converges to a value α as z tends to z_0 along a simple arc in D terminating at z_0 , then α is called an **asymptotic value** of f at z_0 . The totality $A_D(f, z_0)$ of asymptotic values of f at z_0 is called the **asymptotic set** of f at z_0 . If z_0 is an inaccessible boundary point, we let $A_D(f, z_0)$ be the empty set.

B. Iversen-Beurling-Kunugui Theorems

Suppose now that E is empty, and put

$$\Omega = C_D(f, z_0) - C_\Gamma(f, z_0).$$

\dagger Iversen's theorems in the case where D is the unit disk $|z| < 1$ and z_0 is a point on $|z| = 1$ are generalized as follows.

(1) $\Omega - R_D(f, z_0) \subset A_D(f, z_0)$ (K. Noshiro, 1936).

(2) First Beurling-Kunugui theorem: If z_0 is not an isolated boundary point, then Ω is an open set.

(3) Second Beurling-Kunugui theorem: Suppose that the open set Ω is not empty. Then $f(z)$ assumes every value belonging to each component Ω_n of Ω infinitely often, with two possible exceptions belonging to Ω_n , that is, $\Omega_n \cap (\hat{C} - R_D(f, z_0))$ consists of at most two values (an extension of \dagger Picard's theorem on an isolated essential singularity).

Next suppose that E is not empty and of \dagger logarithmic capacity zero, and put $\Omega = C_D(f, z_0) - C_{\Gamma-E}(f, z_0)$. If $\alpha \in \Omega - R_D(f, z_0)$, then either α is an asymptotic value of $f(z)$ at z_0 or there exists a sequence of points $\zeta_n \in E$ ($n = 1, 2, \dots$) converging to z_0 such that α is an asymptotic value of $f(z)$ at each ζ_n (Noshiro, 1937). Furthermore, if z_0 is contained in the closure of $\Gamma - E$, then Ω is an open set (which may be empty), and $\Omega - R_D(f, z_0)$ is at most of logarithmic capacity zero (M. Tsuji, 1943). If E is contained in a single component Γ_0 of the boundary Γ , z_0 is contained in the closure of $\Gamma - E$, and Ω is nonempty, then $w = f(z)$ assumes every value belonging to each component Ω_n of Ω infinitely often, with two possible exceptions belonging to Ω_n (Noshiro, 1950). In par-

ticular, if f is bounded in a neighborhood of z_0 , the number of such exceptional values is at most 1. This is still true if each point of E is contained in a boundary component that is a \dagger continuum containing at least two points and Ω is not empty (M. Hervé, 1955). However, this conclusion does not hold if we remove the hypothesis on the set E (K. Matsumoto, 1960).

C. Cluster Sets of Functions Meromorphic in the Unit Disk

Let D be the unit disk $\{|z| < 1\}$, $z_0 = e^{i\theta_0}$ be a fixed point on the unit circumference Γ , A be an open arc of Γ containing z_0 , and E be a set of \dagger linear measure zero such that $z_0 \in E \subset A$. With every $e^{i\theta} \in A - E$ we associate an arbitrary simple arc Λ_θ in D terminating at $e^{i\theta}$ and the **curvilinear cluster set** $C_{\Lambda_\theta}(f, e^{i\theta})$, defined as the set of all values α such that $z_n \in \Lambda_\theta$, $z_n \rightarrow e^{i\theta}$, $f(z_n) \rightarrow \alpha$. We put

$$C_{\Gamma-E}^*(f, z_0) = \bigcap_{r>0} M_r,$$

where M_r denotes the closure of the union $C_{\Lambda_\theta}(f, e^{i\theta})$ for all $e^{i\theta}$ in the intersection of $A - E$ with $|z - z_0| < r$.

By using the above cluster set $C_{\Gamma-E}^*(f, z_0)$ instead of the boundary cluster set $C_{\Gamma-E}(f, z_0)$, we obtain results similar to those in the preceding section (M. Ohtsuka, 1950; Noshiro, 1955). Many interesting results have been obtained by F. Bagemihl and W. Seidel, E. F. Collingwood, O. Lehto and K. I. Virtanen, and others concerning the cluster sets of functions meromorphic in the unit disk. They studied functions of Seidel's class U , **normal** meromorphic functions, and other functions where the class U is the totality of regular bounded functions in the unit disk possessing almost everywhere on $|z| = 1$ radial limits of the constant modulus 1; a nonconstant meromorphic function $f(z)$ in $|z| < 1$ is normal if the family $\{f(T(z))\}$ is \dagger normal in the sense of Montel, where $T(z)$ is an arbitrary conformal mapping of $|z| < 1$ onto itself.

D. The More General Case

The definitions of cluster sets are also available for arbitrary functions for which neither analyticity nor continuity is assumed. If there exist two simple arcs Λ_1 and Λ_2 in the unit disk D terminating at a point $z = e^{i\theta}$ such that

$$C_{\Lambda_1}(f, e^{i\theta}) \cap C_{\Lambda_2}(f, e^{i\theta}) = \emptyset,$$

then $z = e^{i\theta}$ is called an **ambiguous point** of f . Bagemihl proved the following: The set of ambiguous points of an arbitrary complex-valued function defined in the unit disk D is at

most countable [5]. Under the same hypothesis, the set of points $e^{i\theta}$ such that $C_D(f, e^{i\theta}) \neq C_T(f, e^{i\theta})$ is at most countable (Collingwood, 1960). This result shows the importance of introducing the cluster set $C_{T-E}^*(f, z_0)$ that was previously mentioned.

E. History

The theory of cluster sets originated from the \dagger value distribution theory of analytic functions in the neighborhood of their essential singularities. The first systematic results were those of F. Iversen and W. Gross, obtained about 1920. Subsequent significant contributions were made by Seidel, J. L. Doob, M. L. Cartwright, A. Beurling, and others. Since 1940, some important results have been obtained by K. Kunugui, S. Irie, Y. Tôki, Y. Tumura, S. Kametani, Tsuji, Noshiro, and other Japanese mathematicians. Many results have been extended to \dagger pseudoanalytic functions. As can be seen from the Bagemihl ambiguous point theorem, some properties of cluster sets are not intrinsic to analytic mappings [2, 5]. On the other hand, it seems to be an interesting problem to extend the theory of cluster sets to the case of analytic mappings between open Riemann surfaces.

63 (XVI.3) Coding Theory

A. General Notions of Coding Theory

When we wish to store, to search for, or to send information in the presence of noise efficiently and with the least error, we can

apply various bounds to the efficiency (\rightarrow 213 Information theory). Sophisticated coding operations are required in order to achieve efficiencies as close as possible to the bounds. In the abstract sense, the information is generally understood to be a choice of an element from a finite set X . For implementation, we take a set K of q elements called **alphabets**. Each element of K is called a **letter**. We consider the direct product K^n , i.e., the set of all sequences of n letters. An injection ψ from X into K^n is called **encoding**. The sequence $\psi(x)$ for $x \in X$ is called a **code word**, and the image $\psi(X)$ (a collection of code words) is called a **code**. Such a code is also called a **block code**. The noise is represented by a mapping $\omega: K^n \rightarrow K^n$, but usually it is restricted to a certain subset Ω of the set of such mappings with special properties. For example, we usually assume that the sequences $x \in K^n$ and $\omega(x)$ are different only at less than d letters, where d is a preassigned constant. The inverse mapping φ , i.e., a mapping $\varphi: K^n \rightarrow X$ satisfying $\varphi \circ \psi(x) = x$ for all $x \in X$, is called the **decoding** of ψ . A code ψ satisfying the property $\omega \circ \psi(x) \notin \psi(X)$ for all $x \in X$ and for all $\omega \in \Omega$ is called **error-detecting** with respect to the noise Ω . If ψ has the decoding φ satisfying $\varphi \circ \omega \circ \psi(x) = x$ for all $x \in X$ and for all $\omega \in \Omega$, ψ is called **error-correcting** with respect to the noise Ω . To discuss such properties, we can assume $X = \psi(X) (\subset K^n)$ without restricting the generality, so hereafter we assume this condition. Also, we take $q = 2$ unless explicitly stated otherwise. Because in many communication systems $q = 2$ is commonly adopted, and the generalization for other prime powers q can be obtained naturally.

B. Bounds for the Size of Codes

Let $x = (x_1, \dots, x_n)$, $y = (y_1, \dots, y_n) \in K^n$. The **Hamming distance** $d(x, y) = d_H(x, y)$ between the elements x and y is the total number of unequal bits ($x_i \neq y_i$). We put $d_{\min} = \min\{d_H(x, y) \mid x, y \in X, x \neq y\}$. When $e = \max\{d_H(x, \omega(x)) \mid \omega \in \Omega, x \in X\}$ is less than d_{\min} , the errors due to Ω can be detected, and if $d_{\min} \geq 2e + 1$, the errors can be corrected. The maximal integer t satisfying $d_{\min} \geq 2t + 1$ is often called the **error-correcting capability**. Several important relations are known among d_{\min} , t , n (the length of the code), and $|X|$ (the size of the code word) as follows. **Hamming bound**: $|X| \leq 2^n / \sum_{i=0}^t \binom{n}{i}$. A code satisfying the equality here is called a **perfect code** [6]. **Plotkin bound**: $d_{\min} \leq n|X| / (2(|X| - 1))$. On the other hand, if the **Varsharmov-Gilbert-Sacks bound** $2^{n-k} > \sum_{i=0}^{d_{\min}-2} \binom{n-1}{i}$ is satisfied, there exists an (n, k) -linear code (Section C).

C. Linear Codes

Let $K = GF(2) = \{0, 1\}$, K^n be an n -dimensional vector space over K , and X be a k -dimensional linear subspace. Then X is called a **group code** or (n, k) -**linear code**. In the present case, we can take a suitable basis of K for which there exists a $k \times (n-k)$ matrix P over K such that every vector $\mathbf{x} = (x_1, \dots, x_n)$ representing a code word is expressed as $\mathbf{x} = (\mathbf{z}P, \mathbf{z})$ by a suitable vector \mathbf{z} , and conversely, every vector of this form is a code word, i.e., a vector $\mathbf{x} \in X$ is a code word if and only if

$$(x_1, \dots, x_{n-k}) = (x_{n-k+1}, \dots, x_n)P = \mathbf{0}. \quad (*)$$

Introducing the matrix $H = [I_{n-k}, -P^T]$, where I_{n-k} is the unit matrix of order $n-k$ and T indicates the transpose, the condition $(*)$ is equivalent to $\mathbf{x}H^T = \mathbf{0}$. Therefore, H is called the **parity check matrix**, x_{n-k+1}, \dots, x_n are called the **information bits**, and x_1, \dots, x_{n-k} are called the **check bits**. If \mathbf{x} is deformed to $\mathbf{y} = \omega\mathbf{x}$ by a noise ω , i.e., the original signal \mathbf{x} is transmitted as signal \mathbf{y} , we call $\mathbf{s} = \mathbf{y}H^T = (\mathbf{y} - \mathbf{x})H^T$ the **syndrome** of the transmitted signal \mathbf{y} . If we have an algorithm to determine the error vector $\mathbf{e} = \mathbf{y} - \mathbf{x}$ from the syndrome \mathbf{s} , we have a decoding with error-correcting property. For the linear code, it is evident that $d_{\min} = \min \{ \text{number of nonzero elements of } \mathbf{x} \mid \mathbf{x} (\neq \mathbf{0}) \in X \}$.

The **Hamming code** is given by $n = 2^m - 1$ (m being an integer ≥ 2), $k = n - m$, where the (i, j) -component h_{ij} ($i = 1, \dots, m; j = 1, \dots, n$) of the parity check matrix H is given by the i th bit of the number $j-1$ expressed in the binary (2-adic) number system. The check bits are x_j ($j = 2^0, 2^1, \dots, 2^{m-1}$), and all other bits are the information bits. This code has the error-correcting property with respect to the noise ω for which the nonzero component of $\mathbf{e} = \omega\mathbf{x} - \mathbf{x}$ is at most 1. In fact, from the syndrome $\mathbf{s} = (s_1, \dots, s_m)$, we compute $\hat{j} = s_1 + 2s_2 + \dots + 2^{m-1}s_m$ and put $e_j = 1, e_j = 0$ for all $j \neq \hat{j}$; if $\hat{j} = 0$, we can put $\mathbf{e} = \mathbf{0}$. The Hamming code is a perfect code.

D. Cyclic Codes

The cyclic code is a special case of a linear code. This is the object of one of the most important applications of the theory of finite fields. By using this theory, we can actually construct the codes with high for error-correcting capability in which the encoding and the decoding operations are performed algebraically.

An (n, k) -linear code X over $GF(2)$ is called a **cyclic code** if $\mathbf{x} = (x_1, x_2, \dots, x_n) \in X$ implies $(x_n, x_1, x_2, \dots, x_{n-1}), (x_{n-1}, x_n, x_1, \dots, x_{n-2}), \dots, (x_2,$

$\dots, x_n, x_1) \in X$. To each $\mathbf{x} \in X$, we can associate a polynomial of one variable $x(\xi) = x_1 + x_2\xi + \dots + x_n\xi^{n-1}$ over $GF(2)$. Let $g_X(\xi)$ be the polynomial of the least degree $n-k$ among the polynomials corresponding to $\mathbf{x} \in X$. $g_X(\xi)$ is called the **generator** of X , because the property $\mathbf{x} \in X$ and the property that $x(\xi)$ is divisible by $g_X(\xi)$ are equivalent. $g_X(\xi)$ also divides $\xi^n - 1$. Let the quotient be $h_X(\xi) = (\xi^n - 1)/g_X(\xi)$. Then $\mathbf{x} \in X$ is equivalent to $x(\xi)h_X(\xi) \equiv 0 \pmod{(\xi^n - 1)}$. $h_X(\xi)$ is called the **parity check polynomial**. The **BCH code (Bose-Chaudhuri-Hocquenghem code)** defined below is a typical example of a cyclic code.

Let α be an element of order n in $GF(2^m)$ (the finite field with 2^m elements), and let $g_i(\xi)$ be the polynomial of the lowest degree in $GF(2)[\xi]$ for which α^i is a root ($i = 1, 3, \dots, 2t-1$). The BCH code is given by the least common multiple $g(\xi)$ of the polynomials $g_1(\xi), g_3(\xi), \dots, g_{2t-1}(\xi)$. The BCH code has at least $n - mt$ information bits and satisfies $d_{\min} \geq 2t + 1$, and algebraic decoding methods are known [3, 5]. The Hamming code is a BCH code when $t = 1, n = 2^m - 1$.

E. Other Codes

Other important types of codes include **convolutional codes** (not block codes) for correcting errors in consecutive digits (**burst errors**) and **Goppa codes** (an extension of the BCH class). For correcting burst errors, special cyclic codes or their mixtures are also used. This field of research is closely connected to information theory, algebra, and various applications of combinatorial analysis, such as experimental design [3].

64 (IX.8) Cohomology Operations

A. General Remarks

The notion of cohomology operations was introduced by L. S. Pontryagin and N. E. Steenrod in order to solve homotopy classification problems (\rightarrow 202 Homotopy Theory). Since then, numerous works have proved the importance of cohomology operations as applied to homotopy theory, differential topology, and other branches of topology. In fact, the use of cohomology operations is indispensable in studying problems related to homotopy groups, characteristic classes of manifolds, etc.

We denote by the symbol $H^*(X; A) = \Sigma H^n(X; A)$ the singular cohomology ring of a topological space X with coefficients in an Abelian group A .

B. Primary Cohomology Operations

A (primary) cohomology operation (or simply an operation) φ is a natural transformation

$$\varphi: \prod_{\lambda} H^{\lambda_1}(; A_{\lambda}) \rightarrow \prod_{\mu} H^{\mu_1}(; B_{\mu})$$

between the cohomology functors defined on the category of topological spaces and continuous mappings. That is, φ is a family of mappings satisfying the following conditions:

(I) For each space X , φ defines a mapping

$$\varphi: \prod_{\lambda} H^{\lambda_1}(X; A_{\lambda}) \rightarrow \prod_{\mu} H^{\mu_1}(X; B_{\mu})$$

that is not necessarily additive.

(2) For each mapping $f: X \rightarrow Y$, the commutativity $f^* \circ \varphi = \varphi \circ f^*$ holds in the diagram

$$\begin{array}{ccc} \prod_{\lambda} H^{\lambda_1}(X; A_{\lambda}) & \xrightarrow{\varphi} & \prod_{\mu} H^{\mu_1}(X; B_{\mu}) \\ \uparrow f^* & & \uparrow f^* \\ \prod_{\lambda} H^{\lambda_1}(Y; A_{\lambda}) & \xrightarrow{\varphi} & \prod_{\mu} H^{\mu_1}(Y; B_{\mu}) \end{array}$$

We list here two trivial examples.

(I) Addition of cohomology groups determines an operation $\varphi: H^{\lambda_1}(X; A) \times H^{\lambda_2}(X; A) \rightarrow H^{\lambda_1 + \lambda_2}(X; A)$.

(II) The cup product determines an operation

$$\varphi: H^{\lambda_1}(X; A_1) \times H^{\lambda_2}(X; A_2) \rightarrow H^{\lambda_1 + \lambda_2}(X; A_1 \otimes A_2)$$

denoted by

$$\varphi(\alpha, \beta) = \alpha \smile \beta.$$

The composite of two cohomology operations is defined in the obvious way. Among cohomology operations the most important ones are operations of one variable. A co-

homology operation of type $(A, l; B, m)$ is a natural transformation

$$\varphi: H^l(; A) \rightarrow H^m(; B).$$

$\mathfrak{D}(A, l; B, m)$ denotes the Abelian group consisting of all such operations.

Denote by $H^m(A, l; B)$ the m th cohomology group of an Eilenberg-MacLane space $K(A, l)$, and let $u \in H^l(A, l; A)$ be the fundamental class of $K(A, l)$. If X is a CW complex, by assigning f^*u to each $f: X \rightarrow K(A, l)$, we obtain a one-to-one correspondence between the set of the homotopy classes $\pi(X, K(A, l))$ and the cohomology group $H^l(X; A)$ (\rightarrow 70 Complexes F). Hence by utilizing condition (2), it can be shown that the value of φ on $H^l(X; A)$ is uniquely determined by its operation on $H^l(A, l; A)$. Thus the assignment $\varphi \rightarrow \varphi u$ defines the isomorphism $\mathfrak{D}(A, l; B, m) \cong H^m(A, l; B)$. Here we should remark that the isomorphism $\pi(K(A, l), K(B, m)) \cong H^m(A, l; B)$ defines a one-to-one correspondence $\mathfrak{D}(A, l; B, m) \rightarrow \pi(K(A, l), K(B, m))$. In some cases $H^m(A, l; B)$ vanishes, for example, when $0 < m < l$, $l = 1 < m$, $A = \mathbb{Z}$, $l = 2$, $m = 2m' + 1$, $A = \mathbb{Z}$; $l = 2l' < m = 2m' + 1$, $A = \mathbb{Z} \cdot B = \mathbb{Q}$; $l = 2l' + 1 < m$, $A = \mathbb{Z}$, $B = \mathbb{Q}$; A is finite, $B = \mathbb{Q}$; etc.

The following four types of operations together with the two above are called elementary operations:

(III) Homomorphisms induced by a coefficient homomorphism: There are homomorphisms $\eta_*: H^l(X; A) \rightarrow H^l(X; B)$ induced by a homomorphism $\eta: A \rightarrow B$.

(IV) Bockstein (cohomology) operation: This operation is given by the connecting homomorphisms $\delta^*: H^l(X; C) \rightarrow H^{l+1}(X; A)$ associated with a short exact sequence $0 \rightarrow A \rightarrow B \rightarrow C \rightarrow 0$ of coefficient groups (\rightarrow 200 Homological Algebra). For example, the coefficient sequence $0 \rightarrow \mathbb{Z} \xrightarrow{n} \mathbb{Z} \rightarrow \mathbb{Z}_n \rightarrow 0$ ($\mathbb{Z}_n = \mathbb{Z}/n\mathbb{Z}$) defines a Bockstein operation (or Bockstein homomorphism), which is usually denoted by $(1/n)\delta$ or Δ_n .

(V) Steenrod (or reduced) square operations Sq^i ($i \geq 0$): Sq^i are sequences of operations defined by the following five axioms [2, 5]:

(V1) For each pair of integers $i \geq 0$ and $l \geq 0$,

$$Sq^i: H^l(X; \mathbb{Z}_2) \rightarrow H^{l+i}(X; \mathbb{Z}_2)$$

is a natural transformation of functors that is a homomorphism.

(V2) $Sq^0 = 1$.

(V3) If $\deg x = i$, then $Sq^i x = x \smile x$ (cup product).

(V4) If $\deg x < i$, then $Sq^i x = 0$.

(V5) (Cartan formula)

$$Sq^i(x \smile y) = \sum_{j=0}^i Sq^j x \smile Sq^{i-j} y.$$

These five axioms imply the following two formulas:

(V6) Sq^1 is the Bockstein operation β_2 of the coefficient sequence $0 \rightarrow \mathbf{Z}_2 \rightarrow \mathbf{Z}_4 \rightarrow \mathbf{Z}_2 \rightarrow 0$.

(V7) (**Adem relations**) If $0 < i < 2j$, then

$$Sq^i \circ Sq^j = \sum_{k=0}^{[i/2]} \binom{j-1-k}{i-2k} Sq^{i+j-k} \circ Sq^k.$$

The binomial coefficient is taken mod 2.

We can extend the definition of the Sq^i so that they operate on the relative cohomology groups. Now (V1), (V2), and (V5) imply:

(V8) If $\delta: H^l(Y; \mathbf{Z}_2) \rightarrow H^{l+1}(X, Y; \mathbf{Z}_2)$ is the \dagger coboundary homomorphism, then $\delta \circ Sq^i = Sq^i \circ \delta$.

(V') **Steenrod p th power operations** \mathcal{P}^i ($i \geq 0$): Let p be an odd prime. Then \mathcal{P}^i is a sequence of operations defined by the following five axioms [5].

(V'1) For each pair of integers $i \geq 0$ and $l \geq 0$,

$$\mathcal{P}^i: H^l(X; \mathbf{Z}_p) \rightarrow H^{l+2i(p-1)}(X; \mathbf{Z}_p)$$

is a natural transformation that is a homomorphism.

(V'2) $\mathcal{P}^0 = 1$.

(V'3) If $\deg x = 2k$, then $\mathcal{P}^k x = x^p$.

(V'4) If $\deg x < 2k$, then $\mathcal{P}^k x = 0$.

(V'5) (**Cartan's formula**)

$$\mathcal{P}^i(x \smile y) = \sum_{j=0}^i \mathcal{P}^j x \smile \mathcal{P}^{i-j} y.$$

These axioms imply the **Adem relations** for \mathcal{P}^i and the Bockstein homomorphism β_p associated with the coefficient sequence $0 \rightarrow \mathbf{Z}_p \rightarrow \mathbf{Z}_{p^2} \rightarrow \mathbf{Z}_p \rightarrow 0$ (\rightarrow Appendix A, Table 6.II).

We can extend the definition of \mathcal{P}^i to the relative cohomology groups too, and we obtain $\delta \circ \mathcal{P}^i = \mathcal{P}^i \circ \delta$.

(VI) **Pontryagin p th power operations** \mathfrak{P}_p . Let p be a prime. \mathfrak{P}_p is a system of operations satisfying the following five conditions [3]:

(VI1) For each pair of integers $l \geq 0$ and $h \geq 1$,

$$\mathfrak{P}_p: H^l(X; \mathbf{Z}_{p^h}) \rightarrow H^{pl}(X; \mathbf{Z}_{p^{h+1}})$$

is a natural transformation.

(VI2) If $\eta: \mathbf{Z}_{p^{h+1}} \rightarrow \mathbf{Z}_{p^h}$ is a homomorphism defined by $\eta(1) = 1$, then we have $\eta_* \circ \mathfrak{P}_p x = x^p$.

(VI3) If $p: \mathbf{Z}_{p^h} \rightarrow \mathbf{Z}_{p^{h+1}}$ is a homomorphism defined by $p(1) = p$, then we have

$$\begin{aligned} \mathfrak{P}_p(x + y) \\ = \mathfrak{P}_p x + \mathfrak{P}_p y + \sum_{i=1}^{p-1} \binom{p}{i} p_* (x^i \smile y^{p-i}). \end{aligned}$$

(VI4) $\mathfrak{P}_p(x \smile y) = \mathfrak{P}_p x \smile \mathfrak{P}_p y$.

(VI5) If $p > 2$ and $\deg x = 2k + 1$ (odd), then $\mathfrak{P}_p x = 0$.

Let A, B be finitely generated Abelian groups. Then the computation of $H^*(A, l)$

shows that each element of $\mathfrak{D}(A, l; B, m)$ can be written as the composite of a finite number of the operations of the types (I)–(VI) (H. Cartan).

Here we show some examples. Let u be the fundamental class of $K(\mathbf{Z}_2, 2)$. Then the elements of $H^2(\mathbf{Z}_2, 2; \mathbf{Z}_4) \cong \mathbf{Z}_2$, $H^3(\mathbf{Z}_2, 2; \mathbf{Z}_4) \cong \mathbf{Z}_2$, $H^4(\mathbf{Z}_2, 2; \mathbf{Z}_4) \cong \mathbf{Z}_4$, and $H^5(\mathbf{Z}_2, 2; \mathbf{Z}_4) \cong \mathbf{Z}_4 + \mathbf{Z}_2$ correspond to the cohomology operations $\lambda 2_*$, $\lambda \eta_* \circ (\delta/2)$, $\mu \mathfrak{P}_2$, and $\mu \eta_* \circ (\delta/4) \circ \mathfrak{P}_2 + \lambda 2_* \circ Sq^2 \circ Sq^1$, respectively, where λ, μ denote integers satisfying $0 \leq \lambda \leq 1$, $0 \leq \mu \leq 3$ and $\eta: \mathbf{Z} \rightarrow \mathbf{Z}_4, 2: \mathbf{Z}_2 \rightarrow \mathbf{Z}_4$ stand for the homomorphisms defined by $\eta(1) = 1$, $2(1) = 2$, respectively.

Suppose that we are given sets of integers l_i and m_j . We define the **stable (primary) cohomology operation** φ with respect to these sets of integers l_i and m_j as a system of natural transformations

$$\varphi: \prod_{\lambda} H^{n+l_{\lambda}}(-; A_{\lambda}) \rightarrow \prod_{\mu} H^{n+m_{\mu}}(-; B_{\mu})$$

satisfying the following condition, for all integers $n \geq 0$;

(3) Let $S: H^{l+1}(SX; A) \rightarrow H^l(X; A)$ denote the \dagger suspension. Then the commutativity $S \circ \varphi = \varphi \circ S$ holds in the diagram

$$\begin{array}{ccc} \prod_{\lambda} H^{n+l_{\lambda}}(X; A) & \xrightarrow{\varphi} & \prod_{\mu} H^{n+m_{\mu}}(X; B) \\ \uparrow S & & \uparrow S \\ \prod_{\lambda} H^{n+l_{\lambda}+1}(SX; A) & \xrightarrow{\varphi} & \prod_{\mu} H^{n+m_{\mu}+1}(SX; B). \end{array}$$

This condition is equivalent to the commutativity with the coboundary homomorphisms.

For example, the cohomology operations

$$(-1)^n \beta_p: H^n(X; \mathbf{Z}_p) \rightarrow H^{n+1}(X; \mathbf{Z}_p)$$

define a stable cohomology operation β . Sq^i , \mathfrak{P}^i are also examples of stable cohomology operations.

A stable cohomology operation φ of type (A, B) and of degree q is a sequence of cohomology operations of type $(A, n; B, n+q)$ defined for all integers $n \geq 0$. $\mathfrak{A}(A, B)_q$ denotes the Abelian group consisting of all stable cohomology operations of type (A, B) and of degree q . When $A = B$, $\mathfrak{A}(A) = \sum_{q=0}^{\infty} \mathfrak{A}(A, A)_q$ is a \dagger graded algebra, where multiplication of two operations is given by their composition. Let p be a prime. Then $\mathfrak{A}(\mathbf{Z}_p)$ is called the **Steenrod algebra mod p** and is denoted by $\mathfrak{A}(p)$. $\mathfrak{A}(2)$ is the augmented graded algebra over \mathbf{Z}_2 generated by Sq^i subject to the Adem relations. Suppose that we are given a sequence of non-negative integers $I = (i_1, i_2, \dots, i_k)$. We call I an **admissible sequence** if $i_{s-1} \geq 2i_s$ holds for $2 \leq s \leq k$. We write $Sq^I = Sq^{i_1} \circ Sq^{i_2} \circ \dots \circ Sq^{i_k}$. If I is an admissible sequence, we say that Sq^I is an **admissible monomial**. The admissible monomials form an additive basis for $\mathfrak{A}(2)$, which

has the structure of a \dagger Hopf algebra whose \dagger comultiplication $\psi: \mathfrak{A}(2) \rightarrow \mathfrak{A}(2) \otimes \mathfrak{A}(2)$ is given by $\psi Sq^i = \sum_{j=0}^i Sq^j \otimes Sq^{i-j}$. The dual space $\mathfrak{A}(2)^* = \text{Hom}_{\mathbb{Z}_2}(\mathfrak{A}(2), \mathbb{Z}_2)$ gives a Hopf algebra that is the polynomial algebra generated by ξ_i of degree $2^i - 1$, where ξ_i is the dual element of $Sq^{2^{i-1}} Sq^{2^{i-2}} \dots Sq^1$ with respect to the additive basis. The multiplication $\varphi^*: \mathfrak{A}(2)^* \rightarrow \mathfrak{A}(2)^* \otimes \mathfrak{A}(2)^*$ is given by $\varphi^* \xi_i = \sum_{j=0}^i \xi_{i-j} \otimes \xi_j$.

$\mathfrak{A}(p)$ has properties similar to $\mathfrak{A}(2)$ (p is an odd prime). In particular, $\mathfrak{A}(p)$ is a \dagger Hopf algebra generated by \mathcal{P}^i and β subject to the Adem relations with comultiplication ψ given by $\psi \beta = \beta \otimes 1 + 1 \otimes \beta$ and $\psi \mathcal{P}^i = \sum_{j=0}^i \mathcal{P}^j \otimes \mathcal{P}^{i-j}$. An additive basis of $\mathfrak{A}(p)$ is given by $\{\beta^{\varepsilon_0} \mathcal{P}^{i_1} \beta^{\varepsilon_2} \dots \mathcal{P}^{i_k} \beta^{\varepsilon_k}\}$, where $\varepsilon_i = 0$ or 1 , $i_m \geq p i_{m+1} + \varepsilon_m$ ($m \geq 1$) and $i_k \geq 1$. Such a sequence $I = (\varepsilon_0, i_1, \varepsilon_1, \dots, i_k, \varepsilon_k)$ is also called an **admissible sequence**. Denote the dual element of $\mathcal{P}^{p^{i-1}} \mathcal{P}^{p^{i-2}} \dots \mathcal{P}^1$ and $\mathcal{P}^{p^{i-1}} \mathcal{P}^{p^{i-2}} \dots \mathcal{P}^1 \beta$ by ξ_i and τ_i , respectively; then the dual algebra $\mathfrak{A}(p)^*$ is isomorphic to the tensor product of the polynomial ring over \mathbb{Z}_p generated by ξ_1, ξ_2, \dots and the exterior algebra over \mathbb{Z}_p generated by τ_1, τ_2, \dots . The multiplication φ^* is given by $\varphi^*(\xi_i) = \sum_{j=0}^i \xi_{i-j} \otimes \xi_j$ and $\varphi^*(\tau_i) = \tau_i \otimes 1 + \sum_{j=0}^i \xi_{i-j} \otimes \tau_j$ [5] (\rightarrow Appendix A, Table 6.III).

C. Secondary Cohomology Operations

Here we restrict our attention to a special type of operation treated by J. F. Adams [4] that has been proved to be powerful in applications.

For a specified prime p , we write $H^+(X) = \sum_{i=1}^{\infty} H^i(X; \mathbb{Z}_p)$. We can regard $H^+(X)$ as a \dagger graded left module over $\mathfrak{A}(p)$. Now let C_s ($s=0, 1$) be a pair of \dagger left free modules over $\mathfrak{A}(p)$, and let $d: C_1 \rightarrow C_0$ be a graded homomorphism over $\mathfrak{A}(p)$. Suppose that we are given an element $z \in C_1$ such that $dz=0$. For future purposes, C_0 and C_1 are assumed to have bases $\{c_{0,\lambda}\}$ and $\{c_{1,\mu}\}$ with $\deg c_{0,\lambda} = l_\lambda$ and $\deg c_{1,\mu} = m_\mu$, respectively, in terms of which d has the representation $dc_{1,\mu} = \sum_{\lambda} a_{\mu,\lambda} c_{0,\lambda}$. Then z is expressed in the form $z = \sum_{\mu} b_{\mu} c_{1,\mu}$.

We say that Φ is a **stable secondary cohomology operation** associated with the pair (d, z) if it satisfies the following four axioms:

(1) Let $D^n(d, X)$ be the module consisting of homomorphisms $\varepsilon: C_0 \rightarrow H^+(X)$ over $\mathfrak{A}(p)$ of degree n such that $\varepsilon d = 0$. Putting $\varepsilon(c_{0,\lambda}) = x_\lambda$, we can assume that $D^n(d, X) = \{\varepsilon = \prod_{\lambda} x_\lambda \in \prod_{\lambda} H^{n+l_\lambda}(X) \mid \sum_{\lambda} a_{\mu,\lambda} x_\lambda = 0\}$. Let $Q^n(z, X)$ be the submodule of $H^+(X)$ consisting of elements of the form $\xi(z)$, where ξ is an $\mathfrak{A}(p)$ -homomorphism: $C_1 \rightarrow H^+(X)$ of degree $n-1$.

In other words, $Q^n(z, X) = \sum_{\mu} b_{\mu} H^{n+m_{\mu}-1}(X)$. Then for each $n \geq 0$ and each X , Φ is a mapping

$$\Phi: D^n(d, X) \rightarrow H^+(X)/Q^n(z, X).$$

(2) For each mapping $f: X \rightarrow Y$, the commutativity $f^* \circ \Phi = \Phi \circ f^*$ holds in the diagram

$$\begin{array}{ccc} D^n(d, X) & \xrightarrow{\Phi} & H^+(X)/Q^n(z, X) \\ \uparrow f^* & & \uparrow f^* \\ D^n(d, Y) & \xrightarrow{\Phi} & H^+(Y)/Q^n(z, Y). \end{array}$$

(3) Let $S: H^{n+1}(SX) \rightarrow H^n(X)$ denote the suspension. Then the commutativity $S \circ \Phi = \Phi \circ S$ holds in the diagram

$$\begin{array}{ccc} D^n(d, X) & \xrightarrow{\Phi} & H^+(X)/Q^n(z, X) \\ \uparrow S & & \uparrow S \\ D^{n+1}(d, SX) & \xrightarrow{\Phi} & H^+(SX)/Q^{n+1}(z, SX). \end{array}$$

(4) Let $i: Y \rightarrow X$ be an injection such that $i^* \circ \varepsilon = 0$. That is, $i^* x_\lambda = 0$. We can then find homomorphisms (over $\mathfrak{A}(p)$) $\eta: C_0 \rightarrow H^+(X, Y)$ of degree n and $\zeta: C_1 \rightarrow H^+(Y)$ of degree $n-1$ such that the following diagram commutes:

$$\begin{array}{ccccc} H^+(Y) & \xleftarrow{i^*} & H^+(X) & \xleftarrow{i^*} & H^+(X, Y) & \xleftarrow{\delta^*} & H^+(Y) & \xleftarrow{i^*} & H^+(X) \\ & & \uparrow \eta & & \uparrow \zeta & & & & \\ & & C_0 & \xleftarrow{d} & C_1 & & & & \end{array}$$

Then for any such pair (η, ζ) we have $i^* \circ \Phi \varepsilon \equiv \zeta z \pmod{i^* Q^n(z, X)}$, where δ^* denotes the homomorphism defined by $\delta^* y = (-1)^{\dim y} \delta y$.

For each pair (d, z) , there is at least one associated operation Φ . Existence is proved by means of a \dagger Postnikov system. Let Φ and Φ' be two operations associated with the same (d, z) . Then they differ by a stable primary operation in the sense that there is an element $\varphi \in C_0/dC_1$ such that $\Phi' \varepsilon \equiv \Phi \varepsilon + \varphi \varepsilon \pmod{Q(z, X)}$, where $\varphi \equiv \sum_{\lambda} a_{\lambda} c_{0,\lambda} \pmod{dC_1}$ means $\varphi \varepsilon = \sum_{\lambda} a_{\lambda} x_\lambda$.

For example, define the action of $\mathfrak{A}(2)$ on \mathbb{Z}_2 by the rule $a \cdot v = 0$ if $\deg a > 0$ and $1 \cdot v = v$ for each $v \in \mathbb{Z}_2$. We consider a minimal projective resolution

$$0 \leftarrow \mathbb{Z}_2 \xleftarrow{\varepsilon} C_0 \xleftarrow{d_1} C_1 \xleftarrow{d_2} C_2 \leftarrow \dots$$

(\rightarrow 200 Homological Algebra). First we take $C_0 = \mathfrak{A}(2)$ and define $\varepsilon(1) = 1$. Next we take C_1 to be free over $\mathfrak{A}(2)$ with generators c_i , where $0 \leq i$ and $d_1 c_i = Sq^{2^i}$. Furthermore, we take C_2 to be free over $\mathfrak{A}(2)$ with generators $c_{i,j}$ with $0 \leq i \leq j, j \neq i+1$ and

$$d_2(c_{i,j}) = Sq^{2^j} c_j + \sum_{0 \leq k < j} b_{i,j,k} c_k$$

with $b_{i,j,k} \in \mathfrak{A}(2)$. Here the $d_1 c_i = Sq^{2^i}$ form a minimal set of generators of $\mathfrak{A}(2)$, and the equations $0 = d_1 d_2 c_{i,j} = Sq^{2^j} \circ Sq^{2^j} + \sum_{0 \leq k < j} b_{i,j,k} Sq^{2^k}$ form a minimal set of generators over $\mathfrak{A}(2)$ of the Adem relations. Let $C_1(j)$ be the submodule over $\mathfrak{A}(2)$ generated by c_k with $0 \leq k \leq j$ in C_1 , and let $d_1(j)$ be the restriction of d_1 on $C_1(j)$. We write $z_{i,j} = d_2 c_{i,j}$.

Let $\Phi_{i,j}$ denote an operation associated with $(d_1(j), z_{i,j})$. Then $\Phi_{i,j}$ is defined on the submodule $D_{i,j}^n(X)$ consisting of elements $x \in H^n(X)$ such that $Sq^{2^k}x = 0$ for $0 \leq k \leq j$ and takes values in $H^{n+2^i+2^{j-1}}(X)$ modulo the submodule

$$Q_{i,j}^n(X) = Sq^{2^i}H^{n+2^{j-1}}(X) + \sum_{0 \leq k < j} b_{i,j,k} H^{n+2^k-1}(X).$$

For example, $\Phi_{0,0}: \text{Ker } \beta_2 \rightarrow \text{Cok } \beta_2$ is the generalized Bockstein homomorphism defined by $\delta/2^2$ and $\Phi_{1,1}$ is the operation discovered by J. Adem that appears as the tertiary obstruction of S^n for $n \geq 2$. If $k \geq 3$, we have the relation

$$Sq^{2^{k+1}} \equiv \sum_{\substack{0 \leq i \leq j \leq k \\ j \neq i+1}} a_{i,j,k} \Phi_{i,j} \left(\text{mod } \sum_{\substack{0 \leq i \leq j \leq k \\ j \neq i+1}} a_{i,j,k} Q_{i,j}^n(X) \right).$$

These formulas can be applied to prove the nonexistence of an element with Hopf-invariant 1 in $\pi_{2n-1}(S^n)$ unless $n = 1, 2, 4, 8$ (Adams [4]). Analogous formulas also hold for $\mathfrak{A}(p)$ with $p > 2$. We have no satisfactory theories concerning cohomology operations of orders higher than 2. For cohomology operations in generalized cohomology theory \rightarrow 237 K-Theory.

65 (IX.17) Combinatorial Manifolds

A. Introduction

First of all, we explain some notions in geometric combinatorial topology, also called **PL** (piecewise linear) **topology**, in order to distinguish between the usual topological viewpoint and the combinatorial (or PL) one. By an n -dimensional **simplicial complex** K we mean an n -dimensional, †locally finite and †rectilinear simplicial complex in the Euclidean N -space \mathbf{R}^N , i.e., an n -dimensional †Euclidean simplicial complex (\rightarrow 70 Complexes). The subspace $P = |K|$ of \mathbf{R}^N covered by all simplexes of K is called an n -dimensional **polyhedron**, and K is referred to as a **simplicial division** or simply a **division** of P . A polyhedron covered by a †subcomplex of a division of P is called a subpolyhedron of P . A polyhedron contained in a polyhedron P is a subpolyhedron of P if and only if it is a closed subset of P . An open subset of a polyhedron P is always a polyhedron but not necessarily a subpolyhedron of P [13]. For arbitrary divisions K_1 and K_2 of a polyhedron there is a common †subdivision of K_1 and K_2 . Thus a property of a simplicial complex K which is invariant under subdivision is called a **combinatorial property** of K or of a polyhedron $|K|$. Two polyhedra P and Q are said to be **combinatorially equivalent** if they have †isomorphic divisions K and L , respectively. Then a homeomorphism $f: P \rightarrow Q$ which is induced from an isomorphism $f: K \rightarrow L$ is called a **combinatorial equivalence**. Since a combinatorial equivalence $f: P \rightarrow Q$ is an isomorphism in the category of polyhedra and **PL** (†piecewise linear) **mappings**, (**PL maps**) which is called the **PL category**, it is also called a **PL homeomorphism** or a **PL isomorphism**, and P and Q are said to be **PL homeomorphic** or **PL isomorphic**. A †topological space X which is homeomorphic with an n -dimensional polyhedron P is said to be **triangulable** and is referred to as an n -dimensional topological polyhedron. Then a division K of P , or a homeomorphism $t: P \rightarrow X$, is called a **triangulation** of X . A division K of P is a triangulation of P . However, there is a compact polyhedron of dimension n (≥ 5) which has a triangulation K not combinatorially equivalent to its division (\rightarrow 70 Complexes; for triangulation problems on manifolds \rightarrow Section C below). The notion of a simplicial complex or cell complex had been introduced as a tool to describe topological invariants of triangulable manifolds (H. Poincaré [1]). The notion of an n -dimensional combinatorial manifold (i.e., a

polyhedron locally combinatorially equivalent to an n -dimensional simplex) was established as an important geometric object in combinatorial topology by means of J. H. C. Whitehead's theory of regular neighborhoods [2, 1939, 1940]. The 1960s saw remarkable results in the study of combinatorial manifolds together with the topological study of differentiable manifolds, which gave rise to contemporary combinatorial or PL topology [3, 4]. The fundamental conjecture (Hauptvermutung) for combinatorial manifolds and the combinatorial triangulation problem of manifolds were negatively solved by R. C. Kirby and L. C. Siebenmann [5, 1969]. In the 1970s, important results about general triangulations were obtained by T. A. Chapman [6] R. D. Edwards, and J. W. Cannon [7].

B. Pseudomanifolds and Homology Manifolds

In this section we explain some topological properties of triangulable manifolds which can be defined by means of incidence relations among their triangulations. A n -polyhedron $M = |K|$ is called an n -dimensional **pseudomanifold** if K satisfies the following three conditions: (i) Every simplex of K is either an n -simplex or a face of an n -simplex; (ii) each $(n-1)$ -simplex is a face of at most two n -simplexes; (iii) for any two n -simplexes σ, τ of K , there exists a finite sequence of n -simplexes $\sigma = \sigma_0, \sigma_1, \dots, \sigma_s = \tau$ such that σ_i and σ_{i+1} have an $(n-1)$ -face in common.

Consider the set S of $(n-1)$ -simplexes of K , each of which is a face of only one n -simplex. Then the set of all $\sigma \in S$ together with their faces forms a subcomplex L of K . The polyhedron $|L|$ of L is called the **boundary** of the pseudomanifold $M = |K|$ and is denoted by ∂M as well as by $\partial K = L$. The boundary of a pseudomanifold is not necessarily a pseudomanifold.

Let $|K|$ be an n -dimensional polyhedron (or n -cell complex). A point p in $|K|$ is called a **regular point** of $|K|$ if it has a neighborhood in $|K|$ homeomorphic to an n -dimensional simplex; otherwise, p is called a **singular point**. A pseudomanifold without singular points is a topological manifold, called a **triangulated manifold**. An n -dimensional polyhedron $|K|$ is a pseudomanifold if and only if the set of all regular points in $|K|$ is dense and connected and the set of all the singular points is of dimension less than $n-1$. Thus a connected triangulated manifold is a pseudomanifold whose boundary coincides with the boundary as a topological manifold:

Let τ_1, τ_2 be oriented n -simplexes of an n -dimensional pseudomanifold $M = |K|$. Suppose

that they have an $(n-1)$ -face σ in common. If the incidence numbers of these simplexes with σ satisfy the relation $[\tau_1, \sigma] = -[\tau_2, \sigma]$, then τ_1 and τ_2 are said to be **coherently oriented**. We call $M = |K|$ with all its n -simplexes oriented an **oriented pseudomanifold** if any two n -simplexes τ_1 and τ_2 are coherently oriented whenever they have an $(n-1)$ -face in common. For an oriented pseudomanifold, the formal sum of all its oriented n -simplexes forms an integral cycle of the pair $(M, \partial M)$, which is called the **fundamental cycle** of $(M, \partial M)$. Its homology class, or fundamental class, generates the homology group $H_n(M, \partial M; \mathbb{Z}) = \mathbb{Z}$. When $M = |K|$ is nonorientable, the **fundamental class with coefficient \mathbb{Z}_2** ($\mathbb{Z}_2 = \mathbb{Z}/2\mathbb{Z}$) is similarly defined. A pseudomanifold is **orientable** if and only if the topological manifold consisting of all its regular points is orientable. If for each point p of a polyhedron $M = |K|$ the local homology groups are $H_i(p) = 0$ ($i \neq n$) and $H_n(p) = \mathbb{Z}$ or 0 , we call $M = |K|$ an n -dimensional **homology manifold**, where $H_i(p) = H_i(M, M-p; \mathbb{Z})$. If M is connected, it is also a pseudomanifold. The set ∂M of points p of $M = |K|$ with $H_n(p) = 0$ is called the **boundary** of M and is an $(n-1)$ -dimensional homology manifold without boundary.

Let $M = |K|$ be an n -dimensional homology manifold. Given simplexes σ, τ of K , $\sigma < \tau$ means that σ is a face of τ and $\sigma \neq \tau$. By definition, a vertex of the n -barycentric subdivision $Sd K$ of K is the barycenter of a simplex of K , and a k -simplex τ of $Sd K$ is defined to be $|\hat{\sigma}_0 \hat{\sigma}_1 \dots \hat{\sigma}_k|$, where $\sigma_0, \sigma_1, \dots, \sigma_k$ are simplexes of K such that $\sigma_0 < \sigma_1 < \dots < \sigma_k$ and $\hat{\sigma}_i$ is the barycenter of σ_i . In the following we denote $Sd K$ by K' . For a q -simplex σ of K , we denote by $K(\sigma)$ the union of all $(n-q)$ -simplexes $|\hat{\sigma} \hat{\sigma}_1 \dots \hat{\sigma}_{n-q}|$ of K' such that $\sigma < \sigma_1 < \dots < \sigma_{n-q}$. Then $K(\sigma)$ is an $(n-q)$ -dimensional homology manifold and pseudomanifold contained in M . $K(\sigma)$ is called the $(n-q)$ -**dual cell** or simply the **dual** of σ . Let K_σ be the subcomplex of K' consisting of simplexes of K' contained in $K(\sigma)$. Thus we have $|K_\sigma| = |K(\sigma)|$. We denote by $(K(\sigma))'$ the union of simplexes of K_σ which do not intersect with σ . The set of dual cells $K^* = \{K(\sigma) | \sigma \in K\}$ of simplexes of K is called the **dual complex** of K ; and K^* is also called the **dual subdivision** of $|K|$. K^* satisfies the following conditions:

- (i) $\bigcup_{\sigma \in K} K(\sigma) = |K|$. Each $K(\sigma)$ is the n -join $\hat{\sigma} * (K(\sigma))'$ of the barycenter $\hat{\sigma}$ and $(K(\sigma))'$.
- (ii) $\sigma < \tau \Leftrightarrow (K(\sigma))' \supset K(\tau)$ ($\sigma, \tau \in K$), $(K(\sigma))' = \bigcup_{\sigma < \tau \in K} K(\tau)$.
- (iii) If $K(\sigma) \cap K(\tau) \neq \emptyset$, then there exist simplexes of K with σ and τ as faces, and for the least simplex ρ of K with σ and τ as faces, it holds that $K(\sigma) \cap K(\tau) = K(\rho)$.

The boundary $\partial(K(\sigma))$ of the $(n-q)$ -

dimensional homology manifold $K(\sigma)$ satisfies $\partial(K(\sigma)) = (K(\sigma))' \cup ((\partial K)(\sigma))$, where $(\partial K)(\sigma)$ denotes the dual cell of σ in ∂K , and we understand that $(\partial K)(\sigma) = \emptyset$ if $\sigma \notin \partial K$. $K^* \cup (\partial K)^*$ is called the **dual complex** of $(K, \partial K)$ and is denoted by $(K, \partial K)^*$. For an r -simplex σ ($0 \leq r \leq n-1$), it holds that

$$H_i((K(\sigma))', (\partial K(\sigma))'; \mathbb{Z}) = 0, \quad i \neq n-r-1,$$

$$H_{n-r-1}((K(\sigma))', (\partial K(\sigma))'; \mathbb{Z}) \cong \mathbb{Z}.$$

Let $|K^*|^q$ be the union of i -dual cells of $(K, \partial K)^* = K^* \cup (\partial K)^*$ such that $i \leq q$. Let $C_q(K^*) = \tilde{H}_q(|K^*|^q / |K^*|^{q-1})$, and let $\partial_q: C_q(K^*) \rightarrow C_{q-1}(K^*)$ be the \dagger connecting homomorphism $\partial_*: \tilde{H}_q(|K^*|^q / |K^*|^{q-1}) \rightarrow \tilde{H}_{q-1}(|K^*|^{q-1} / |K^*|^{q-2})$ in the \dagger reduced homology exact sequence of $(|K^*|^q, |K^*|^{q-1}, |K^*|^{q-2})$ (\rightarrow 201 Homology Theory F). Then $C_q(K^*)$ is a free Abelian group generated by the q -dual cells of $(K, \partial K)^*$, and $C(K^*) = \{C_q(K^*), \partial_q\}$ is a \dagger chain complex. It follows from the property of $H_*(K(\sigma))', (\partial K(\sigma))'; \mathbb{Z}$ as above that $H_q(C(K^*)) = H_q(|K|)$ as in the case of a \dagger CW complex.

Now suppose that K is oriented. For a q -simplex $\sigma = |a_0 a_1 \dots a_q|$ we give an \dagger orientation $[a_0, a_1, \dots, a_q]$. Furthermore, we choose $a_{q+1}, a_{q+2}, \dots, a_n$ so that $[a_0, a_1, \dots, a_n]$ is the orientation of $|a_0 a_1 \dots a_n|$ induced from the orientation of K , and we give $K(\sigma)$ the orientation determined by $[\hat{\sigma}, \hat{\sigma}_1, \dots, \hat{\sigma}_{n-q}]$, where $\sigma_i = |a_0 a_1 \dots a_{q+i}|$. We define $\sigma \cdot K(\sigma) = 1$ for σ and $K(\sigma)$ thus oriented, and $\tau \cdot K(\sigma) = 0$ if $\tau \neq \sigma$. Let $c = \sum \lambda_i \sigma_i \in C_q(K)$ and $c^* = \sum \mu_j K(\sigma_j)$. Then we define $c \cdot c^* \in \mathbb{Z}$ by $c \cdot c^* = \sum_{i,j} \lambda_i \mu_j (\sigma_i \cdot K(\sigma_j))$. The integer $c \cdot c^*$ is called the **intersection number** of c and c^* . For homology classes $[z] \in H_q(K)$ and $[z^*] \in H_{n-q}(K^*)$, the intersection number $z \cdot z^*$ is independent of the choice of representing cycles, and thus we define the **intersection number** $[z] \cdot [z^*] = z \cdot z^*$.

When X is compact, the isomorphism of the Poincaré-Lefschetz duality theorem $H_q(X, \partial X; \mathbb{R}) \cong H^{n-q}(X; \mathbb{R})$ is given in terms of intersection numbers.

C. Combinatorial Manifolds and PL Manifolds

A polyhedron which is PL homeomorphic with a k -dimensional simplex or its boundary is called a **PL k -ball** or a **PL $(k-1)$ -sphere** and is denoted by B^k, S^{k-1} , respectively. A simplicial complex K or a polyhedron $M = |K|$ is called an n -dimensional **combinatorial manifold** if the \dagger star of each vertex in K is a PL k -ball. If M is an n -dimensional combinatorial manifold, then so is an open subset of M . An n -dimensional PL manifold is a topological manifold X with a distinguished maximal coordinate system $\pi = \{(U_i, h_i)\}$, called a **PL**

structure on X , which consists of homeomorphisms $h_i: U_i \rightarrow V_i$ from open subsets U_i onto open subsets V_i of an n -dimensional simplex such that $h_i \circ h_i^{-1}: h_i(U_i \cap U_j) \rightarrow h_j(U_i \cap U_j)$ are PL homeomorphisms. For a PL manifold (X, π) there is a triangulation $t: M \rightarrow X$ from a combinatorial manifold M such that for each $(U_i, h_i) \in \pi$, $h_i \circ t|_{t^{-1}(U_i)}$ is a PL homeomorphism from an open subset $t^{-1}(U_i)$ of M onto $h_i(U_i)$. Thus the notions of combinatorial manifold and PL manifold are essentially the same. For a \dagger smooth manifold (X, σ) , there is a unique PL homeomorphism class of a combinatorial manifold by means of a \dagger smooth triangulation. In this sense, smooth manifolds are combinatorial manifolds; but the converse of this is not true (\rightarrow 114 Differential Topology C). A triangulation of a topological manifold which is a combinatorial manifold is called a **combinatorial triangulation**. The triangulation problem for n -dimensional topological manifolds, especially the existence and uniqueness problem of their combinatorial triangulations, a long-standing problem, is stated as follows. **CT_n (Combinatorial Triangulation Problem)**: Is every n -dimensional topological manifold homeomorphic with a combinatorial manifold? **CH_n (Hauptvermutung for combinatorial manifolds)**: Homeomorphic n -dimensional combinatorial manifolds should be PL homeomorphic. When $n \leq 3$, CT_n and CH_n hold; this was shown for $n=2$ by T. Radó [15] and for $n=3$ by E. E. Moise [16]. Moreover, in this case, topological manifolds admit unique smooth structures, and homology manifolds are combinatorial manifolds. For $n \geq 5$, \dagger surgery theory was used and developed as an obstruction theory for "homotoping" a homeomorphism $h: M \rightarrow M'$ between n -dimensional combinatorial manifolds to a PL homeomorphism by D. Sullivan (1967). By the discovery of the torus-unfurling method for "isotoping" $h: M \rightarrow M'$ to a PL homeomorphism, Kirby reduced CT_n and CH_n for $n \geq 5$ to CH_n for some specific manifolds, such as thickened tori modulo the boundary, for which surgery methods had been sufficiently developed (for isotopy \rightarrow Section D). The solutions (1)–(9) can be stated as follows.

(1) Classification of combinatorial triangulations. Assume $n \geq 5$. Existence: An n -dimensional closed topological manifold X admits a combinatorial triangulation if and only if an obstruction $\Delta(X) \in H^4(X; \mathbb{Z}_2)$ vanishes. Uniqueness: A homeomorphism $h: M \rightarrow M'$ between n -dimensional closed combinatorial manifolds is isotopic (\rightarrow Section D) to a PL homeomorphism if and only if an obstruction $\Delta(h) \in H^3(X; \mathbb{Z}_2)$ vanishes (Kirby and Siebenmann [5]).

In fact, for each $n \geq 5$, there is an n -

dimensional combinatorial manifold which is homeomorphic to a torus $S^1 \times \dots \times S^1$ but is not PL homeomorphic, and there is an n -dimensional closed manifold which is not homeomorphic to a combinatorial manifold (Siebenmann [18]).

As a special case, the following conjecture is proved for $n \geq 5$.

(2) The n -dimensional **annulus conjecture**.

The closed region bounded by two mutually disjoint locally flat $(n-1)$ -dimensional topological spheres S_1 and S_2 in an n -dimensional sphere S^n is homeomorphic with an n -dimensional annulus $S^{n-1} \times [0, 1]$ (Kirby [19]).

Regarding the uniqueness problem for (not necessarily combinatorial) triangulations of topological manifolds, we mention the following deep result.

(3) **Double suspension theorem** for homology spheres. The double suspensions of homology n -spheres are homeomorphic with S^{n+2} , where a homology n -sphere is a closed topological manifold with the same homology groups as those of S^n (Cannon [7]).

For each $n \geq 3$, there is a homology n -sphere P^n which is a combinatorial manifold with the nontrivial fundamental group (for $n=3$, see Poincaré [1, 1904] and for $n \geq 4$, see M. Newman, 1948). The suspension of P^n is an example of an $(n+1)$ -dimensional homology manifold which is not a topological manifold. The double suspension of P^n is not a combinatorial manifold but is homeomorphic with S^{n+2} . The problem of whether every n -dimensional topological manifold is homeomorphic to a polyhedron is still open for $n \geq 4$. This problem is reduced to a problem in homology 3-spheres (T. Matumoto; D. E. Galewski and R. J. Stern).

In the following we list some results on combinatorial manifolds focusing on Whitehead's theory of regular neighborhoods [2]. Let $M = |K|$ be an n -dimensional combinatorial manifold without boundary. The dual complex K^* consists of PL balls. Thus the division K of M gives rise to a decomposition into PL handles $H(K)$ of M in such a way that for each k -dimensional simplex $\sigma \in K$, the star $St_{K''}(\sigma)$ of its barycenter σ in the second barycentric subdivision K'' of K is a PL handle of index k . If L is a subcomplex of K or K^* , then the star $St_{K''}(|L|)$ of $|L|$ in K'' is a subhandlebody of $H(K)$ or of its dual handlebody $H^*(K) = H(K^*)$, denoted by $H_K(L)$ or $H_{K^*}(L)$, respectively. In particular, if M is closed, orientable, and of dimension 3, then $U = H_K(K^{(1)})$ and $V = H_{K^*}(K_{(1)}^*)$ are PL homeomorphic with a PL boundary-connected sum of some copies of a solid torus $S^1 \times B^2$, and $M = U \cup V$, $U \cap V = \partial U = \partial V$, where $K^{(k)}$ and $K_{(k)}^*$ stand for the k -skele-

ton of K and K^* , respectively. This decomposition $(U, V; \partial U = \partial V)$ of M is called a **Heegaard decomposition** (or **splitting**) of M [12]. We say that a simplicial complex L collapses elementarily to a subcomplex L_1 of L , referred to as an **elementary collapse** $L \searrow L_1$, if $L - L_1 = \{\sigma, \tau\}$, where σ is a k -dimensional simplex of L and τ is a $(k-1)$ -dimensional face of σ which is not a face of any simplex in $L - \{\sigma, \tau\}$. We say that a polyhedron P collapses to a subpolyhedron Q of P or Q expands to P , referred to as a **collapse** $P \searrow Q$ or **expansion** $Q \nearrow P$, if there is a division L of P containing a subcomplex L_1 dividing Q so that there is a sequence of elementary collapsings $L \searrow L_1 \searrow \dots \searrow L_r$. For a subpolyhedron P of a combinatorial manifold M , a subpolyhedron U of M is called a **regular neighborhood** of P in M if (1) U is a combinatorial manifold which is a closed neighborhood of P in M and (2) $U \searrow P$. In general, for a subcomplex L of a simplicial complex K , the star $St_{K''}(|L|)$ of $|L|$ in the second barycentric subdivision K'' of K is called a **second barycentric derived neighborhood** or simply a **derived neighborhood** of $|L|$ in $|K|$ (E. C. Zeeman [4]).

(4) **Regular neighborhood theorem**. Let P be a compact subpolyhedron of a combinatorial manifold M . Existence: Every derived neighborhood of P in M is a regular neighborhood. Uniqueness: Any two regular neighborhoods of P in M are PL homeomorphic by a mapping keeping P pointwise fixed [2, 1939]. On one hand, this theorem is regarded as a combinatorial counterpart to the tubular neighborhood theorem of differential topology. For a topological manifold X with boundary ∂X , there are a neighborhood U of ∂X in X and a homeomorphism $h: \partial X \times [0, 1] \rightarrow U$, called a collar of ∂X in X , such that $h(x, 0) = x$ ($x \in \partial X$). In particular, for a combinatorial manifold $M = X$ we can take U as a derived neighborhood of ∂M in M and h as a PL homeomorphism, called a PL collar of ∂M in M . (For more about normal bundle theory → 147 Fiber Bundles Q). On the other hand, it is also regarded as a combinatorial deformation theorem of a handlebody decomposition $H_{K''}(L)$ of a derived neighborhood $St_{K''}(|L|)$.

Two polyhedra P and Q are said to be **simple homotopy equivalent** if Q is obtained from P by a finite sequence of collapsings and expansions. A composite mapping $f: P \rightarrow Q$ of the inclusion mappings and deformation retractions associated naturally to the expansions and the collapsings from P to Q is called a **simple homotopy equivalence**. Moreover, if P and Q are subpolyhedra of a combinatorial manifold M and those collapsings and expansions take place in M , then their regular neighborhoods are PL homeomorphic [2, 1940].

(5) A simply homotopy equivalence is clear-

ly a homotopy equivalence. Conversely, we have the **simple homotopy theorem**: For the homotopy class of a homotopy equivalence $f: P \rightarrow Q$ between compact connected polyhedra P and Q , there is a well-defined element $W(f)$, called the **Whitehead torsion** of f , in the t Whitehead group $Wh(G)$ of the fundamental group $G = \pi_1(P)$ such that f is homotopic to a simple homotopy equivalence if and only if $W(f) = 0$, ([2, 1950]; \rightarrow also J. W. Milnor [20]).

Let W be a compact combinatorial manifold of dimension $n + 1$. If ∂W consists of two connected components M and N such that the inclusion mappings $M \subset W$ and $N \subset W$ are simple homotopy equivalences, then $(W; M, N)$ is called an **s-cobordism** of dimension $n + 1$. The following theorem of D. Barden, B. Mazur, and J. Stallings is the nonsimply connected PL version of Smale's t h-cobordism theorem.

(6) **s-Cobordism theorem**. For $n \geq 5$, an s-cobordism $(W; M, N)$ of dimension $n + 1$ is PL homeomorphic with $(M \times [0, 1]; M \times 0, M \times 1)$ (B. Mazur [21]; M. Kervaire [22]; C. Weber [23]; J. F. P. Hudson [8]).

(7) Topological invariance of simple homotopy types. Two homeomorphic compact polyhedra are simple homotopy equivalent (T. A. Chapman [6]).

The famous **Poincaré conjecture** that a simply connected closed manifold of dimension 3 is homeomorphic to a 3-sphere is still unsolved despite much effort by many mathematicians. This conjecture is generalized for dimension n as follows.

(8) **Generalized Poincaré conjecture** in dimension n . Any homotopy n -sphere Σ^n is homeomorphic to an n -sphere, where a homotopy n -sphere is defined to be an n -dimensional topological manifold homotopy equivalent to an n -sphere.

This has been affirmatively answered for $n \geq 5$. The first proof was given by S. Smale (\rightarrow 114 Differential Topology F, K). From the viewpoints of collapsing and general position (\rightarrow Section D), J. Stallings [3, 1960] and E. C. Zeeman [11, 198–204] proved the following.

(9) **Engulfing lemma**. For a compact polyhedron P of dimension m in the interior $\mathring{M} = M - \partial M$ of an n -dimensional combinatorial manifold M , there is a PL n -ball in \mathring{M} containing P in its interior (i.e., engulfing P), provided that M is m -connected (i.e., $\pi_i(M) = 0$ ($i \leq m$)) and $n - m \geq 3$. (For the topological version \rightarrow M. H. A. Newman [24].) If a combinatorial manifold $M = |K|$ is a homotopy n -sphere ($n \geq 5$), then by the engulfing lemma, there are PL n -balls B_1 and B_2 engulfing $H_{K^{(n-3)}}$ and $H_{K^{(n-2)}}$ so that $\hat{B}_1 \cup \hat{B}_2 = M$. By the generalized Schoenflies theorem (\rightarrow Section G), $B_2 - \hat{B}_1 = M - \hat{B}_1$ is homeomorphic to

an n -ball. It follows that by the Alexander trick (\rightarrow Section D) M is homeomorphic to an n -sphere. Since CH_n holds for S^n ($n \geq 5$), the homotopy PL n -sphere M is actually PL homeomorphic with S^n .

D. Embeddings of Combinatorial Manifolds

An injective PL mapping $f: P \rightarrow Q$ between polyhedra is called a **PL embedding** if $f(P)$ is a subpolyhedron of Q (\rightarrow Section A). Namely, a PL embedding $f: P \rightarrow Q$ is a PL mapping which is induced from a simplicial injection $f: K \rightarrow L$, called a division of f , for some divisions K and L of P and Q , respectively. In the following we explain PL embeddings from an m -dimensional combinatorial manifold M into an n -dimensional combinatorial manifold N . For a PL embedding $f: M \rightarrow N$, $c = n - m$ is called the **codimension** of f . If $f^{-1}(\partial N) = \partial M$, f is said to be **proper**. Since an injective PL mapping $f: M \rightarrow N$ is a PL embedding if and only if it is proper as a mapping between topological spaces M and N (i.e., the preimages of compact sets are compact), this term “proper” for PL embeddings should not be confused with the term “proper” for mappings. Two PL embeddings $f: M \rightarrow N$ and $f': M' \rightarrow N'$ are said to be (PL) **equivalent** if there is a PL homeomorphism $h: N \rightarrow N'$, called an equivalence from f to f' , such that $h \circ f(M) = f'(M')$. When $M = M'$, f and f' are said to be (PL) **isomorphic** if there is an equivalence $h: N \rightarrow N'$ from f to f' such that $h \circ f = f'$. A **submanifold** of N is defined as a subpolyhedron of N which is a combinatorial manifold. Thus the equivalence class of a PL embedding $f: M \rightarrow N$ is nothing but the PL homeomorphism class of a pair $(N, f(M))$ of N and its submanifold $f(M)$. For a submanifold of N , the same terms as those for the inclusion mapping are used. For every division $f: K \rightarrow L$ of a (proper) PL embedding $f: M \rightarrow N$ and for $x \in M$ we have a (proper) PL embedding $f|_{\text{St}_K(x)}$ from a PL m -ball $\text{St}_K(x)$ into a PL n -ball $\text{St}_L(f(x))$ which represents the t germ of f at $x \in M$. A PL embedding of a PL m -sphere into a PL n -sphere is called a **PL (n, m) -knot** or (n, m) -sphere pair and a proper PL embedding of a PL m -ball into a PL n -ball is called a **PL (n, m) -ball knot** or (n, m) -ball pair. A PL (n, m) -knot (a PL (n, m) -ball knot) is said to be **trivial** or **unknotted** if it is equivalent to the inclusion mapping $\partial I^{m+1} \times 0 \subset \partial I^{n+1}$ ($I^m \subset I^n$), where $I = [-1, 1]$. Then we have the following statements (1)–(5).

(1) **Zeeman's unknotting theorem**. Every PL (n, m) -knot and every PL (n, m) -ball knot are unknotted, provided that $n - m \geq 3$.

In general, an injection $g: X \rightarrow Y$ between

topological manifolds is said to be **locally flat** if for each point $x \in X$, there is a neighborhood U of x in X so that the local germ of f at x is equivalent to the inclusion mapping $U \times 0 \subset U \times I^n$. Then f is necessarily proper, i.e., $f^{-1}(\partial Y) = \partial X$. A PL embedding $f: M \rightarrow N$ is said to be **locally flat** if it is locally flat in the PL category. Namely, $f|_{\text{St}_K(x)}$ is equivalent to $I^m \times 0 \subset I^n$. Conversely, Zeeman's unknotting theorem implies the following.

(2) Every proper PL embedding of codimension ≥ 3 is locally flat.

Since every locally flat PL embedding $f: M \rightarrow N$ admits a normal \dagger block bundle, the classification of $F: M \rightarrow U$ up to isomorphism is reduced to the classification of block bundles (\rightarrow 147 Fiber Bundles Q), where U is a derived neighborhood of $f(M)$ in N . (For the general classification of locally flat PL embeddings by surgical methods \rightarrow C. T. C. Wall [25, Corollary 11.3.1]).

In the codimension 2 case, there exist non-trivial knots (the classical knots) (\rightarrow 235 Knot Theory) and there is a proper PL submanifold which is not locally flat. For example, a complex projective curve V defined by $x^n + y^{n-1}z = 0$ can be regarded as a PL 2-sphere in the complex projective plane CP^2 , and for the inclusion mapping $i: V \subset CP^2$, at $0 = (0:0:1)$, $i|_{\text{St}_V(0)}$ is PL equivalent to a cone of a torus knot $k: S^1 \subset S^3$ of type $(n, n-1)$. For further results in higher-dimensional knot theory (\rightarrow 235 Knot Theory) we mention the works of M. Kato and Y. Matsumoto [26] and S. Capell and J. Shaneson [27].

Here we consider only proper PL embeddings of a fixed m -dimensional combinatorial manifold M into a fixed connected n -dimensional combinatorial manifold N , so that a codimension 0 PL embedding is a PL homeomorphism. Two PL embeddings $f_0, f_1: M \rightarrow N$ are said to be pseudoisotopic if there is a proper PL embedding $F: M \times [0, 1] \rightarrow N \times [0, 1]$, called a pseudoisotopy from f_0 to f_1 , such that $F(x, 0) = (f_0(x), 0)$ and $F(x, 1) = (f_1(x), 1)$ ($x \in M$). Moreover, if F satisfies the level-preserving condition $F(M \times \{t\}) \subset N \times \{t\}$ ($0 \leq t \leq 1$), then f_0 and f_1 are said to be **isotopic**, and F or a homotopy $\{f_t\}$ defined by $F(x, t) = (f_t(x), t)$ ($(x, t) \in M \times [0, 1]$) is called an **isotopy** from f_0 to f_1 . When $M = N$, a PL homeomorphism which is isotopic to the identity, or the isotopy of the identity itself, is called an **ambient isotopy** of N . Two PL embeddings from M to N are said to be **ambient isotopic** if they are isomorphic by an ambient isotopy of N .

Since I^k ($I = [-1, 1]$) is a k -dimensional \dagger convex cell and is a cone $0 * \partial I^k$ of ∂I^k from the center 0, each point x of $I^k - \{0\}$ can be written uniquely as $x = t \cdot u$ for $0 < t \leq 1$ and $u \in \partial I^k$. Thus a PL embedding $f: \partial I^m \rightarrow \partial I^n$ can

be extended to a PL embedding $F: I^m \rightarrow I^n$, called a **cone extension** or simply a **cone** of f , by setting $F(0) = 0$ and $F(t \cdot u) = t \cdot f(u)$ for $t \cdot u \in I^m - \{0\}$. This method of cone extension is often referred to as **Alexander's trick**. By using Alexander's trick and the uniqueness of regular neighborhoods, one can show without much difficulty that (i) the isotopy classes of PL homeomorphisms of PL spheres or PL balls onto themselves are classified by their \dagger degrees ($= \pm 1$) (V. K. A. M. Gugenheim, 1953), and (ii) every PL (n, m) -knot or PL (n, m) -ball knot is equivalent to the standard one $\partial I^{m+1} \times 0 \subset \partial I^{n+1}$ or $I^m \times 0 \subset I^n$ up to isotopy, provided that $n - m \geq 1$. This is why we define the notion of ambient isotopy in a different way from the differentiable category, where the smooth isotopy is always covered by the ambient isotopy. However, for codimension ≥ 3 , because of Zeeman's unknotting theorem, the following holds.

(3) The pseudoisotopy class, the isotopy class, and the ambient isotopy class of a PL embedding of codimension ≥ 3 are the same (J. F. P. Hudson and E. C. Zeeman, 1964).

In order to construct a PL embedding from a continuous mapping within its homotopy class, the notion of general position is useful. A PL mapping $\varphi: M \rightarrow N$ is said to be in **general position** if $\dim \varphi^{-1}(y) \leq 0$ ($y \in N$) and $\dim S(\varphi) \leq 2m - n$, where $S(\varphi)$ is the closure of $\{x \in M \mid \varphi^{-1}(\varphi(x)) \neq \{x\}\}$ in M (J. F. P. Hudson [8]).

(4) **General position theorem.** Every continuous mapping $\psi: M \rightarrow N$ can be approximated by a PL mapping $\varphi: M \rightarrow N$ which is in general position.

The following theorem can be proved by sharpening the general position theorem and the engulfing lemma.

(5) **Irwin's embedding theorem.** Let $\psi: M \rightarrow N$ be a continuous mapping from a compact combinatorial manifold of dimension m into a combinatorial manifold of dimension n such that $\psi|_{\partial M}$ is a PL embedding from ∂M into ∂N . Assume that (i) M is d -connected, (ii) N is $(d+1)$ -connected, and (iii) $n - m \geq 3$, where $d = 2m - n$. Then $\psi: M \rightarrow N$ is homotopic to a proper PL embedding $f: M \rightarrow N$ relative to ∂M . Moreover, if M and N are closed and if (i*) M is $(d+1)$ -connected and (ii*) N is $(d+2)$ -connected, then two homotopic PL embeddings from M into N are ambient isotopic (M. C. Irwin, 1965).

E. 3-Manifolds

There has been a great deal of research done on 3-manifolds, and we have, among others, the following results (1)–(4).

(1) **Sphere theorem.** Let M be an orientable 3-manifold with $\pi_2(M) \neq 0$. Then there exists a PL embedding f of a 2-sphere into M such that f is not homotopic to 0 in M (C. Papakyriakopoulos [28]).

(2) **Dehn's lemma.** Let D be a 2-cell with self-intersections in a 3-manifold M , with its boundary a simple polygon C . If some neighborhood U of C in D has no singularities, then there exists a 2-cell in M without singularities whose boundary is C . In 1910, M. Dehn asserted this lemma, but his proof was incomplete. In 1957, Papakyriakopoulos and T. Homma proved the lemma independently [28, 29].

(3) **Loop theorem.** Let N be the boundary of a 3-manifold M and U be an open set in a component of N . If there is a closed curve in U which is homotopic to 0 in M but not in N , then there exists a simple closed curve in U homotopic to 0 in M but not in N (Papakyriakopoulos [30], J. Stallings [31]).

(4) **Unique decomposition theorem** for a 3-manifold (J. W. Milnor [32], H. Kneser). We assume that all manifolds are connected, oriented, and triangulated 3-manifolds without boundaries and that all homeomorphisms are piecewise linear. Two manifolds M, M' are said to be isomorphic ($M \approx M'$) if there exists an orientation-preserving homeomorphism of M onto M' . Removing an open 3-cell from each of two 3-manifolds M, M' and identifying the boundaries of these removed cells, we obtain a 3-manifold $M \# M'$, called the **connected sum** of M and M' . A manifold that is not isomorphic to the 3-sphere S^3 is called nontrivial. A nontrivial manifold P is called prime if P cannot be decomposed as $P = M_1 \# M_2$ with M_1 and M_2 both nontrivial. A manifold M is called **irreducible** if every 2-sphere in M bounds a 3-cell. Then from the sphere theorem the following results can be deduced: If a compact 3-manifold M is nontrivial, then M is isomorphic to a connected sum $P_1 \# P_2 \# \dots \# P_k$ of prime manifolds P_i ($i = 1, 2, \dots, k$), where P_1, P_2, \dots, P_k are determined uniquely up to order. Every irreducible 3-manifold M has $\pi_2(M) = 0$. Conversely, if a 3-manifold M has $\pi_2(M) = 0$, then M is irreducible, provided that the Poincaré conjecture is correct. (For further results on 3-manifolds \rightarrow F. Waldhausen [10] and J. Hempel [12].)

Irreducible sufficiently large 3-manifolds [10] can further be decomposed into Seifert fibered spaces and "simple manifolds" which contain no essential tori (W. Jaco and P. B. Shalen, K. Johannson). Existence of hyperbolic structures on "simple manifolds" has been extensively studied by W. Thurston.

F. Wild Spaces

Nonclosed 3-manifolds behave very differently from closed 3-manifolds. For example, there exists an open 3-manifold U that has the same homotopy type as an open 3-cell but is not homeomorphic to it (M. H. A. Newman and J. H. C. Whitehead, 1937). The construction of this and similar examples generally involves infinite processes. Such examples, which do not exhibit the properties we expect, are commonly termed **pathological** (or **wild**) spaces. For the manifold U above, the product $U \times \mathbf{R}^1$ is found to be homeomorphic to the Euclidean 4-space \mathbf{R}^4 . R. Moore proved that the quotient space of the Euclidean 2-space \mathbf{R}^2 by any upper semicontinuous decomposition consisting of continua not separating \mathbf{R}^2 is homeomorphic to \mathbf{R}^2 . On the other hand, R. H. Bing (1959) gave an example of a similar upper semicontinuous decomposition of \mathbf{R}^3 for which the quotient space B is not homeomorphic to \mathbf{R}^3 and is not even a manifold. This quotient space has the property $B \times \mathbf{R}^1 \approx \mathbf{R}^4$. Bing (1957) also proved that at most countably many copies of a wild closed surface can simultaneously be embedded in \mathbf{R}^3 . On the other hand, Stallings (1960) proved that there exists a wild disk of which a set of copies with the power of the continuum can simultaneously be embedded in \mathbf{R}^3 [11].

The study of the quotient space of n -dimensional manifolds by cell-like decompositions has been fully generalized by Edwards and Cannon [7] for $n \geq 5$ to prove the double suspension theorem of homology spheres (\rightarrow Section C (3)).

G. The Schoenflies Theorem

In 1906, A. M. Schoenflies proved that every simple closed curve in the plane is the boundary of a 2-cell. This result is sharper than the Jordan curve theorem and is called the **Schoenflies theorem**. However there was a gap in the proof, and the complete proof was given by L. E. J. Brouwer in 1910.

The following higher-dimensional analog of the above theorem is called the **Schoenflies problem**: Is every $(n-1)$ -sphere embedded in the n -dimensional Euclidean space \mathbf{R}^n ($n \geq 3$) the boundary of an embedded n -disk?

For the case where the embedding is topological, L. Antoine constructed a counterexample, called **Antoine's necklace**, for $n = 3$ in 1921 and solved this problem negatively. Also, J. W. Alexander constructed another counterexample, called **Alexander's horned sphere**, in 1924 (Fig. 1). A similar example was given by R. H. Fox and E. Artin in 1948 by making use

of knot theory (Fig. 2). The study of wild embeddings began with these examples, and many interesting results were obtained (Bing).

For the case where the embedding is PL or smooth, the Schoenflies problem has been solved affirmatively for $n=3$ (Alexander).

M. Brown (1960) and B. Mazur (1959) proved the following: Let $h: S^{n-1} \times [-1, 1] \rightarrow S^n$ be a topological embedding; then $S^n - h(S^{n-1} \times \{0\})$ consists of connected open sets D_+ and D_- of S^n , and the closures of D_+ and D_- are both homeomorphic to the n -disk. This result solves the Schoenflies problem affirmatively for $n \geq 5$ when the embedding is PL and locally flat or smooth.

66 (XVI.10) Combinatorics

A. General Review of Combinatorics

Combinatorics is concerned mainly with problems of discrete sets, such as the enumeration of subsets satisfying certain conditions, or their actual construction and the selection of an optimal subset with respect to a suitable criterion. Generally speaking, both the theoretical analysis and the construction of discrete sets are much more difficult than those problems in analysis concerning infinite sets with suitable topologies.

The main emphasis and the name of this field have changed from time to time and from person to person. Other names such as **combinatorial analysis**, **combinatorial theory**, or **combinatorial mathematics** are commonly used and mean almost the same thing. Recently, the expression “**discrete mathematics**” has also been used to describe the same field. In many cases a problem originally conceived as number-theoretic, algebraic, analytic, or geometric has eventually turned out to be combinatorial (\rightarrow 102 Design of Experiments, 241 Latin Squares).

[†]Graph theory, originally a combinatorial study of 1-dimensional topological complexes, has developed into an important branch of mathematics.

In this article we discuss various topics not yet considered to be established branches or organized fields of mathematics. The topics treated under the title “combinatorics” are at present not unified, and consist of a mixture of isolated techniques. However, recent progress with electronic computers is playing an important role in the solution of various combinatorial problems arising from large systems, and the study of combinatorics is now quite active both in theoretical development and application. We now have special journals in this field, such as the *Journal of Combinatorial Theory* (Academic Press), *Combinatorica* (Elsevier), the *European Journal of Combinatorics* (Academic Press), *Discrete Mathematics* (North-Holland), and *Discrete Applied Mathematics* (North-Holland).

B. Three Fundamental Principles

The most fundamental among the various principles in combinatorics are the following three principles for enumeration problems. Let Ω be a finite set and let $|A|$ denote the number of elements in a subset A of Ω .

(1) **Rule of sums:** If $A \cap B = \emptyset$, then $|A + B| = |A| + |B|$.

(2) **Rule of products:** $|A \times B| = |A| \times |B|$, where $A \times B$ is the [†]direct product of the two sets A and B .

(3) **Principle of inclusion and exclusion:**

$$\begin{aligned}
 &|A_1 \cup A_2 \cup \dots \cup A_n| \\
 &= \sum_i |A_i| - \sum_{i < j} |A_i \cap A_j| + \sum_{i < j < k} |A_i \cap A_j \cap A_k| \\
 &\quad - \dots + (-1)^{n-1} |A_1 \cap A_2 \cap \dots \cap A_n|.
 \end{aligned}$$

These principles can be generalized as statements concerning various measures.

C. Möbius Inversion Formula

Let P be an ordered set whose arbitrary interval is a finite set. Let $[P \times P] = \{(x, y) \in P \times P \mid x \leq y\}$ be the set of intervals of P . A function satisfying the following two conditions is determined uniquely and is called the **Möbius function** over P :

- (i) $\mu(x, x) = 1$ for all $x \in P$;
- (ii) $\sum_{x: x \leq z \leq y} \mu(x, z) = 0$ for all $x, y \in P$ with $x < y$ and $x \neq y$.

When K is a field, for a mapping $f: [P \times P] \rightarrow K$, we can define another mapping $g: [P \times P]$

$P \rightarrow K$ by

$$g(x, y) = \sum_{z \in [x, y]} f(x, z).$$

Then we have the **Möbius inversion formula**

$$f(x, y) = \sum_{z \in [x, y]} g(x, z) \mu(z, y).$$

This formula implies, as its special cases, many important formulas, such as the Möbius inversion formula in number theory, the principle of inclusion and exclusion, and the inverse relation of difference and summation.

D. Some Special Sequences

In the enumeration problem, many important sequences $\{a_n\}$ are given by the generating function $f(x) = \sum a_n x^n$. Typical examples are as follows: (1) Binomial coefficients: $(1+x)^m = \sum \binom{m}{n} x^n$. (2) Multinomial coefficients: $(x_1 + \dots + x_r)^m = \sum \binom{m}{n_1, \dots, n_r} x_1^{n_1} \dots x_r^{n_r}$. (3) Multiple combination $a_n = {}_m H_n = \binom{m+n-1}{n} (1-x)^{-m} = \sum \binom{m}{n} H_n x^n$. (4) Bell numbers: $\exp(e^x - 1) = \sum B_n x^n / n!$ (5) The **Stirling number of the second kind** S_m^n is the total number of bijections from N_n to N_m divided by $m!$, where $N_n = \{1, 2, \dots, n\}$. This is equivalent to the total number of partitions of N_n into m nonempty blocks: $(e^x - 1)^m / m! = \sum_{n=m}^{\infty} S_m^n x^n / n!$.

In general, when the generating function $f(x)$ is an analytic function of one or several variables as above, we can obtain recurrence formulas for the sequence from the functional equations or the differential equations which $f(x)$ satisfies; or we can get asymptotic estimates by using the saddle point method.

E. Pólya's Enumeration Theorem

Let U be a finite set, V be a (finite or infinite) set, G be a transformation group operating on U , and w be a function assigning to each element of V a "weight." A weight is an element of a ring and is usually defined by a suitable generating function. The weight of a function $f: U \rightarrow V$ is defined by $w(f) = \prod_{u \in U} w(f(u))$. Two functions f_1 and f_2 are considered identical ($f_1 \equiv f_2$) if there exists a $\pi \in G$ such that $f_1 = f_2 \circ \pi$. Put $F = V^U / (\Xi)$, the set of all equivalence classes of the relation Ξ . $w(\tilde{f})$ is well-defined for $\tilde{f} \in F$, because $f_1 \equiv f_2$ implies $w(f_1) = w(f_2)$. Then we have the equality $\sum_{\tilde{f} \in F} w(\tilde{f}) = P_G(\sum_{v \in V} w(v), \sum_{v \in V} w(v)^2, \dots, \sum_{v \in V} w(v)^m)$. Here, $P_G(y_1, y_2, \dots, y_m)$ is the **cycle index** of G , which is given by $n^{-1} \sum_{\pi \in G} y_1^{j_1(\pi)} y_2^{j_2(\pi)} \dots y_m^{j_m(\pi)}$, where $n = |G|$, $m = |U|$, and $j_k(\pi)$ is the number of cyclic permutations of length k contained in π . This is called **Pólya's enumeration theorem**.

When $G = S_m$ (the symmetric group), $P_{S_m}(y_1, \dots, y_m) = \sum_{\lambda_k \geq 0, \sum k \lambda_k = m} (\lambda_1! 2^{\lambda_2} \lambda_2! \dots m^{\lambda_m} \lambda_m!)^{-1} y_1^{\lambda_1}$

$\dots y_m^{\lambda_m}$. When $G = A_m$ (the alternating group), $P_{A_m}(y_1, \dots, y_m) = \sum_{\lambda_k \geq 0, k \lambda_k = m, \sum \lambda_k = \text{even}} 2 (\lambda_1! 2^{\lambda_2} \lambda_2! \dots m^{\lambda_m} \lambda_m!)^{-1} y_1^{\lambda_1} \dots y_m^{\lambda_m}$. When $G = C_m$ (the cyclic group), $P_{C_m}(y_1, \dots, y_m) = m^{-1} \sum_{k|m} \varphi(k) y_k^{m/k}$, where $\varphi(k)$ is the Euler function, i.e., the number of integers less than k and coprime to k . This theorem is widely applicable to various problems with suitable choices of weights. Several generalizations have also been studied (see, e.g., [3]).

F. The Notion of Polymatroids

The theory of matroids was originally introduced as an abstraction of the notion of linear dependence in a vector space or of some properties of graphs or of the notion of algebraic dependence in the theory of fields (see, e.g., [4, 5]). But recently, as many important applications were discovered, it has become an important branch of combinatorics (see [6–8]).

Let μ be a function from a lattice L to a totally ordered module R . μ is called **submodular** if $\mu(x) + \mu(y) \geq \mu(x \vee y) + \mu(x \wedge y)$ for every pair of elements $x, y \in L$. The set of $a \in L$ such that $\mu(a) = \min_{x \in L} \mu(x)$ constitutes a sublattice in L . Let L be the family of all subsets of a finite set E . The sublattices K in $L = 2^E$ and the pseudo-orders over E correspond in a one-to-one manner as follows (here pseudo-order means a binary relation taken as an ordering without assuming the antisymmetric law): (i) The class of a partition P of E corresponds to the difference of two subsets which are the immediate predecessor and immediate successor in K , or the complement with respect to E of the maximum element in K , or the complement of the minimum element. (ii) The complement of the maximum element in K is maximum in the order of P , and the minimum element in K is minimum in the order of P . (iii) Two classes ξ_1, ξ_2 in P , given as the difference of two elements in K , satisfy the relation $\xi_1 \geq \xi_2$ with respect to the order of P if and only if all elements of K such that $x \supset \xi_1$ in E satisfy $x \supset \xi_2$.

Now let E be a finite set, $L = 2^E$, and let \mathbf{R} be the real number field with the usual addition and order relations. If a submodular function $\mu: 2^E \rightarrow \mathbf{R}$ satisfies the following conditions, then $\mathbf{P} = (E, \mu)$ is called a **polymatroid** over E , and μ is called the **rank function** over \mathbf{P} . (i) $\mu(\emptyset) = 0$, where \emptyset is the empty set. (ii) $x \subset y$ ($\subset E$) implies $\mu(x) \leq \mu(y)$. A function $u: E \rightarrow \mathbf{R}$ is automatically extended to $u: 2^E \rightarrow \mathbf{R}$ by $u(x) = \sum_{e \in x} u(e)$ ($x \subset E$), which is also denoted by the same symbol u . If a function u satisfies $0 \leq u(x) \leq \mu(x)$ for every $x \in E$, then u is called an **independent vector** over \mathbf{P} . An independent

vector u with $u(E) = \mu(E)$ is called a **base** of \mathbf{P} . A function $u: E \rightarrow \mathbf{R}$ is identified with an element in \mathbf{R}^n , where $n = |E|$. Then a set of independent vectors in \mathbf{P} forms a \dagger convex polyhedron in \mathbf{R}^n . If we denote the polyhedron by \mathbf{P} , then such a \mathbf{P} is characterized by the following two conditions: (P1) If $u \in \mathbf{P}$ then each v satisfying $0 \leq v(e) \leq u(e)$ for every $e \in E$ also belongs to \mathbf{P} . (P2) If two $u, v \in \mathbf{P}$ satisfy $u(E) < v(E)$, then there exists $w \in \mathbf{P}$, $w \neq u$, satisfying $u(e) \leq w(e) \leq \max[u(e), v(e)]$ for every $e \in E$. If there are two polymatroids $\mathbf{P}_1 = (E, \mu_1)$ and $\mathbf{P}_2 = (E, \mu_2)$ over the same finite set E , then we have $\max\{u(E) \mid u \in \mathbf{P}_1 \cap \mathbf{P}_2\} = \min\{\mu_1(x) + \mu_2(E - x) \mid x \subseteq E\}$. According to \dagger information theory, an example of a polymatroid (E, μ) is given by the following: $\mu(x)$, $x \subseteq E$, is the simultaneous \dagger entropy of a subset x of the information source E with correlation.

G. Matroids

A polymatroid $\mathbf{P} = (E, \mu)$ is called a **matroid** if the values of μ are always integers and $\mu(x) \leq |x|$ = the cardinality of the set x . A set $x \subseteq E$ is called an **independent set** if $\mu(x) = |x|$, and a **dependent set** otherwise. An independent set with maximal cardinality is called a **base**. A minimal dependent set is called a **circuit**. The set y with $\max\{|y| \mid y \supset x, \mu(x) = \mu(y)\}$ is uniquely determined by x , which is called the **closure** of x and denoted by $\text{cl } x$. Several axioms stated in terms of these notions exist, and can be used to characterize matroids. Some of them are:

(1) The axiom for the family of independent sets \mathcal{I} : (i) $\emptyset \in \mathcal{I}$; (ii) $x \in \mathcal{I}$ and $y \subset x$ implies $y \in \mathcal{I}$; (iii) If $x, y \in \mathcal{I}$ and $|x| < |y|$, then there exists an $e \in E$ in $y - x$ such that $x \cup \{e\} \in \mathcal{I}$.

(2) The axiom for the family of bases \mathcal{B} : (i) \mathcal{B} is not empty; (ii) If $b, b' \in \mathcal{B}$ and $b \neq b'$, then for every $e \in b - b'$, there exists an e' such that $e' \in b' - b$ and $(b - \{e\}) \cup \{e'\} \in \mathcal{B}$.

(3) The axiom for the family of circuits \mathcal{C} : (i) $\emptyset \in \mathcal{C}$; (ii) For every pair $x, y \in \mathcal{C}$, y is not a proper subset of x ; (iii) If $x, y \in \mathcal{C}$ and $x \neq y$, then for every $e \in x \cap y$ there exists a $z \in \mathcal{C}$ such that $z \subset x \cup y - \{e\}$.

(4) The axiom for the closure function cl : $2^E \rightarrow 2^E$: (i) $x \subset \text{cl } x = \text{cl}(\text{cl } x)$ for every $x \subseteq E$; (ii) $x \subset y$ implies $\text{cl } x \subset \text{cl } y$; (iii) If $e \in \text{cl}(x \cup \{e'\}) - \text{cl } x$, then $e' \in \text{cl}(x \cup \{e'\}) - \text{cl } x$.

The following are typical examples of matroids: (1) Let E be the family of finite set of vectors in a vector space V and \mathcal{I} be the family of sets of linearly independent vectors. (2) Let E be the set of edges of a \dagger graph and \mathcal{C} be the set of edges constituting a fundamental circuit. (3) Let E be a finite set and S be a family of subsets of E . $x = \{e_1, \dots, e_r\} \subseteq E$ is

defined to be independent if there exist different elements s_1, \dots, s_r in S such that $e_i \in s_i$ for every $i = 1, \dots, r$.

Let a weight function $w: E \rightarrow \mathbf{R}$ be defined for every element $e \in E$ in a matroid (E, μ) . To obtain a base b of the matroid with minimal weight $w(b) = \sum_{e \in b} w(e)$, we can apply the following procedure, called the **greedy algorithm**: (1) Arrange the elements e_1, \dots, e_n of E in such a manner that $w(e_1) \leq \dots \leq w(e_n)$. (2) Put $b^{(0)} := \emptyset$, and $i := 0$. (3) If $x \equiv b^{(i)} \cup \{e_{i+1}\} \in \mathcal{I}$, then $b^{(i+1)} := x$; otherwise, $b^{(i+1)} := b^{(i)}$. (4) Repeat process (3) for $i = 0, 1, \dots, n-1$. Then the final $b^{(n)}$ is the base of minimal weight.

H. Operations on Matroids

For a matroid $M = (E, \mu)$ with the family \mathcal{B} of its base, $\mathcal{B}^* = \{E - x \mid x \in \mathcal{B}\}$ also satisfies the axioms of the base. The matroid $M^* = (E, \mu^*)$ with \mathcal{B}^* as its base is called the **dual** of M . Here we define $\mu^*(x) = |x| + \mu(E - x) - \mu(E)$. When $F \subset E$, $M|F = (F, \mu_F)$ is called the **reduction** of $M = (E, \mu)$ to F , where μ_F is the restriction of μ on 2^F . A matroid $M \times F = (M^*|F)^*$ is called the **contraction** of M to F . A matroid given by the form $(M|F) \times F'$ is called a **minor** of M . From two matroids $M_1 = (E, \mu_1)$ and $M_2 = (E, \mu_2)$ over the same set E , we can construct a matroid $M = M_1 \vee M_2 = (E, \mu)$ whose rank function $\mu(x)$ is defined by the minimum of $\{\mu_1(y) + \mu_2(y) + |x - y| \mid y \subset x\}$. This is called the **union** of M_1 and M_2 .

Let $M = (E, \mu)$ be a matroid and α be a positive constant. The function $\tilde{\mu}(x) = \mu(x) - \alpha|x|$ is submodular. The set L of x which minimizes $\tilde{\mu}(x)$ is a sublattice of 2^E . The partition of E and the order relation of its classes defined by L are called the **principal partition** of M with respect to the parameter α . When the value of the parameter α is not specified, α is taken to be 2.

As was seen in example (1) at the end of the preceding section, the family of vectors in a vector space V over a field K is a matroid M . A matroid isomorphic to such an M is called **linearly representable** over K . If $K = GF(p)$, the finite field with p elements, then it is called a **p -ary matroid**. A matroid linearly representable over any field is called **regular**. If $[G]$ is a matroid isomorphic to the matroid defined by the family of edges of a graph as shown in example (2), it is called **graphic**. If the dual M^* is graphic, M is called **cographic**. Graphic and cographic matroids are always regular. There exist matroids not linearly representable over a field K , or linearly representable over a particular field K but not regular, or regular but neither graphic nor cographic. If $[G]$ is a matroid isomorphic to

the matroid of the type in example (3), it is called **transversal**. Such a matroid is linearly representable when the cardinality of the field K is sufficiently large.

67 (III.11) Commutative Rings

A. General Remarks

A ring R (\rightarrow 368 Rings) whose multiplication is commutative is called a **commutative ring**. Throughout this article, we mean by a ring a commutative ring with unity element.

B. Ideals

Since our rings are commutative, we need not distinguish right or left ideals from \dagger ideals. A subset \mathfrak{a} of a ring R is an ideal of R if and only if \mathfrak{a} is an R -submodule of R (\rightarrow 277 Modules), if and only if \mathfrak{a} is the \dagger kernel of a ring homomorphism from R into some ring (except for the case $\mathfrak{a} = R$). Given an ideal \mathfrak{a} of a ring R , the set of elements which are \dagger nilpotent modulo \mathfrak{a} , i.e., $\{x \in R \mid x^n \in \mathfrak{a} \ (\exists n)\}$, is called the **radical** of \mathfrak{a} and is often denoted by $\sqrt{\mathfrak{a}}$. The radical of the zero ideal is called the **radical**

of R , or more precisely, the **nilradical** of R (\rightarrow 368 Rings H).

For a subset S of a ring R , the smallest ideal \mathfrak{a} containing S is called the ideal **generated** by S , and S is called a **basis** for \mathfrak{a} ; if S is a finite set, then S is called a **finite basis**. When \mathfrak{a}_λ ($\lambda \in \Lambda$) are ideals of R , the **sum** of these ideals, denoted by $\sum \mathfrak{a}_\lambda$, is defined to be the ideal generated by the union of the ideals \mathfrak{a}_λ ($\lambda \in \Lambda$). If Λ is a finite set, say $\{1, 2, \dots, n\}$, then the sum is denoted also by $\mathfrak{a}_1 + \dots + \mathfrak{a}_n$, and in this case, the sum is also called a finite sum. Note that $\mathfrak{a}_1 + \dots + \mathfrak{a}_n = \{\mathfrak{a}_1 + \dots + \mathfrak{a}_n \mid \mathfrak{a}_i \in \mathfrak{a}_i\}$. The **product** $\mathfrak{a}_1 \dots \mathfrak{a}_n$ of a finite number of ideals $\mathfrak{a}_1, \dots, \mathfrak{a}_n$ is defined to be the ideal generated by the set $\{\mathfrak{a}_1 \dots \mathfrak{a}_n \mid \mathfrak{a}_i \in \mathfrak{a}_i\}$. The intersection of an arbitrary number of ideals is an ideal. When \mathfrak{a} is an ideal of a ring R and S is a subset of R , the **quotient** $\mathfrak{a} : S$ is defined to be the ideal $\{x \in R \mid xS \subset \mathfrak{a}\}$. If $\mathfrak{a}, \mathfrak{b}, \mathfrak{c}, \mathfrak{d}_\lambda$ ($\lambda \in \Lambda$) are ideals, we have $(\mathfrak{a} : \mathfrak{b}) : \mathfrak{c} = \mathfrak{a} : \mathfrak{bc}$, $\mathfrak{a} : \sum \mathfrak{d}_\lambda = \bigcap_\lambda (\mathfrak{a} : \mathfrak{d}_\lambda)$.

C. Prime Ideals

An ideal \mathfrak{p} of a ring R is called a **prime ideal** if R/\mathfrak{p} is an \dagger integral domain; \mathfrak{p} is a prime ideal if and only if $\mathfrak{p} \neq R$ and also $ab \in \mathfrak{p}$ ($a, b \in R$) implies $a \in \mathfrak{p}$ or $b \in \mathfrak{p}$ (some literature includes the ring R itself in the set of prime ideals). Let S be a **multiplicatively closed subset** of a ring R , i.e., a nonempty \dagger subsemigroup of R with respect to multiplication. A maximal member among the set of ideals which do not meet S is called a **maximal ideal with respect to S** . Such a member is necessarily a prime ideal; when $S = \{1\}$, it is called a **maximal ideal** of R . An ideal \mathfrak{m} is a maximal ideal of R if and only if R/\mathfrak{m} is a field.

D. Jacobson Radical

The intersection J of all maximal ideals of a ring R is called the **Jacobson radical** of R ; in some cases, this intersection J is called the radical of R (\rightarrow 368 Rings H). Let N be an R -submodule of a finite R -module M . If $MJ + N = M$, then $M = N$ (**Krull-Azumaya lemma** or **Nakayama lemma**).

E. Krull Dimension

For a prime ideal \mathfrak{p} of a ring R , the maximum of the lengths n of \dagger descending chains of prime ideals $\mathfrak{p} = \mathfrak{p}_0 \supsetneq \mathfrak{p}_1 \supsetneq \dots \supsetneq \mathfrak{p}_n$ which begin with \mathfrak{p} (or ∞ if the maximum does not exist) is called the **height** or **rank** of the prime ideal \mathfrak{p} . For an ideal \mathfrak{a} , the minimum of the heights of prime ideals containing \mathfrak{a} is called the **height** of the ideal \mathfrak{a} . The maximum of heights of prime

ideals of R is called the **Krull dimension** (or **altitude**) of the ring R . For an ideal α of R , the Krull dimension of R/α is called the **Krull dimension** (or **depth**) of the ideal α . (The meanings of the terms *rank*, *dimension*, and *depth* now depend on the writings in which they are found; standardization of definition of these terms is becoming more and more of a necessity.)

F. Primary Ideals

For an ideal q of R , if $q \neq R$ and every zero divisor of R/q is nilpotent, then q is called a **primary ideal**. (If R is included in the set of prime ideals, then R is regarded as a primary ideal.) In this case, $p = \sqrt{q}$ is a prime ideal, and q is then said to **belong** to p or to be a **p-primary ideal**. The intersection of a finite number of primary ideals belonging to the same prime ideal p is **p-primary**. Assume that an ideal α is expressed as the intersection $\alpha = q_1 \cap \dots \cap q_n$ of a finite number of primary ideals q_1, \dots, q_n . If this intersection is **irredundant**, that is, if none of the q_i is superfluous in the expression of α , then the set of $\sqrt{q_i}$ ($i = 1, \dots, n$) is uniquely determined by α . The $\sqrt{q_i}$ are called **prime divisors** (or **associated prime ideals**) of the ideal α ; a minimal one among these is called a **minimal** (or **isolated**) **prime divisor** of the ideal α , and those which are not minimal are called **embedded prime divisors** of the ideal α . A maximal one among the prime divisors of α is called a **maximal prime divisor** of the ideal α . (For definitions of these concepts in the case where α is an arbitrary ideal, see [4].) If, in the expression of α as above, n is the smallest occurring in similar expressions, then the expression is called the **shortest representation** of the ideal α by primary ideals. In this case, each q_i is called a **primary component** of the ideal α ; if $\sqrt{q_i}$ is isolated, then q_i is called an **isolated primary component** of the ideal α , and otherwise q_i is called an **embedded primary component** of the ideal α . Isolated primary components are uniquely determined by α , but embedded primary components are not.

G. Rings of Quotients

Let R be a ring. Then the set U of elements of R which are not zero divisors is multiplicatively closed. In the set $R \times U = \{(r, u) | r \in R, u \in U\}$, we define a relation \equiv by $(r, u) \equiv (r', u') \Leftrightarrow ru' = r'u$. Then \equiv is an equivalence relation, and the equivalence class of (r, u) is denoted by r/u . In the set Q of these r/u , addition and multiplication are defined by $r/u + r'/u' = (ru' + r'u)/uu'$, $(r/u)(r'/u') = rr'/uu'$. Then

Q becomes a ring, and $r/1$ can be identified with r . Thus Q is a ring containing R , generated by R and inverses of elements of U . This property characterizes Q , which is called the **ring of total quotients** of the ring R . If R is an integral domain, then Q is a field, called the **field of quotients** of the integral domain R . Let S be a multiplicatively closed subset of R such that $0 \notin S$, and let n be $\{x \in R | xs = 0 (\exists s \in S)\}$ and ϕ be the natural homomorphism $R \rightarrow R/n$. Then none of the elements of $\phi(S)$ is a zero divisor. The subring of the ring of total quotients of R/n , generated by R/n and inverses of elements of $\phi(S)$, is called the **ring of quotients of the ring R with respect to S** , and is denoted by R_S ($R[S^{-1}]$ or RS^{-1}). When M is an R -module, $M \otimes_R R_S$ is called the **module of quotients of the R -module M with respect to S** . It is significant that R_S is tR -flat. There is a one-to-one correspondence between the set of primary ideals q of R which do not meet S and the set of primary ideals \mathfrak{Q} of R_S such that q corresponds to \mathfrak{Q} if and only if $\mathfrak{Q} = qR_S$ ($q = \mathfrak{Q} \cap R$). When p is a prime ideal of R , the complement $R - p$ is multiplicatively closed, and R_{R-p} is called the **local ring of p** or the **ring of quotients of the ring R with respect to the prime ideal p** , and is denoted by R_p (\rightarrow 284 Noetherian Rings C, D). A ring of quotients is also called a **ring of fractions**.

H. Divisibility

In a ring R , if $a = bc$ ($a, b, c \in R$), then we say that b is a **divisor** (or **factor**) of a , and that a is a **multiple** of b , or a is **divisible** by b . We denote this by $b|a$. This relation between $a, b \in R$ is called **divisibility relation** in R . If, in this situation, c has its inverse in R , we say that a is an **associate** of b . A factor b of a is called a **proper factor** if b is neither an associate of a nor invertible. An element which has no proper factor is called an **irreducible element**. A nonzero element which generates a prime ideal is called a **prime element**.

If in an integral domain R every nonzero element is a product of prime elements (up to invertible factors), then we say that the **unique factorization theorem** holds in R , and that R is a **unique factorization domain** (or simply u.f.d.).

Let $A = \{a_1, \dots, a_n\}$ be a set of nonzero elements of a ring R . A **common divisor** of A is an element which is a factor of a_i . A **common multiple** of A is defined similarly. The **greatest common divisor** (G.C.D.) of A is a common divisor which is a multiple of any common divisor; the **least common multiple** (L.C.M.) of A is a common multiple m which is a factor of any common multiple. Thus, the G.C.D. and L.C.M. exist if R is a u.f.d.

I. Integral Dependence

Let R be a subring of a ring R'' sharing a unity element with R'' . An element $a \in R''$ is said to be **integral** (or **integrally dependent**) over R if there are a natural number n and elements c_i of R such that $a^n + c_1 a^{n-1} + \dots + c_n = 0$. If every element of a subset S of R'' is integral over R , we say that S is **integral** over R . (When R has no unity element, a similar definition is given under an additional condition that $c_i \in R^i$. An important special case is where R is an ideal. See D. G. Northcott and D. Rees, *Proc. Cambridge Philos. Soc.*, 50 (1954); M. Nagata, *Mem. Coll. Sci. Univ. Kyôto*, 30 (1956).) The set \tilde{R} of elements of R'' which are integral over R is a ring and is called the **integral closure** of R in R'' . If $\tilde{R} = R$, then R is said to be **integrally closed** in R'' . If R is integrally closed in its ring of total quotients, we say that R is **integrally closed**. An integrally closed integral domain is called a **normal ring**. (In some literature, an integrally closed ring is called a normal ring.) An element $a \in R''$ is called **almost integral** over R if there is an element b of R such that b is not a zero divisor and $a^n b \in R$ for every natural number n . If an element a of the ring of total quotients of R is integral over R , then a is almost integral over R . R is said to be **completely integrally closed** if its ring of total quotients contains no elements which are almost integral over R except the elements of R itself.

J. Group Theorem

Let Q be the ring of total quotients of a ring R . An R -submodule α of Q is called a **fractional ideal** of R if there is a non-zero-divisor c of R such that $c\alpha \subset R$. The product of fractional ideals is defined similarly as in the case of products of ideals. The inverse α^{-1} of the fractional ideal α is defined to be $\{x \in Q \mid x\alpha \subset R\}$. If α contains an element which is not a zero divisor, then α^{-1} is also a fractional ideal. When R is completely integrally closed, we define fractional ideals α and β to be equivalent if $\alpha^{-1} = \beta^{-1}$. This gives rise to an equivalence relation between fractional ideals. The set of equivalence classes of fractional ideals which contain non-zero-divisors forms a group. This result is called the **group theorem**.

An integral domain R is called a **Krull ring** if (i) for every prime ideal \mathfrak{p} of height 1, the ring $R_{\mathfrak{p}}$ is a \dagger discrete valuation ring; (ii) R is the intersection of all the valuation rings $R_{\mathfrak{p}}$ and (iii) every nonzero element a of R is contained in only a finite number of prime ideals of height 1. In a Krull ring R , for an arbitrary nonzero fractional ideal α , there is a uniquely determined product of powers of prime ideals

of height 1 which is equivalent to α in the sense stated above (\rightarrow 439 Valuations).

K. Dedekind Domains and Principal Ideal Domains

A ring R is called a **Dedekind domain** if (i) R is a \dagger Noetherian integral domain, (ii) R is a normal ring, and (iii) the Krull dimension of R is 1. For an integral domain R which is not a field, R is a Dedekind domain if and only if the set of all nonzero fractional ideals is a group, if and only if every nonzero ideal of R is expressed as the product of a finite number of prime ideals and such expression is unique up to the order of prime factors. An important example of a Dedekind domain is the ring of all \dagger algebraic integers, i.e., the \dagger principal order of an \dagger algebraic number field of finite degree. In general, if R is a Dedekind domain with field of quotients K and L is a finite algebraic extension of K , then the integral closure of R in L and any ring R' such that $R \subset R' \subsetneq K$ are Dedekind domains.

An ideal generated by an element is called a **principal ideal**; a fractional ideal generated by an element is called a **principal fractional ideal** (or simply **principal ideal**). In a Dedekind domain, the set P of nonzero principal fractional ideals is a subgroup of the group I of nonzero fractional ideals; I/P is called the **ideal class group** of R , and a member of it is called an **ideal class**. The \dagger order of I/P is called the **class number** of R (\rightarrow 14 Algebraic Number Fields). There are many Dedekind domains whose class numbers are infinite.

A ring R is called a **principal ideal ring** if every ideal is principal; furthermore, if R is an integral domain, then R is called a **principal ideal domain**. A principal ideal ring is the direct sum of a finite number of rings of which each direct summand is either a principal ideal domain or a \dagger local ring whose maximal ideal is a principal nilpotent ideal. A principal ideal domain which is not a field is a Dedekind domain and a u.f.d. We consider, for an arbitrary natural number n and a principal ideal ring R , the set $M(n, R)$ of all $n \times n$ matrices over R . Given an element A of $M(n, R)$, there exist elements X, Y in $M(n, R)$ such that (i) X^{-1}, Y^{-1} are in $M(n, R)$, and (ii) denoting by b_{ij} the (i, j) -entry of XAY , we have $b_{11}R \supset b_{22}R \supset \dots \supset b_{nn}R$ and $b_{ij} = 0$ if $i \neq j$. The nonzero members of the set $\{b_{11}, b_{22}, \dots, b_{nn}\}$ are called the **elementary divisors** of the matrix A . Applying this to a finite module M over the principal ideal ring R , we see that M is the direct sum of $m_1 R, \dots, m_r R$ ($m_i \in M$) such that, with $\alpha_i = \{x \in R \mid m_i x = 0\}$, we have $\alpha_1 \subset \alpha_2 \subset \dots \subset \alpha_r$ (\rightarrow 2 Abelian Groups B; 269 Matrices E).

L. Euclid Rings

A ring R is called a **Euclid ring** if there is a map φ of $R - \{0\}$ into a \dagger well-ordered set W (the set of natural numbers is a special case) satisfying the condition that if $a, b \in R$, $a \neq 0$, then there are $r, q \in R$ such that $b = aq + r$ and either $r = 0$ or $\varphi(r) < \varphi(a)$.

Every Euclid ring is a principal ideal ring. Besides the ring \mathbf{Z} of rational integers, there are several familiar examples of Euclid rings, such as $\mathbf{Z}[\sqrt{-1}]$, $\mathbf{Z}[\sqrt{-2}]$, $\mathbf{Z}[\omega]$ ($\omega^3 = 1$, $\omega \neq 1$), and the polynomial ring of one variable over a field.

68 (XII.10) Compact and Nuclear Operators

A. General Remarks

Let X be a finite-dimensional linear space. Then a linear operator in X is surjective if and only if it is injective. If X is infinite-dimensional, this is no longer the case in general. For an operator of the form $1 + K$ with an integral operator K of continuous kernel, I. Fredholm [1] developed the theory of determinants and retrieved the above equivalence (\rightarrow 217 Integral Equations). Later, F. Riesz [3] simplified the proof and showed that the equivalence holds if K is a compact operator in a Banach space. I. Ts. Gokhberg and M. G. Krein [4] reformulated the result as

the stability of indices of operators. The concept of compact operators itself was introduced by D. Hilbert (who used the terminology, “completely continuous operators”). The Hilbert-Schmidt class is also due to him. These classes of operators are employed in the spectral theory of integral operators [2]. The trace class of operators in Hilbert spaces is defined as the class of operators for which the trace has meaning. A. Grothendieck [5] introduced nuclear operators, extending the definition of trace class operators to general Banach spaces. Nuclear operators and related classes of operators, such as integral operators and absolutely summing operators, play important roles in the theory of topological tensor products [5], determinants [6], vector measures, and measures in linear spaces [7].

B. Compact Operators

A \dagger linear operator T from a \dagger Banach space X to a Banach space Y is said to be **compact** (or **completely continuous**) if T maps any \dagger bounded set of X to a \dagger relatively compact set of Y . In other words, T is compact if, for any bounded sequence $\{x_n\}$ in X , the sequence $\{Tx_n\}$ in Y contains a \dagger strongly convergent subsequence. A compact operator is necessarily \dagger bounded and hence continuous. A compact operator from X to Y maps any \dagger weakly convergent sequence in X to a strongly convergent sequence in Y . If X is \dagger reflexive, the converse is also true.

In this article the set of all bounded (resp. compact) linear operators from X to Y are denoted by $\mathbf{B}(X, Y)$ (resp. $\mathbf{B}^{(c)}(X, Y)$).

C. Examples of Compact Operators

(1) **Degenerate operators.** An operator $T \in \mathbf{B}(X, Y)$ is said to be degenerate or of **finite rank** if the \dagger range $R(T)$ of T is finite-dimensional. A degenerate operator is necessarily compact. The \dagger identity operator in X is compact ($Y = X$) if and only if X is finite-dimensional. (2) **\dagger Integral operators with continuous kernel.** Let E and F be bounded closed regions in the Euclidean spaces \mathbf{R}^m and \mathbf{R}^n , respectively, and let $k = k(t, s)$, $t \in F$, $s \in E$, be a continuous function defined on $F \times E$. Then the integral operator T with \dagger kernel k ,

$$(Tx)(t) = \int_E k(t, s)x(s)ds, \quad t \in F, \quad (1)$$

is a compact operator from the Banach space $C(E)$ to $C(F)$. (For the notation for various function spaces \rightarrow 168 Function Spaces.) (3) **Integral operators of Hilbert-Schmidt type.** In example (2) let E and F be \dagger Lebesgue mea-

surable sets, and let $k \in L_2(F \times E)$. Then the integral operator T determines a compact operator from the Hilbert space $L_2(E)$ to the Hilbert space $L_2(F)$. (4) Let Ω be a bounded open set in \mathbb{R}^n , $s < t$ two real numbers, and $H^s(\Omega)$ the Sobolev space of order s (\rightarrow 168 Function Spaces). Then the natural injection from $H^t(\Omega)$ into $H^s(\Omega)$ is compact (F. Rellich's lemma).

D. Properties of Compact Operators

Any linear combination of compact operators is again compact. If a sequence $\{T_n\}$ of compact operators converges in the norm (i.e., in the uniform operator topology), then the limit T is compact. Thus $\mathbf{B}^{(c)}(X, Y)$ is a closed subspace of the Banach space $\mathbf{B}(X, Y)$ with the operator norm. Any product of a compact operator and a bounded operator is compact. Namely, $A \in \mathbf{B}^{(c)}(X, Y)$, $B \in \mathbf{B}(Y, Z)$, and $C \in \mathbf{B}(Z, X)$ imply $BA \in \mathbf{B}^{(c)}(X, Z)$ and $AC \in \mathbf{B}^{(c)}(Z, Y)$. In particular, $\mathbf{B}^{(c)}(X) = \mathbf{B}^{(c)}(X, X)$ forms a closed two-sided ideal of $\mathbf{B}(X) = \mathbf{B}(X, X)$. An operator $T \in \mathbf{B}(X, Y)$ is compact if and only if its dual operator $T' \in \mathbf{B}(Y', X')$ is compact. The range of a compact operator is always separable. Let X and Y be Hilbert spaces. Then for any $T \in \mathbf{B}^{(c)}(X, Y)$ there exist orthonormal sets $\{\varphi_n\}$ in X and $\{\psi_n\}$ in Y and a sequence $\{c_n\}$ of nonnegative numbers with $\lim c_n = 0$ such that

$$Tu = \sum_n c_n (u, \varphi_n) \psi_n, \quad u \in X.$$

Consequently, any compact operator between Hilbert spaces X, Y can be approximated by a sequence of degenerate operators in the operator norm. However, there are Banach spaces X and Y for which the statement is no longer true. In fact, a Banach space X (resp. the dual Y' of a Banach space Y) has the approximation property (\rightarrow 37 Banach Spaces L) if and only if every $T \in \mathbf{B}^{(c)}(Y, X)$ is the limit in norm of a sequence of degenerate operators for any Banach space Y (resp. X).

E. The Riesz-Schauder Theorem

Let $T \in \mathbf{B}^{(c)}(X)$ and consider a pair of linear equations

$$u - Tu = f, \quad f \in X, \quad (2)$$

$$\varphi - T'\varphi = g, \quad g \in X', \quad (3)$$

where $T' \in \mathbf{B}(X')$ is the dual operator of T in the dual space X' of X . Put $\mathcal{M} = \{u \in X \mid u = Tu\}$ and $\mathcal{M}' = \{\varphi \in X' \mid \varphi = T'\varphi\}$. Then one and only one of the following two cases (i) and (ii) occurs. (i) $\mathcal{M} = \{0\}$, $\mathcal{M}' = \{0\}$; for any $f \in X$

equation (2) has a unique solution; and for any $g \in X'$ equation (3) has a unique solution. (ii) $\dim \mathcal{M} = \dim \mathcal{M}' = m$, $1 \leq m < \infty$; (2) has a solution if and only if f is orthogonal to \mathcal{M}' (i.e., $(f, \varphi) = 0$ for any $\varphi \in \mathcal{M}'$); and (3) has a solution if and only if g is orthogonal to \mathcal{M} (i.e., $(g, u) = 0$ for any $u \in \mathcal{M}$). This is called the **Riesz-Schauder theorem**. In particular, when T is an integral operator in a suitable function space, this theorem is also called **Fredholm's alternative theorem** for integral equation (2).

F. Fredholm Operators and Their Indices

Let T be a closed linear operator from a Banach space X to a Banach space Y . T is called a **Fredholm operator** or an **operator with index** if both $\text{Ker } T$ ($=$ null space $N(T)$) and $\text{Coker } T$ ($= Y/R(T)$) are finite-dimensional. Then the integer $\text{ind } T = \dim \text{Ker } T - \dim \text{Coker } T$ is called the **index** of T . If a closed linear operator T has $\text{Coker } T$ of finite dimension, then the range $R(T)$ is closed. Moreover, if $R(T)$ is closed and the domain $D(T)$ is dense, then $\dim \text{Coker } T = \dim \text{Ker } T'$, where T' is the dual of T , and hence $\text{ind } T = \dim \text{Ker } T - \dim \text{Ker } T'$. A linear operator K from X to Y is said to be **T -compact** if the domain $D(K)$ contains $D(T)$ and if K from $D(T)$ with the graph norm into Y is compact, i.e., for any bounded sequence $\{x_n\}$ in $D(T)$ with $\sup \|Tx_n\| < \infty$, the sequence $\{Kx_n\}$ contains a strongly convergent subsequence.

The following are basic properties of Fredholm operators [4, 11]: (1) If T is Fredholm and K is T -compact, then $T + K$ is Fredholm and $\text{ind}(T + K) = \text{ind } T$. (2) If T is Fredholm and another linear operator S is sufficiently close to T in (graph) norm, then S is also Fredholm and $\text{ind } S = \text{ind } T$. (3) If T is a Fredholm operator from X into Y and S is a Fredholm operator with dense domain in Y into Z , then ST is Fredholm and $\text{ind } ST = \text{ind } S + \text{ind } T$. If $D(T)$ is dense, then $D(ST)$ is also dense. (4) Let T be a closed linear operator with dense domain; then T is Fredholm if and only if the dual T' is Fredholm, and then $\text{ind } T' = -\text{ind } T$.

Fredholm operators and their indices were first studied by Russian mathematicians in connection with boundary value problems of differential equations and singular integral equations. M. F. Atiyah and I. M. Singer have proved that an elliptic linear differential operator P of order m on a compact differentiable manifold M is a Fredholm operator from the Sobolev space $H^s(M)$ into $H^{s-m}(M)$ for any s and that its index is computed from the symbol of P and the characteristic classes of M (\rightarrow 237 K -Theory). Similarly, the indices of linear ordinary differential operators (and

more generally of maximally overdetermined systems of linear partial differential operators) are computed in various spaces of functions and generalized functions (H. Komatsu, B. Malgrange, J.-P. Ramis, M. Kashiwara).

G. Spectra of Compact Operators

The following structure of the \dagger spectrum of compact operators $T \in \mathbf{B}^{(c)}(X)$ is derived from the Riesz-Schauder theorem. The spectrum $\sigma(T)$ of T consists of at most countably many points and has no accumulation points except possibly for 0. Any nonzero point of $\sigma(T)$ is an \dagger eigenvalue of T . When X is infinite-dimensional, 0 always belongs to $\sigma(T)$ but is not necessarily an eigenvalue of T . Each nonzero eigenvalue of T has finite (algebraic) \dagger multiplicity, and hence the \dagger eigenspace $\mathcal{M}_\lambda(T) = \{u \mid Tu = \lambda u\}$, $\lambda \neq 0$, is finite-dimensional. If λ is an eigenvalue of T , then $\bar{\lambda}$ is an eigenvalue of the \dagger adjoint operator T^* of T with the same (either algebraic or geometric) multiplicity as that of λ .

H. Spectral Representations of Compact Normal Operators

Let T be a compact \dagger normal operator in a Hilbert space H . Then we can find a \dagger complete orthonormal set consisting solely of eigenvectors of T . Namely, for each nonzero eigenvalue λ_j of T , take an orthonormal basis $\{\varphi_k^{(j)}\}$ of the eigenspace associated with λ_j . Rearrange all the $\varphi_k^{(j)}$ into a sequence $\{\varphi_n\}$ and add to it, if 0 is an eigenvalue, a complete orthonormal set of the eigenspace associated with 0. Then we obtain a desired complete orthonormal set of H . Let μ_n be the eigenvalue associated with φ_n . Then the sequence $\{\mu_n\}$ is precisely an enumeration of nonzero eigenvalues of T with repetitions according to multiplicity. In terms of $\{\varphi_n\}$ and $\{\mu_n\}$, a \dagger spectral representation of T is given as

$$Tu = \sum_{n=1}^{\infty} \mu_n (u, \varphi_n) \varphi_n, \quad u \in H.$$

The eigenvalue problem of a compact nonnegative \dagger self-adjoint operator T can be solved by means of the following **Rayleigh principle**. Consider **Rayleigh's quotient** $R(x) = (Tx, x) / \|x\|^2$, $x \neq 0$. The largest eigenvalue μ_1 is obtained as $\mu_1 = \max_{x \in X} R(x)$ and any vector x_1 which attains this maximum is an eigenvector. When the largest $n-1$ eigenvalues μ_1, \dots, μ_{n-1} and eigenvectors x_1, \dots, x_{n-1} are determined, the n th eigenvalue μ_n is the maximum of $R(x)$ on the subspace orthogonal to x_1, \dots, x_{n-1} and any vector which attains the

maximum is an eigenvector. A more direct characterization of μ_n , involving no previous eigenvectors, is given by

$$\mu_n = \min_{\substack{f_1, \dots, f_{n-1} \in X \\ f_1, \dots, f_{n-1} \neq 0}} \left(\max_{\substack{(x, f_j) = 0 \\ j=1, \dots, n-1}} R(x) \right).$$

This formula is referred to as the **minimax principle**.

I. Classification of Compact Operators in Hilbert Spaces

Let H and K be Hilbert spaces. Then a $T \in \mathbf{B}(H, K)$ is compact if and only if $(Te_n, f_n) \rightarrow 0$ for any orthonormal sequences e_n in H and f_n in K . J. von Neumann and R. Schatten (*Ann. Math.*, 49 (1948)) classified operators $T \in \mathbf{B}^{(c)}(H, K)$ in the following way. The operator $A = (T^*T)^{1/2}$ is a compact nonnegative self-adjoint operator. Let $\alpha_1 \geq \alpha_2 \geq \dots$ be the enumeration in decreasing order of the positive eigenvalues of A , with each repeated according to its multiplicity. The $\alpha_n = \alpha_n(T)$ are sometimes called the **characteristic numbers** of T . For any $p > 0$ the set of all $T \in \mathbf{B}^{(c)}(H)$ such that

$$\|T\|_p = \left(\sum_{n=1}^{\infty} \alpha_n^p \right)^{1/p} < +\infty$$

is denoted by $\mathbf{B}_p(H)$ (or simply \mathbf{B}_p). Among these classes, \mathbf{B}_1 and \mathbf{B}_2 are most important. \mathbf{B}_1 is called the **trace class** and \mathbf{B}_2 the **Hilbert-Schmidt class**. Correspondingly, $\|T\|_1$ and $\|T\|_2$ are called the **trace norm** and **Hilbert-Schmidt norm** of T , respectively. \mathbf{B}_1 is also called the **nuclear class** and any operator $T \in \mathbf{B}_1$ a **\dagger nuclear operator**. The norm $\|T\|_p$ can also be defined more directly as follows. (i) If $1 < p < \infty$, $\|T\|_p = \sup \| (Te_n, f_n) \|_{l_p}$; (ii) If $0 < p \leq 2$, $\|T\|_p = \inf \| (\|Te_v\|) \|_{l_p}$; (iii) If $2 \leq p < \infty$, $\|T\|_p = \sup \| (\|Te_v\|) \|_{l_p}$, where e_n and f_n range over the orthonormal sequences in H and K , and e_v over the orthonormal bases in H . The class \mathbf{B}_p is a two-sided $*$ ideal in the Banach algebra \mathbf{B} . Moreover precisely, $T \in \mathbf{B}_p$ and $R \in \mathbf{B}$ imply $\|RT\|_p \leq \|R\| \|T\|_p$, $\|TR\|_p \leq \|R\| \|T\|_p$ and $\|T^*\|_p = \|T\|_p$. When $1 \leq p < \infty$, the class \mathbf{B}_p becomes a Banach space with the norm $\|T\|_p$. It is always a \dagger quasi-Banach space, in which the set of all degenerate operators is dense.

The norm $\|T\|_p$ ($T \neq 0$) is a decreasing function of p . Hence $\mathbf{B}_p \subset \mathbf{B}_q$ if $p \leq q$. Also, $T \in \mathbf{B}_p$ and $S \in \mathbf{B}_q$ imply $TS \in \mathbf{B}_r$, where $1/r = 1/p + 1/q$. Let $T \in \mathbf{B}_p$, and let $\{\mu_j\}$ be an enumeration of eigenvalues of T with repetitions according to (either geometric or algebraic) \dagger multiplicity. Then

$$\sum_j |\mu_j|^p \leq \|T\|_p^p.$$

Hilbert-Schmidt class. For an arbitrary complete orthonormal set $\{u_k\}$, we have

$$\|T\|_2^2 = \sum \|Tu_k\|^2.$$

Thus \mathbf{B}_2 can be defined as the set of all $T \in \mathbf{B}$ such that the sum on the right-hand side is finite for a certain complete orthonormal set $\{u_k\}$. A linear operator $T: L_2(E) \rightarrow L_2(F)$ is of Hilbert-Schmidt class if and only if it is an integral operator of Hilbert-Schmidt type (example (3) in Section C). The space \mathbf{B}_2 with the norm $\|T\|_2$ becomes a Hilbert space with the inner product defined by

$$(T, S)_2 = \sum (Tu_k, Su_k),$$

where $\{u_k\}$ is as above.

Trace class. For an operator $T \in \mathbf{B}_1$, the trace $\text{tr}(T)$ of T is defined as

$$\text{tr}(T) = \sum (Tu_k, u_k).$$

Here the right-hand side converges absolutely and does not depend on the complete orthonormal set $\{u_k\}$. The trace is a bounded linear functional on the Banach space \mathbf{B}_1 . The product of two operators of Hilbert-Schmidt type belongs to the trace class, and the converse is also true. If $1 < p, q < \infty$ satisfy $1/p + 1/q = 1$, then the inner product $\langle T, S \rangle$ of $T \in \mathbf{B}_p(H, K)$ and $S \in \mathbf{B}_q(K, H)$ is defined by $\langle T, S \rangle = \text{tr}(ST)$. Under this inner product the dual of the Banach space $\mathbf{B}_p(H, K)$ is identified with $\mathbf{B}_q(K, H)$. Similarly, the dual of $\mathbf{B}^{(c)}(H, K)$ is isomorphic to $\mathbf{B}_1(K, H)$, and the dual of $\mathbf{B}_1(K, H)$ to $\mathbf{B}(H, K)$ (J. Dixmier, Schatten).

J. Volterra Operators

A compact operator T in a Hilbert space is said to be a **Volterra operator** if it is \dagger quasinilpotent, i.e., its \dagger spectral radius is 0. The integral operator

$$(Tx)(t) = \int_t^b k(t, s)x(s)ds, \quad x \in L_2(a, b),$$

appearing in the integral equation of Volterra type is a Volterra operator. Conversely, a Volterra operator satisfying a suitable condition is unitarily equivalent to such an integral operator (M. S. Livshits, Gokhberg and Kreĭn [13]). A Volterra operator admits an abstract triangular representation in a manner similar to Jordan's canonical form (\rightarrow 390 Spectral Analysis of Operators H).

K. Nuclear Operators

Extending the definition of trace class to operators in Banach spaces, A. Grothendieck [5] defined a **nuclear operator** (or **Fredholm**

operator according to [6]) from a Banach space X into a Banach space Y to be a linear operator $T: X \rightarrow Y$ that is represented as $Tx = \sum \lambda_j \langle x, a_j \rangle b_j$ with a sequence $\lambda_j \geq 0$ in l_1 , a bounded sequence a_j in X , and a bounded sequence b_j in Y . In other words, a linear operator $T: X \rightarrow Y$ is nuclear if and only if it is decomposed as the product

$$X \xrightarrow{A} l_\infty \xrightarrow{\Lambda} l_1 \xrightarrow{B} Y, \quad (4)$$

where A and B are bounded linear operators and Λ is multiplication by λ_j in l_1 . The infimum of $\|A\| \|\lambda_j\|_{l_1} \|B\|$ is called the **nuclear norm** of T and is denoted by $\|T\|_1$. When X and Y are Hilbert spaces, this coincides with the trace norm. The integral operator T defined by (1) is nuclear with $\|T\|_1 = \int \sup_t |k(t, s)| ds$. The totality $\mathbf{B}_1(X, Y)$ of nuclear operators $T: X \rightarrow Y$ forms a Banach space under the nuclear norm. If T is nuclear and A is bounded, then $\|TA\|_1 \leq \|T\|_1 \|A\|$ and $\|AT\|_1 \leq \|A\| \|T\|_1$. If T is nuclear, then the dual T' is nuclear, and $\|T'\|_1 \leq \|T\|_1$. Suppose that X and Y are Banach spaces satisfying one of the following conditions: (i) Y is the dual of a Banach space; (ii) X' has the approximation property; (iii) Y'' has the approximation property. Then conversely a $T \in \mathbf{B}(X, Y)$ is nuclear if the dual T' is nuclear, and $\|T\|_1 = \|T'\|_1$. However, this is not necessarily the case in general (T. Figiel and W. B. Johnson).

Replacing l_1 by l_p , we obtain the definition of **operators $T: X \rightarrow Y$ of summable p th power**. Grothendieck [5] considered the case $0 < p \leq 1$ and showed that if T_1, \dots, T_n are of summable p_1, \dots, p_n th power, then the product $T_1 \dots T_n$ is of summable r th power, where r is given by $1/r = (\sum 1/p_i) - (n+1)/2$.

L. Traces and Determinants of Operators

Let T be a linear operator of \dagger finite rank in a linear space X . There are a finite number of elements $a_i \in X'$ and $b_i \in X$ such that

$$Tx = \sum_{i=1}^n \langle x, a_i \rangle b_i. \quad (5)$$

Then $\text{tr}(T) = \sum \langle b_i, a_i \rangle$ and $\det(1 - T) = \det(\delta_{i,j} - \langle b_i, a_j \rangle)$ are independent of the representation (5). Let X be a Banach space. If $T \in \mathbf{B}_1(X)$ is represented as $Tx = \sum \lambda_j \langle x, a_j \rangle b_j$, then it seems reasonable that the **trace** $\text{tr}(T)$ be defined by $\sum \lambda_j \langle b_j, a_j \rangle$, but the sum may depend on the representation. It is known that a Banach space X has the approximation property if and only if the sum does not depend on the representation for any nuclear operator T . However, if T is of summable $(2/3)$ rd power, the trace $\text{tr}(T)$ is always defined uniquely. If X or T satisfies the afore-

mentioned condition, then the **determinant** $\det(1 - T)$ is also defined uniquely as the limit of $\det(1 - T_n)$, where T_n is the n th partial sum. $\det(1 - zT)$ is an entire function of z and its zeros are exactly the reciprocals of the nonzero eigenvalues of T . If $\det(1 - zT) \neq 0$, then the resolvent $(1 - zT)^{-1}$ is given by **Fredholm's formula** extending \dagger Cramer's rule. Eigenvectors are also computed explicitly [6].

Let H be a Hilbert space, and let $T \in \mathbf{B}_1(H)$. Then $\det(1 - zT) = \prod_j (1 - z\lambda_j)$, where λ_j are the nonzero eigenvalues of T , and is an entire function of genus 0. Moreover, let $p \geq 2$ be an integer. Then the modified determinant

$$\det_p(1 - zT) = \prod_j \left[(1 - z\lambda_j) \exp \left(\sum_{k=1}^{p-1} k^{-1} z^k \lambda_j^k \right) \right]$$

is defined for $T \in \mathbf{B}_p(H)$ and is an entire function of genus $p - 1$. This type of determinant was introduced by T. Carleman (*Math. Z.*, 9 (1921)) for the Hilbert-Schmidt class of operators (\rightarrow also Hilbert [2]). It is utilized to prove the completeness of the \dagger root vectors of T and many other facts [9, 12, 13].

M. Weakly Compact Operators

A linear operator from a Banach space X to a Banach space Y is said to be **weakly compact** if T maps any bounded set of X to a relatively weakly compact set. Weakly compact operators are bounded. They have properties similar to those of compact operators. The following are equivalent conditions for a bounded linear operator $T: X \rightarrow Y$. (1) T is weakly compact; (2) $T': Y' \rightarrow X'$ is weakly compact; (3) $T'': X'' \rightarrow Y''$ maps X'' into Y ; (4) There is a reflexive Banach space Z and bounded linear operators $S: X \rightarrow Z$ and $R: Z \rightarrow Y$ such that $T = RS$. The last characterization is due to W. J. Davis, Figiel, Johnson, and A. Pełczyński. Any linear combination of weakly compact operators is weakly compact. The uniform limit of a sequence of weakly compact operators is weakly compact. The product of a weakly compact operator and a bounded operator is weakly compact.

Dunford-Pettis theorem ([9]; R. S. Phillips, *Trans. Amer. Math. Soc.*, 48 (1940)). Let (Ω, μ) be a σ -finite measure space and X a Banach space. If $T: L_1(\Omega) \rightarrow X$ is a weakly compact linear operator, then there exists a bounded strongly measurable function g on Ω with values in X such that

$$Tf = \int f(t)g(t)d\mu(t).$$

Then T maps weakly convergent sequences in $L_1(\Omega)$ into strongly convergent sequences in X . In particular, the product of two weakly com-

pact linear operators in $L_1(\Omega)$ is compact. Similarly, Grothendieck and R. G. Bartle, N. Dunford, and J. Schwartz (\rightarrow [9]) have proved the following: Let Ω be a compact Hausdorff space and X a Banach space. If $T: C(\Omega) \rightarrow X$ is a weakly compact linear mapping, then there is a \dagger vector measure μ defined on the \dagger Borel sets in Ω with values in X such that $\langle \mu, x' \rangle$ is a \dagger Radon measure for any $x' \in X'$ and

$$Tf = \int f(t)d\mu(t).$$

T maps weakly convergent sequences in $C(\Omega)$ into strongly convergent sequences in X . The product of two weakly compact linear operators in $C(\Omega)$ is also compact.

N. Absolutely Summing Operators

A linear operator T from a Banach space X to a Banach space Y is called an **integral operator** if there is a positive \dagger Radon measure μ on the product $A \times B$ of the unit ball A in X' and the unit ball B in Y'' both equipped with the weak* topology such that

$$\langle Tx, y' \rangle = \int \langle x, x' \rangle \langle y', y'' \rangle d\mu(x', y''),$$

or equivalently if $T: X \rightarrow Y''$ is decomposed as (4) with l_∞ and l_1 replaced by $L_\infty(M)$ and $L_1(M)$ for a suitable compact space M with a Radon measure. Nuclear operators are clearly integral. Integral operators are weakly compact, but they are not necessarily compact or nuclear. However, the product of an integral operator and a weakly compact operator is nuclear, and hence every integral operator in a reflexive Banach space is nuclear.

If a compact (resp. weakly compact) operator T from a Banach space X to a Banach space Y maps a closed linear subspace X_1 of X into a closed linear subspace Y_1 of Y , then the restriction $T_1: X_1 \rightarrow Y_1$ and the induced operator $T^1: X/X_1 \rightarrow Y/Y_1$ are also compact (resp. weakly compact). The corresponding result does not hold for nuclear operators and integral operators. The following conditions are equivalent for a bounded linear operator $T: X \rightarrow Y$: (i) There is a Banach space $\tilde{Y} \supset Y$ such that $T: X \rightarrow \tilde{Y}$ is integral; (ii) there is a positive Radon measure μ on the unit ball A of X' such that

$$\|Tx\| \leq \int |\langle x, x' \rangle| d\mu(x');$$

(iii) there is a constant C such that

$$\sum \|Tx_i\| \leq C \sup \{ \sum |\langle x_i, x' \rangle| \mid \|x'\| \leq 1 \}$$

holds for any finite set $\{x_1, \dots, x_n\}$ in X ; (iv) if $\sum x_i$ is an \dagger unconditionally convergent series

in X , then $\sum \|Tx_i\|$ converges. Grothendieck called such an operator a **right semi-integral** in view of property (i), and A. Pietsch called it **absolutely summing** in view of (iv). Similarly, a bounded linear operator $T: X \rightarrow Y$ is called a **left semi-integral** if there is a Banach space \tilde{X} such that $X = \tilde{X}/\tilde{X}_1$ for a closed subspace \tilde{X}_1 , and the product $\tilde{T}: \tilde{X} \rightarrow Y$ is integral. The product of two right (resp. left) semi-integral operators is nuclear. A bounded linear operator in a Hilbert space is right (or left) semi-integral if and only if it is of Hilbert-Schmidt class. A bounded linear operator T from a Banach space X into a Banach space Y is integral if and only if the dual T' is integral. It is a right (resp. left) semi-integral if and only if T' is a left (resp. right) semi-integral.

For other related classes of operators \rightarrow Grothendieck's paper in *Boletim Soc. Mat. São Paulo*, 8 (1953).

69 (IV.8) Compact Groups

A. Compact Groups

A * topological group G is called a **compact group** if the underlying topological space of G is a * compact Hausdorff space. The * torus group $\mathbf{T}^n = \mathbf{R}^n/\mathbf{Z}^n$ ($n = 1, 2, \dots$) (commutative group), the * orthogonal group $O(n)$, the * unitary group $U(n)$, the * symplectic group $Sp(n)$, and the additive group \mathbf{Z}_p of * p -adic integers are compact groups (\rightarrow 60 Classical Groups; for other compact Lie groups \rightarrow 249 Lie Groups, 248 Lie Algebras). Let $C(G)$ be the * linear space formed by all the complex-valued continuous functions f, g, h, \dots defined on a compact group G ; $C(G)$ is a * Banach space with the norm

$$\|f\| = \sup_{x \in G} |f(x)|.$$

Since a compact group G is * locally compact, there exists a right-invariant * Haar measure on G . Because of the compactness of G , the total measure of G is finite, and the measure is also left-invariant. By the condition that the total measure is 1, such a measure is uniquely determined. The integral of f in $C(G)$ relative to this measure is called the **mean value** of f . Since for $f, g \in C(G)$, $f(xy^{-1})g(y)$ is continuous in two variables x, y , the * convolution $f \times g(x) = \int f(xy^{-1})g(y)dy$ also belongs to $C(G)$. $C(G)$ constitutes a ring under the multiplication defined by the convolution. This ring can be considered as an extension of the notion of a * group ring for finite groups; it is called the **group ring** of the compact group G . The function $x \rightarrow f(x^{-1})$ will be denoted by f^* , and the inner product in the * function space $L_2(G)$ will be written as (f, g) .

B. Representations of Compact Groups

Let $G(E)$ be the group of units of * bounded linear operators on a Banach space E , and suppose that we have a homomorphism U of a topological group G into $G(E)$. The homomorphism U is called a **strongly (weakly) continuous representation** on E of G if, for any $a \in E$, the map $x \rightarrow U(x)a$ of G into E is continuous with respect to the * strong (* weak) topology on E . When E is a * Hilbert space, a strongly continuous representation U such that every

$U(a)$ is a unitary operator is called a \dagger unitary representation. Let U be any strongly continuous representation of a compact group G on a Hilbert space E ; for a, b in E , let $\langle a, b \rangle$ be the mean value of the \dagger inner product $(U(x)a, U(x)b)$ on E . Then U is a unitary representation on the Hilbert space E with the new inner product $\langle a, b \rangle$.

A representation U of G on a Banach space E is said to be **irreducible** if E contains no closed subspace other than $\{0\}$ and E , which is invariant under every $U(x)$ ($x \in G$). If a weakly continuous representation of a compact group on a Banach space E is irreducible, then E is finite-dimensional. Moreover, any unitary representation U of a compact group on a Hilbert space E can be decomposed into a discrete \dagger direct sum of irreducible representations. Namely, there exists a family $\{E_\alpha\}_{\alpha \in A}$ of irreducible (hence finite-dimensional) invariant subspaces E_α of E which are orthogonal to each other such that $E = \sum_{\alpha \in A} E_\alpha$. In particular, any continuous representation of a compact group on a finite-dimensional space is \dagger completely reducible. In $L_2(G)$ with respect to the \dagger Haar measure on a \dagger locally compact group G , the representation U defined by $(U(x)f)(y) = f(yx)$ ($x, y \in G, f \in L_2(G)$) is a unitary representation of G . This representation U is called the (right) **regular representation** of G . Decomposition of the regular representation of a compact group G into irreducible representations is given by the **Peter-Weyl theory**, described later.

In the rest of this article, the representations under consideration will be (continuous) representations by matrices of finite degree. Let $D_1(x) = (d_{ij}^{(1)}(x))$ and $D_2(x) = (d_{ij}^{(2)}(x))$ be irreducible unitary representations which are not mutually \dagger equivalent. Then from \dagger Schur's lemma follow the orthogonality relations $(d_{ij}^{(1)}, d_{kl}^{(2)}) = 0$ and $(\sqrt{n_1} d_{ij}^{(1)}, \sqrt{n_1} d_{mn}^{(1)}) = \delta_{im} \delta_{jn}$ (where n_1 is the degree of the representation D_1). From each \dagger class D_α of irreducible representations of G , choose a unitary representative $D_\alpha(x) = (d_{ij}^\alpha(x))$, and let n_α denote its degree. Then from the orthogonality relations it follows that the $\sqrt{n_\alpha} d_{ij}^\alpha(x)$ form an \dagger orthonormal system of $L_2(G)$.

Let $h \in C(G)$ and consider the map $H: f \rightarrow h \times f$ of $C(G)$ to $C(G)$. Then H is a \dagger compact operator in $C(G)$. Since $C(G)$ is contained in $L_2(G)$, we can define the inner product in $C(G)$. By $(h \times f, g) = (f, h^* \times g)$, $h = h^*$ implies $(Hf, g) = (f, Hg)$; that is, H is a \dagger Hermitian operator. For a given f in $C(G)$, there exists $h (= h^*)$ in $C(G)$ such that $h \times f$ is uniformly arbitrarily near f . From the theory of compact Hermitian operators, Hf can be uniformly approximated by linear combinations of the \dagger eigenfunctions of H . Since the \dagger eigenspace of H is finite-

dimensional and invariant under $U(a)$, the eigenfunctions of H are linear combinations of a finite number of $\sqrt{n_\alpha} d_{ij}^\alpha(x)$. Hence any function f in $C(G)$ can be uniformly approximated by linear combinations of a finite number of $\sqrt{n_\alpha} d_{ij}^\alpha(x)$. This fact, like the similar result in \dagger Fourier series, is called the **approximation theorem**. From this, it follows that the orthonormal system $\{\sqrt{n_\alpha} d_{ij}^\alpha(x)\}$ is \dagger complete; i.e., if an element of $C(G)$ is orthogonal to each element in this system, then it is 0.

Since $C(G)$ is dense in $L_2(G)$, $\{\sqrt{n_\alpha} d_{ij}^\alpha(x)\}$ is a \dagger complete orthonormal system of the Hilbert space $L_2(G)$. Hence for any $f \in L_2(G)$, its "Fourier series" $\sum_\alpha \sum_{ij} c_{ij}^\alpha \sqrt{n_\alpha} d_{ij}^\alpha(x)$ (where $c_{ij}^\alpha = (f, \sqrt{n_\alpha} d_{ij}^\alpha)$) converges to f in the mean of order 2 (i.e., with respect to the \dagger metric of $L_2(G)$). In particular, if G is a compact \dagger Lie group and f is sufficiently many times differentiable, then this series converges uniformly to f .

The space V_i^α of dimension n_α spanned by the elements $d_{ij}^\alpha(x)$ ($1 \leq j \leq n_\alpha$) in the i th row of the matrix $D_\alpha(x)$ is invariant under the right regular representation U . The representation on V_i^α given by U can only be D_α . Then the fact that $\{\sqrt{n_\alpha} d_{ij}^\alpha(x)\}$ is an orthonormal system of $L_2(G)$ means that the regular representation U of a compact group G is decomposable into a discrete direct sum of finite-dimensional irreducible representations. Each irreducible representation D_α is contained in U with multiplicity equal to its degree n_α .

If a function $\varphi(x)$ in $C(G)$ satisfies $\varphi(y^{-1}xy) = \varphi(x)$ for any x, y , then it is called a **class function**. The set $K(G)$ of all the continuous class functions coincides with the \dagger center of the group ring $C(G)$. The \dagger character of an irreducible representation of G is a class function, and the set $\{\chi_\alpha(x)\}$ of all characters plays the same role as the orthogonal system $\{\sqrt{n_\alpha} d_{ij}^\alpha(x)\}$ in $C(G)$. Namely, $\{\chi_\alpha(x)\}$ is a complete orthonormal system in (the \dagger completion of) $K(G)$, and any class function can be uniformly approximated by linear combinations of a finite number of these characters.

The preceding paragraphs give a brief description of the Peter-Weyl theory. If G is the 1-dimensional \dagger torus group $\mathbf{T}^1 = \mathbf{R}/\mathbf{Z}$, namely, the compact group of real numbers mod 1, then this is actually the theory of Fourier series concerning periodic functions on the line. (For concrete irreducible representations of $O(n)$, $U(n)$, $Sp(n)$, and formulas for characters \rightarrow 60 Classical Groups. For representations of compact Lie groups \rightarrow 249 Lie Groups, 248 Lie Algebras.) The theory of compact groups was completed by F. Peter and H. Weyl (*Math. Ann.*, 97 (1927)), and J. von Neumann's theory concerning almost periodic functions in a group (1934) united the

theory of compact groups with H. Bohr's theory of almost periodic functions (\rightarrow 18 Almost Periodic Functions).

C. Structure of Compact Groups

Let a be an element of a compact group G different from e . Since the underlying space of a topological group is a \dagger completely regular space, there exists a function in $C(G)$ such that $f(a) \neq f(e)$. Hence there exists a representation $D(x)$ of G such that $D(a)$ is not equal to the unit matrix. This means that any compact group G can be expressed as a \dagger projective limit group of compact Lie groups. Beginning with this fact, von Neumann (1933) showed that a \dagger locally Euclidean compact group is a Lie group (\rightarrow 423 Topological Groups N).

D. Set of Representations

The set $G' = \{D\}$ of representations of G by matrices admits the following operations: (i) $D_1 \otimes D_2$ (\dagger tensor product representation); (ii) $D_1 \oplus D_2 = \begin{pmatrix} D_1 & 0 \\ 0 & D_2 \end{pmatrix}$ (\dagger direct sum representation); (iii) $P^{-1}DP$ (equivalent representation); and (iv) \bar{D} (complex conjugate representation). Let M be a subset of G' such that $\bar{D} \in M$ whenever $D \in M$ and the irreducible components of $D_1 \otimes D_2$ are in M whenever $D_1, D_2 \in M$. Then M is called a **module of representations** of G . There is a one-to-one correspondence between closed normal subgroups H of G and modules M formed by all the representations of G/H .

A representation of G' is a correspondence which assigns to each D a matrix $A(D)$ of the same degree as that of D and preserves the operations of G' : $A(D_1 \otimes D_2) = A(D_1) \otimes A(D_2)$, $A(D_1 \oplus D_2) = A(D_1) \oplus A(D_2)$, $A(P^{-1}DP) = P^{-1}A(D)P$, and $A(\bar{D}) = \overline{A(D)}$. Let G'' be the set of all the representations of G' . Define the product of $A_1, A_2 \in G''$ by $A_1 A_2(D) = A_1(D)A_2(D)$ and a topology on G'' by the \dagger weak topology of the functions $A(D)$ of D . Namely, a typical neighborhood of A_0 is of the form $U(A_0; D_1, \dots, D_s; \varepsilon) = \{A \mid \|A(D_i) - A_0(D_i)\| < \varepsilon, i = 1, \dots, s\}$. G'' is a topological group under this multiplication and topology. Then the **Tannaka duality theorem** states that $G'' \cong G$ holds (T. Tannaka, *Tôhoku Math. J.*, 45 (1939)). Let $R(G)$ be the \dagger algebra over the complex number field \mathbb{C} formed by the set of all the linear combinations of a finite number of $d_{ij}^{\lambda}(x)$, and let $\text{Aut } R(G)$ be the automorphism group of this algebra $R(G)$. Let G^* be the set of all the elements σ in $\text{Aut } R(G)$ which commute with every left translation $L(x)$ ($(L(x)f)(y) = f(xy)$) and which satisfy

$\sigma(\bar{f}) = \overline{\sigma(f)}$. Then G^* is a topological group with respect to the weak topology, and the Tannaka duality theorem implies that the correspondence which assigns to each $x \in G$ the right translation $R(x)$ (the restriction of $U(x)$ to $R(G)$) is an isomorphism of G onto G^* as topological groups. For the case where G is a compact Lie group, C. Chevalley restated the Tannaka duality theorem as one giving a relation between compact Lie groups and complex algebraic groups (\rightarrow 249 Lie Groups U).

70 (IX.5) Complexes

A. General Remarks

The notion of complexes was introduced by H. Poincaré to study the topology of \dagger manifolds by combinatorial methods (\rightarrow 65 Combinatorial Manifolds). Various kinds of complexes have been introduced in the course of the development of topology. These will be dealt with individually in the sections that follow.

B. Euclidean Simplicial Complexes

Let \mathbb{R}^N be the N -dimensional \dagger Euclidean space, and let a_0, a_1, \dots, a_m be points of \mathbb{R}^N with coordinates $a_i = (a_i^{(1)}, a_i^{(2)}, \dots, a_i^{(N)})$ for $i = 0, 1, \dots, m$. For real numbers $\lambda_0, \lambda_1, \dots, \lambda_m$, we denote by $\lambda_0 a_0 + \lambda_1 a_1 + \dots + \lambda_m a_m$ the point $(\sum_{i=0}^m \lambda_i a_i^{(1)}, \sum_{i=0}^m \lambda_i a_i^{(2)}, \dots, \sum_{i=0}^m \lambda_i a_i^{(N)})$ of \mathbb{R}^N .

A set of $n+1$ points a_0, a_1, \dots, a_n of \mathbb{R}^N is said to be **independent** or in **general position** if vectors $\overrightarrow{a_0 a_1}, \overrightarrow{a_0 a_2}, \dots, \overrightarrow{a_0 a_n}$ are linearly independent. For given independent points a_0, a_1, \dots, a_n , let $|a_0 a_1 \dots a_n|$ denote the subset of \mathbb{R}^N given by

$$|a_0 a_1 \dots a_n| = \{\lambda_0 a_0 + \lambda_1 a_1 + \dots + \lambda_n a_n \mid \lambda_0 + \lambda_1 + \dots + \lambda_n = 1, \lambda_i \geq 0\}.$$

$|a_0 a_1 \dots a_n|$ is called an n -**simplex** with **vertices** a_0, a_1, \dots, a_n . Simplexes are denoted by $\Delta, \Delta', \sigma, \tau$, etc. For example, a 0-simplex $|a_0|$ is a point a_0 , a 1-simplex $|a_0 a_1|$ is a segment $\overline{a_0 a_1}$, and a 2-simplex $|a_0 a_1 a_2|$ is a triangle $\Delta a_0 a_1 a_2$.

We attach to $\lambda_0 a_0 + \lambda_1 a_1 + \dots + \lambda_n a_n$ the coordinates $(\lambda_0, \lambda_1, \dots, \lambda_n)$, called the **barycentric coordinates**. If $|a_0 a_1 \dots a_n|$ is an n -simplex, every subset $\{a_{i_0}, a_{i_1}, \dots, a_{i_q}\}$ of $\{a_0, a_1, \dots, a_n\}$ is independent. A q -simplex $|a_{i_0} a_{i_1} \dots a_{i_q}|$ is called a q -**face** of $|a_0 a_1 \dots a_n|$.

A set \mathfrak{R} of simplexes in a Euclidean space \mathbf{R}^N is called a **Euclidean (simplicial) complex** in \mathbf{R}^N if \mathfrak{R} satisfies the following three conditions: (i) Every face of a simplex belonging to \mathfrak{R} is also an element of \mathfrak{R} . (ii) The intersection of two simplexes belonging to \mathfrak{R} is either empty or a face of each of them. (iii) Each point of a simplex belonging to \mathfrak{R} has a neighborhood in \mathbf{R}^N that intersects only a finite number of simplexes belonging to \mathfrak{R} . A Euclidean complex is also called a **geometric complex** (or **rectilinear complex**). Each 0-simplex in \mathfrak{R} is called a **vertex** in \mathfrak{R} . We define the **dimension** of \mathfrak{R} to be n if \mathfrak{R} contains an n -simplex but no $(n+1)$ -simplex, and ∞ if \mathfrak{R} contains n -simplexes for all $n \geq 0$.

By a **subcomplex** of a Euclidean complex \mathfrak{R} we mean a Euclidean complex that is a subset of \mathfrak{R} . For a Euclidean complex \mathfrak{R} , its r -**section** (or r -**skeleton**) is defined to be the subcomplex of \mathfrak{R} consisting of all n -simplexes ($n \leq r$) in \mathfrak{R} .

If \mathfrak{R} is a Euclidean complex in \mathbf{R}^N , we denote by $|\mathfrak{R}|$ the set of points in \mathbf{R}^N belonging to simplexes in \mathfrak{R} . This set $|\mathfrak{R}|$ is called the **Euclidean polyhedron** of \mathfrak{R} .

By **subdivision** \mathfrak{R}' of a Euclidean complex \mathfrak{R} we mean a Euclidean complex such that $|\mathfrak{R}'| = |\mathfrak{R}|$ and each simplex in \mathfrak{R}' is contained in a simplex in \mathfrak{R} .

Specifically, we can construct a subdivision \mathfrak{R}' of \mathfrak{R} utilizing \dagger barycenters of simplexes in \mathfrak{R} ; namely, we let \mathfrak{R}' be the set of all r -simplexes whose vertices consist of barycenters of the series $\Delta_0 \subset \Delta_1 \subset \dots \subset \Delta_r$ of simplexes in \mathfrak{R} . Then \mathfrak{R}' is a subdivision of \mathfrak{R} , called the **barycentric subdivision** of \mathfrak{R} and denoted by $\text{Sd } \mathfrak{R}$.

Given a Euclidean complex \mathfrak{R} and a subset A of $|\mathfrak{R}|$, we define the **star** of A in \mathfrak{R} to be the subcomplex of \mathfrak{R} that consists of simplexes $\{\Delta\}$ and their faces such that $\Delta \cap A \neq \emptyset$. Furthermore, we define the **open star** of A in \mathfrak{R} as the union of \dagger open simplexes (the interiors of simplexes) of \mathfrak{R} whose closures intersect A . We denote by $\text{St}_{\mathfrak{R}}(A)$ the star of A in \mathfrak{R} and by $O_{\mathfrak{R}}(A)$ the open star of A in \mathfrak{R} ; then $O_{\mathfrak{R}}(A)$ is an open set whose closure is $|\text{St}_{\mathfrak{R}}(A)|$.

The notion of Euclidean simplicial complexes can be generalized to that of **Euclidean cell complexes**; this is done by replacing the term *simplex* by \dagger *convex cell* in the definition of Euclidean simplicial complex. For a Euclidean cell complex \mathfrak{R} , the notions of vertex, dimension, subcomplex, r -section, and subdivision are defined similarly as in the case of Euclidean simplicial complexes.

C. Simplicial Complexes

Given a Euclidean simplicial complex \mathfrak{R} , let K denote the set of all the vertices in \mathfrak{R} , and let Σ denote the set consisting of those subsets $\{v_0, \dots, v_r\}$ of K for which there exist simplexes Δ in \mathfrak{R} such that $\{v_0, \dots, v_r\}$ coincide with the set of vertices of Δ . Then we have (1) if $s \in \Sigma$ and $s \supset s'$, $s' \neq \emptyset$, then $s' \in \Sigma$; (2) every set consisting of a single element in K is in Σ , and the empty set is not in Σ .

In general, if a pair (K, Σ) of a set K and a set Σ consisting of finite subsets of K satisfy (1) and (2), then the pair (or the set K) is called an **abstract simplicial complex** (or simply **simplicial complex**). If K is a simplicial complex, each element of the set K is called a **vertex** in K , and each set of Σ is called a **simplex** in K . A simplex consisting of $n+1$ vertices is called an n -**simplex**. We say that a simplicial complex K is **finite** if it consists of a finite number of vertices; it is **locally finite** if every vertex of K belongs to only finitely many simplexes in K . We define similarly **countable simplicial complexes** and **locally countable simplicial complexes**. The **dimension** and r -**section** of a simplicial complex are defined as in the case of Euclidean complexes. By a **subcomplex** of a simplicial complex K we mean a simplicial complex K_0 such that each simplex of K_0 is a simplex in K .

Let K and L be simplicial complexes. A mapping $\varphi: K \rightarrow L$ is called a **simplicial mapping** (**simplicial map**) of K to L if the following condition is satisfied: If v_0, v_1, \dots, v_n are vertices of a simplex of K , then $\varphi(v_0), \varphi(v_1), \dots, \varphi(v_n)$ are vertices of some simplex of L . Two simplicial complexes K and L are said to be **isomorphic** if there exist simplicial mappings $\varphi: K \rightarrow L, \psi: L \rightarrow K$ such that $\psi \circ \varphi$ and $\varphi \circ \psi$ are the identity mappings.

Given a simplicial complex K , let $|K|$ denote the set of all functions x from the set of vertices of K to the closed interval $I = [0, 1]$ satisfying the following conditions: (i) The set $\{v \in K | x(v) \neq 0\}$ is a simplex of K . (ii) $\sum_{v \in K} x(v) = 1$. The value $x(v)$ is called the **barycentric coordinate** of the point $x \in |K|$ with respect to the vertex v . Each vertex v of K is identified with the point of $|K|$ whose barycentric coordinate with respect to the vertex v is 1 and is called a **vertex** in $|K|$. For a simplex $s = \{v_0, v_1, \dots, v_n\}$ in K , we define $|s| = \{x \in |K| | x(v) = 0 (v \notin s)\}$, which is called a **simplex** in $|K|$. We call $\{x \in |s| | x(v_i) > 0 (i = 0, 1, \dots, n)\}$ an **open simplex** of $|K|$ or the **interior** of $|s|$. We remark here that for an arbitrary simplex s in K a point $x \in |s|$ can be written in the form $x = \sum_{v \in s} x(v) \cdot v$. We can define a metric d on $|K|$ by $d(x, y) = (\sum_{v \in K} (x(v) - y(v))^2)^{1/2}$. However, $|K|$ is usually supplied with a \dagger stronger topology

defined as follows: (1) Each simplex $|s|$ in $|K|$ has the topology given by the metric d . (2) A subset U of $|K|$ is open if and only if $U \cap |s|$ is an open subset of $|s|$ for each simplex s of K . Henceforward, by the topology of $|K|$ we mean the topology just defined unless otherwise stated. The set $|K|$ with such a topology is called the **polyhedron** of K . The topology of $|K|$ coincides with the above metric topology if and only if K is locally finite. If simplicial complexes K and L are isomorphic, then $|K|$ and $|L|$ are homeomorphic. If K is the simplicial complex defined by a Euclidean simplicial complex \mathfrak{K} , then $|K|$ and $|\mathfrak{K}|$ are homeomorphic. When K is finite, there exists an Euclidean simplicial complex \mathfrak{K} whose simplicial complex is isomorphic to K . Accordingly $|K|$ is homeomorphic to the Euclidean polyhedron $|\mathfrak{K}|$.

If K and L are simplicial complexes, a mapping $f: |K| \rightarrow |L|$ satisfying the following condition is said to be **linear**: If $s = \{v_0, v_1, \dots, v_n\}$ is a simplex in K and $x = \lambda_0 v_0 + \dots + \lambda_n v_n$ ($\lambda_0 + \dots + \lambda_n = 1, \lambda_i \geq 0$), then $f(v_0), \dots, f(v_n)$ belong to a simplex in L and $f(x) = \lambda_0 f(v_0) + \dots + \lambda_n f(v_n)$. The linear mapping determined by a simplicial mapping $\varphi: K \rightarrow L$ is denoted by $|\varphi|: |K| \rightarrow |L|$ and is also called a **simplicial mapping** and denoted by the same letter φ . Let K and K' be simplicial complexes. If there exists a linear mapping $l: |K'| \rightarrow |K|$, which is a homeomorphism, then we identify $|K|$ and $|K'|$ by l and call K' a **subdivision** of K . The **barycentric subdivision** $Sd K$ of a simplicial complex K is defined as in the case of Euclidean complexes. We also have notions of **star** $St_K(A)$ and **open star** $O_K(A)$ for a simplicial complex K and a subset A of $|K|$. If K and L are simplicial complexes, a mapping $f: |K| \rightarrow |L|$ is called a **piecewise linear mapping** if there exist subdivisions K' and L' of K and L , respectively, such that $f: |K'| \rightarrow |L'|$ is linear.

Given an open \dagger covering $\mathfrak{M} = \{M_v\}_{v \in K}$ of a topological space X , the index set K becomes a simplicial complex if we consider each finite nonempty subset s of K such that $\bigcap_{v \in s} M_v \neq \emptyset$ (empty) to be a simplex. The resulting simplicial complex K is called the **nerve** of the open covering \mathfrak{M} . Furthermore, if $\mathfrak{M} = \{M_v\}_{v \in K}$ and $\mathfrak{N} = \{N_w\}_{w \in L}$ are open coverings of a set X , \mathfrak{N} is a refinement of the covering \mathfrak{M} , and L is the nerve of \mathfrak{N} , then a simplicial mapping $\varphi: L \rightarrow K$ is defined by sending each vertex w in L to a vertex v in K such that $N_w \subset M_v$.

Given two disjoint simplicial complexes K and L , a simplicial complex $K * L$, called the **join** of K and L , is defined by the following: (1) the vertices of $K * L$ are the vertices of K and the vertices of L . (2) A nonempty subset of vertices is a simplex of $K * L$ if and only if its

subsets in K and L are empty or simplexes there. In particular, the join of a simplicial complex K and a single point is called the **cone** of K .

A simplicial complex K is said to be **ordered** if a \dagger partial ordering is given in the set of vertices in K such that the set of vertices of each simplex is \dagger totally ordered. Given ordered simplicial complexes K and L , an ordered simplicial complex $K \times L$, called the **Cartesian product** of K and L , is defined by the following:

(1) The vertices in $K \times L$ are pairs (v, w) , where v and w are any vertices in K and L , respectively. (2) A set of vertices $(v_0, w_0), \dots, (v_n, w_n)$ such that $v_0 \leq \dots \leq v_n$ and $w_0 \leq \dots \leq w_n$ is a simplex in $K \times L$ if (v_0, \dots, v_n) and (w_0, \dots, w_n) are simplexes in K and L , respectively; all simplexes in $K \times L$ are obtained in this manner. (3) $(v_1, w_1) \leq (v_2, w_2)$ if and only if $v_1 \leq v_2$ and $w_1 \leq w_2$.

Assume that either K or L is locally finite or that both K and L are locally countable. Let X and Y be topological spaces and I be the closed interval $[0, 1]$. We define an equivalence relation \sim in the topological space $X \cup (X \times Y \times I) \cup Y$ by $x \sim (x, y, 0)$ and $y \sim (x, y, 1)$, where $x \in X, y \in Y$. The quotient space of $X \cup (X \times Y \times I) \cup Y$ by this relation is called the **join** of X and Y and is denoted by $X * Y$. Then the polyhedron $|K \times L|$ is homeomorphic to the product space $|K| \times |L|$ of the topological spaces $|K|$ and $|L|$. And the polyhedron $|K * L|$ is homeomorphic to $|K| * |L|$.

By a **triangulation** T of a topological space X we mean a pair (K, t) consisting of a simplicial complex K and a homeomorphism $t: |K| \rightarrow X$. A triangulation is also called a **simplicial decomposition**. If $T = (K, t)$ is a triangulation of X , the various concepts defined for K can be transferred to X by means of the mapping t . For example, by a **simplex** of the triangulation T we mean the image of a simplex of $|K|$ under t . We say that a triangulation $T = (K, t)$ is **finite** if K is a finite simplicial complex. If $T = (K, t)$ is a triangulation and (K', l) is a subdivision of K , then $T' = (K', t \circ l)$ is called a **subdivision** of T . If $T_1 = (K_1, t_1), T_2 = (K_2, t_2)$ are triangulations of topological spaces X_1, X_2 , respectively, a mapping $f: X_1 \rightarrow X_2$ is called a **simplicial mapping** relative to T_1 and T_2 if $t_2^{-1} \circ f \circ t_1: |K_1| \rightarrow |K_2|$ is a simplicial mapping. The following two problems on triangulations are famous: (1) Under what topological conditions is it possible for a given topological space to be supplied with a triangulation? (2) Given two triangulations T_1, T_2 of a space X , are there subdivisions $T'_1 = (K'_1, t'_1), T'_2 = (K'_2, t'_2)$ of T_1 and T_2 , respectively, such that K'_1 and K'_2 are isomorphic? Concerning the second problem, the conjecture asserting the existence of subdivisions T'_1

and T'_2 as above is known as the **fundamental conjecture (Hauptvermutung)** in topology. Every 3-dimensional manifold is triangulable, and any two of its triangulations admit subdivisions satisfying the condition in (2) (E. E. Moise [7]).

In 1961, J. Milnor showed that the fundamental conjecture is not true for polyhedra [8]. The triangulation problem and the fundamental conjecture for topological manifolds were negatively solved by R. Kirby and L. Siebenmann [9] (\rightarrow 65 Combinatorial Manifolds). Any \dagger differentiable manifold is triangulable, and the fundamental conjecture holds for its $\dagger C^r$ -triangulations ($r \geq 1$) [6] (\rightarrow 114 Differential Topology).

Let T_1, T_2 be triangulations of topological spaces X_1, X_2 , respectively, and let $f: X_1 \rightarrow X_2$ be a continuous mapping. Then a simplicial mapping $\varphi: X_1 \rightarrow X_2$ relative to T_1 and T_2 is called a **simplicial approximation** to f if, for each $x \in X$, the image $\varphi(x)$ lies on the simplex of T_2 whose interior contains $f(x)$. The following existence theorem is called the **simplicial approximation theorem**: For every continuous mapping $f: X_1 \rightarrow X_2$, there exist a subdivision T'_1 of T_1 and a simplicial mapping $\varphi: X_1 \rightarrow X_2$ relative to T'_1 and T_2 that is a simplicial approximation of f . If the triangulation T_1 is finite, then for a sufficiently large n we can choose $\text{Sd}^n T_1$ as the T'_1 above (where $\text{Sd}^0 T = T$ and $\text{Sd}^n T = \text{Sd}(\text{Sd}^{n-1} T)$ ($n \geq 1$)). If $\varphi: X_1 \rightarrow X_2$ is a simplicial approximation to a continuous mapping f , then f and φ are \dagger homotopic.

D. Cell Complexes

Let V^n be the \dagger unit n -disk, S^{n-1} be the \dagger unit $(n-1)$ -sphere, and X be a Hausdorff space. For a subset e of X , let \bar{e} be the closure of e in X , and let $\dot{e} = \bar{e} - e$. A subset e of the space X is called an n -cell, or **open n -cell** in X if there is a relative homeomorphism $\varphi: (V^n, S^{n-1}) \rightarrow (\bar{e}, \dot{e})$, i.e., a continuous mapping $\varphi: V^n \rightarrow \bar{e}$ such that $\varphi(S^{n-1}) \subset \dot{e}$ and $\varphi: V^n - S^{n-1} \rightarrow \bar{e} - \dot{e}$ is a homeomorphism. For example, $S^n - \{p\}$ ($p \in S^n$) is an n -cell. A set $\{e_\lambda | \lambda \in \Lambda\}$ of cells in the Hausdorff space X is called a **cellular decomposition** of X if the following three conditions are satisfied: (i) $e_\lambda \cap e_\mu$ is empty if $\lambda \neq \mu$; (ii) $X = \bigcup_{\lambda \in \Lambda} e_\lambda$; (iii) If the dimension of e_λ is $n+1$, then $\dot{e}_\lambda \subset X^n$, where X^n is the union of all the cells e_μ ($\mu \in \Lambda$) whose dimensions are not greater than n . For example, the n -sphere S^n has a cellular decomposition consisting of a single 0-cell and a single n -cell.

A Hausdorff space X together with its cellular decomposition $\{e_\lambda\}$ is called a **cell complex**, and each e_λ is called a **cell** in the cell

complex X . For a cell complex, the notions of **vertex**, **n -section**, and **dimension** are defined in the same way as the corresponding notions in Euclidean complexes. Let X be a cell complex and A a topological subspace of X such that the closure of each cell of X intersecting A is contained in A . Then the set of cells e such that $e \cap A \neq \emptyset$ forms a cellular decomposition of A . The set A together with this cellular decomposition is called a **subcomplex** of the cell complex X . A cell complex X with its cells $\{e_\lambda\}$ is said to be **finite** if the number of e_λ is finite. If each point in a cell complex X is an interior point of some finite subcomplex of X , then X is said to be **locally finite**. We define similarly a **countable cell complex** and a **locally countable cell complex**. If the closure of each n -cell of a cell complex X is homeomorphic to V^n ($n=0, 1, \dots$), X is said to be **regular**. If X and Y are cell complexes, a continuous mapping $f: X \rightarrow Y$ such that $f(X^n) \subset Y^n$ ($n=0, 1, \dots$) is called a **cellular mapping**. If X and Y are cell complexes, the set of \dagger topological products $e_1 \times e_2$, where e_1, e_2 run over all cells of X, Y , respectively, is a cellular decomposition of the product space $X \times Y$. The resulting cell complex $X \times Y$ is called the **product complex** of the cell complexes X and Y .

A cell complex X is said to be **closure finite** if each cell in X is contained in a finite subcomplex of X ; and X is said to have the **weak topology** if a subset $U \subset X$ is open if and only if $U \cap \bar{e}$ is relatively open in \bar{e} for each cell e of X . We call a cell complex a **CW complex** if it is closure finite and has the weak topology. The cellular decomposition of a CW complex is called a **CW decomposition**. A locally finite cell complex is a CW complex.

Fundamental properties of CW complexes are as follows: (i) A CW complex is a \dagger paracompact (hence \dagger normal) space and is \dagger locally contractible. (ii) A subcomplex A of a CW complex X is a closed subspace of X , and A itself is a CW complex. (iii) A mapping $f: X \rightarrow Y$ of a CW complex X to a topological space Y is continuous if and only if the restriction $f|_{\bar{e}}$ is continuous for each cell e of X . (iv) If X and Y are CW complexes and $f: X \rightarrow Y$ is any continuous mapping then there exists a cellular mapping of X to Y that is homotopic to f (**cellular approximation theorem**). (v) A pair (X, A) consisting of a CW complex X and its subcomplex A has the \dagger homotopy extension property for any topological space. (vi) A CW complex has the \dagger covering homotopy property for any \dagger fiber space. (vii) The product complex $X \times Y$ of two CW complexes X and Y is not necessarily a CW complex, but it is \dagger homotopy equivalent to a CW complex. (viii) If either X or Y is locally finite, or if both X and Y are locally countable, then the product

complex $X \times Y$ is a CW complex. (ix) For CW complexes X and Y , the mapping space Y^X is homotopy equivalent to a CW complex. (x) The covering space of a CW complex has a CW decomposition.

If K is a simplicial complex, the polyhedron $|K|$ is a regular CW complex whose cells are all open simplexes in $|K|$. A simplicial complex K is (locally) finite if and only if the CW complex $|K|$ is (locally) finite. In particular, the Euclidean polyhedron of a Euclidean simplicial (or cell) complex is a locally finite CW complex. A polyhedron $|K|$ generally admits a CW decomposition whose cells are far smaller in number than the simplexes constituting a simplicial decomposition of K . For any CW complex X , there exists a polyhedron $|K|$ that is homotopy equivalent to X . In particular, if X is an n -dimensional finite (countable) CW complex, we can choose as K an n -dimensional finite (locally finite and countable) simplicial complex.

E. Semisimplicial Complexes

By an **ordered simplex** in a simplicial complex K we mean a finite sequence (v_0, v_1, \dots, v_n) ($n \geq 0$) of vertices in K , contained in the set of vertices of a simplex in K . Let $O(K)_n$ be the set of all ordered simplexes of K of length $n+1$, and define mappings $\partial_i: O(K)_n \rightarrow O(K)_{n-1}$ and $s_i: O(K)_n \rightarrow O(K)_{n+1}$ for $i=0, 1, \dots, n$ by $\partial_i(v_0, \dots, v_n) = (v_0, \dots, v_{i-1}, v_{i+1}, \dots, v_n)$ and $s_i(v_0, \dots, v_n) = (v_0, \dots, v_{i-1}, v_i, v_i, v_{i+1}, \dots, v_n)$. Then the following relations hold:

$$\begin{aligned} \partial_i \circ \partial_j &= \partial_{j-1} \circ \partial_i \quad (i < j), \\ s_i \circ s_j &= s_{j+1} \circ s_i \quad (i \leq j), \\ \partial_i \circ s_j &= s_{j-1} \circ \partial_i \quad (i < j), \\ \partial_i \circ s_j &= s_j \circ \partial_{i-1} \quad (i > j+1), \\ \partial_i \circ s_i &= \partial_{i+1} \circ s_i = \text{identity}. \end{aligned} \quad (1)$$

Let Δ^n be the n -dimensional simplex in \mathbf{R}^n with vertices $e_0 = (0, 0, \dots, 0)$, $e_1 = (1, 0, \dots, 0)$, \dots , $e_n = (0, \dots, 1)$. By a **singular n -simplex** in a topological space X we mean a continuous mapping $T: \Delta^n \rightarrow X$. Let $S(X)_n$ be the set of all singular n -simplexes in X , and define mappings $\partial_i: S(X)_n \rightarrow S(X)_{n-1}$ and $s_i: S(X)_n \rightarrow S(X)_{n+1}$ for $i=0, 1, \dots, n$ by $\partial_i T(\lambda_0, \dots, \lambda_n) = T(\lambda_0, \dots, \lambda_{i-1}, 0, \lambda_i, \dots, \lambda_n)$ and $s_i T(\lambda_0, \dots, \lambda_{n+1}) = T(\lambda_0, \dots, \lambda_{i-1}, \lambda_i + \lambda_{i+1}, \lambda_{i+1}, \dots, \lambda_{n+1})$, where $(\lambda_0, \dots, \lambda_n)$ is the point $\sum_{i=0}^n \lambda_i e_i$, $\lambda_i \geq 0$, $\sum_{i=0}^n \lambda_i = 1$. Then relation (1) holds between ∂_i and s_i .

Because of the importance of relation (1), which is basic in defining homology of simplicial complexes and topological spaces (\rightarrow 201 Homology Theory), S. Eilenberg and J. A. Zilber gave the following definition: A **semi-**

simplicial complex K consists of a sequence of sets K_n ($n=0, 1, \dots$) together with mappings $\partial_i: K_n \rightarrow K_{n-1}$, $s_i: K_n \rightarrow K_{n+1}$ ($i=0, 1, \dots, n$) satisfying relations (1). An element of K_n is called an **n -simplex** in K , and ∂_i , s_i are called the **i th face operator** and the **i th degeneracy operator**, respectively. A simplex is said to be **degenerate** if it is the image of a simplex under some s_i . A semisimplicial complex is abbreviated as **s.s. complex**. The s.s. complexes $O(K) = \{O(K)_n, \partial_i, s_i\}$ and $S(X) = \{S(X)_n, \partial_i, s_i\}$ are called the **ordered complex** of K and the **singular complex** of X , respectively.

Let K be an s.s. complex, and let L_n be a subset of K_n for $n=0, 1, \dots$. If $\partial_i(L_n) \subset L_{n-1}$ and $s_i(L_n) \subset L_{n+1}$ for each i , then $L = \{L_n, \partial_i|L_n, s_i|L_n\}$ is an s.s. complex, and L is called a **subcomplex** of the s.s. complex K . If A is a subspace of a topological space X , $S(A)$ is a subcomplex of $S(X)$. If K is an ordered simplicial complex, a subcomplex $O'(K)$ of $O(K)$ is obtained by considering the set of all ordered simplexes (v_0, v_1, \dots, v_n) such that $v_0 \leq v_1 \leq \dots \leq v_n$ ($n=0, 1, \dots$). If K and L are s.s. complexes, a sequence $f = \{f_n\}$ of mappings $f_n: K_n \rightarrow L_n$ defined for each n is called an **s.s. mapping** if $\partial_i \circ f_n = f_{n-1} \circ \partial_i$ and $s_i \circ f_n = f_{n+1} \circ s_i$ ($0 \leq i \leq n$). If $f: X \rightarrow Y$ is a continuous mapping of topological spaces, then f determines an s.s. mapping $S(f): S(X) \rightarrow S(Y)$ by $S(f)(T) = f \circ T$. Two s.s. complexes K and L are said to be **isomorphic** if there is a bijective s.s. mapping of K to L . For two s.s. complexes K and L , we define the **Cartesian product** $K \times L$ to be the s.s. complex given by $(K \times L)_n = K_n \times L_n$, $\partial_i(\sigma, \tau) = (\partial_i \sigma, \partial_i \tau)$, $s_i(\sigma, \tau) = (s_i \sigma, s_i \tau)$ ($\sigma \in K_n, \tau \in L_n$). If K and L are ordered simplicial complexes, the s.s. complexes $O'(K) \times O'(L)$ and $O'(K \times L)$ are isomorphic. If X and Y are topological spaces, the s.s. complexes $S(X) \times S(Y)$ and $S(X \times Y)$ are isomorphic.

Given an s.s. complex K , we construct a topological space $|K|$ as follows: First, we provide K_n with the discrete topology and consider the topological space $\bar{K} = \bigcup_{n \geq 0} K_n \times \Delta^n$. Next we consider simplicial mappings $\varepsilon^i: \Delta^{n-1} \rightarrow \Delta^n$ and $\eta^i: \Delta^{n+1} \rightarrow \Delta^n$ defined by $\varepsilon^i(p_j) = p_j$ ($j < i$), $\varepsilon^i(p_j) = p_{j+1}$ ($j \geq i$) and $\eta^i(p_j) = p_j$ ($j \leq i$), $\eta^i(p_j) = p_{j-1}$ ($j > i$), where p_0, \dots, p_n are the vertices of Δ^n . The topological space $|K|$ is defined to be the quotient space of \bar{K} with respect to an equivalence relation \sim that is defined by the following: $(\partial_i \sigma, y) \sim (\sigma, \varepsilon^i(y))$ ($\sigma \in K_n, y \in \Delta^{n-1}$), $(s_i \sigma, y) \sim (\sigma, \eta^i(y))$ ($\sigma \in K_n, y \in \Delta^{n+1}$), where $i=0, 1, \dots, n$. The space $|K|$ is called the **(geometric) realization of the s.s. complex** K . Given an s.s. mapping $f: K \rightarrow L$, we obtain a continuous mapping $|f|: |K| \rightarrow |L|$ defined by $|f|((\sigma, y)) = |f(\sigma), y|$, where $|\sigma, y|$ is the point in $|K|$ represented by $(\sigma, y) \in \bar{K}$. We call $|f|$ the **realization of the s.s. mapping** f .

The realization $|K|$ of an s.s. complex K is a CW complex whose cells are in one-to-one correspondence with the nondegenerate simplexes in K . For a topological space X , a \dagger weak homotopy equivalence $\rho: |S(X)| \rightarrow X$ is defined by $\rho(|T, y|) = T(y)$ ($T \in S(X)_n, y \in \Delta^n$). This mapping gives rise to a homotopy equivalence when X is a CW complex.

The singular complex $S(X)$ of a topological space X has the following property: Given simplexes $\sigma_0, \dots, \sigma_{k-1}, \sigma_{k+1}, \dots, \sigma_{n+1} \in K_n$ with $\partial_i \sigma_j = \partial_{j-1} \sigma_i$ ($i < j, i, j \neq k$), there exists a simplex $\sigma \in K_{n+1}$ with $\partial_i \sigma = \sigma_i$ ($i \neq k$). An s.s. complex K with this property is called a **Kan complex**. If, in addition, $\partial_i \sigma = \partial_i \sigma'$ ($\sigma, \sigma' \in K_n, i \neq k$) imply $\partial_k \sigma = \partial_k \sigma'$, we call K a **minimal complex**. For every Kan complex K , there are minimal subcomplexes M of K that are isomorphic to each other. Moreover, $|M|$ is a \dagger deformation retract of $|K|$. For a Kan complex K , the \dagger homotopy group can be defined combinatorially.

Two CW complexes X and Y are homotopy equivalent if and only if the minimal subcomplexes of $S(X)$ and $S(Y)$ are isomorphic.

F. Eilenberg-MacLane Complex

Given an integer $n \geq 1$ and a group π (Abelian if $n \geq 2$), there exists an \dagger arcwise connected topological space X for which the \dagger homotopy groups $\pi_i(X)$ are trivial for $i \neq n$ and $\pi_n(X) \cong \pi$. Such a space is called an **Eilenberg-MacLane space** of type (π, n) . Let $\Omega(X; X, *)$ be the \dagger path space over X , and let $p_0: \Omega(X; X, *) \rightarrow X$ be the natural projection. If X is an Eilenberg-MacLane space of type (π, n) , then $(\Omega(X; X, *), p_0, X)$ gives rise to a standard \dagger contractible \dagger fiber space whose fiber is an Eilenberg-MacLane space of type $(\pi, n-1)$. Assume that X is an Eilenberg MacLane space of type (π, n) with Abelian group π . Then X is $(n-1)$ -connected; hence the \dagger Hurewicz theorem can be utilized to show the existence of an isomorphism $h: \pi_n(X) \cong H_n(X)$, while the universal coefficient theorem can be utilized to show that $H^n(X; \pi) \cong \text{Hom}(H_n(X), \pi)$. Since in this case we have $\pi_n(X) \cong \pi$, the element $h^{-1} \in \text{Hom}(H_n(X), \pi_n(X))$ can be regarded as an element of $\text{Hom}(H_n(X), \pi)$. Now the **fundamental class** of X is defined to be the cohomology class $u \in H^n(X; \pi)$ corresponding to h^{-1} . Let Y be a \dagger CW complex and $\pi(Y; X)$ be the set of \dagger homotopy classes of continuous mappings from Y to X . Then there exists a one-to-one correspondence $\pi(Y; X) \rightarrow H^n(Y; \pi)$ given by the assignment $[f] \rightarrow f^* u$ (\rightarrow 305 Obstructions). Let $S(X)$ be the singular complex of X , and let $M(X)$ be a minimal complex of $S(X)$. If X is an Eilenberg-MacLane space

of type (π, n) , $M(X)$ is isomorphic to a certain complex determined uniquely by π and n . This complex is called the **Eilenberg-MacLane complex** of type (π, n) and is denoted by $K(\pi, n)$. The notation $K(\pi, n)$ is also used to mean the space X itself.

Let $\Delta(q)$ be a simplicial complex whose simplexes are all nonvacuous subsets of $\{0, 1, \dots, q\}$. Let $\varepsilon_i: \Delta(q-1) \rightarrow \Delta(q)$ be the simplicial mapping defined by $\varepsilon_i(j) = j$ ($0 \leq j \leq i-1$), $\varepsilon_i(j) = j+1$ ($i \leq j \leq q-1$), and let $\eta_i: \Delta(q+1) \rightarrow \Delta(q)$ be the mapping defined by $\eta_i(j) = j$ ($0 \leq j \leq i$), $\eta_i(j) = j-1$ ($i+1 \leq j \leq q+1$). Now $K(\pi, n)$ is a Kan complex defined by $K(\pi, n)_q = Z^n(\Delta(q); \pi)$, $\partial_i \sigma = \sigma \circ \varepsilon_i$, $s_i \sigma = \sigma \circ \eta_i$, where $Z^0(\Delta(q); \pi) = \pi$, $Z^1(\Delta(q); \pi)$ is the set of π -valued functions defined on the set of pairs (i, j) such that $0 \leq i < j \leq q$ and satisfying the equality $\sigma(j, k) \cdot \sigma(i, k)^{-1} \cdot \sigma(i, j) = 1$ for $0 \leq i < j < k \leq q$, and $Z^n(\Delta(q); \pi)$ ($n \geq 2$) is the group of \dagger oriented cocycles of the simplicial complex $\Delta(q)$. If π is Abelian, the structure of the Abelian group $Z^n(\Delta(q); \pi)$ gives $K(\pi, n)$ the structure of an Abelian group in the s.s. category. This structure yields a one-to-one correspondence $K(\pi, n)_q \rightarrow K(\pi, n-1)_{q-1} \times \dots \times K(\pi, n-1)_0$ for $n \geq 1$ and leads to the expression of $\tau \in K(\pi, n)_q$ in the form $\langle \sigma_{q-1}, \dots, \sigma_0 \rangle$ with $\sigma_i \in K(\pi, n-1)_i$. The **W-construction** of $K(\pi, n-1)$ for $n \geq 1$ is a Kan complex $W(\pi, n-1)$ defined by $W(\pi, n-1)_q = K(\pi, n-1)_q \times K(\pi, n)_q$ and $\partial_0(\sigma_q \times \tau_q) = (\partial_0 \sigma_q) \cdot \sigma_{q-1} \times \partial_0 \tau_q$, $\partial_i(\sigma_q \times \tau_q) = \partial_i \sigma_q \times \partial_i \tau_q$ for $1 \leq i \leq q$, $s_i(\sigma_q \times \tau_q) = s_i \sigma_q \times s_i \tau_q$, where $\sigma_q \in K(\pi, n-1)_q$ and $\tau_q = \langle \sigma_{q-1}, \dots, \sigma_0 \rangle \in K(\pi, n)_q$. Let $p: W(\pi, n-1) \rightarrow K(\pi, n)$ be a natural projection. Then $(W(\pi, n-1), p, K(\pi, n))$ plays the role of the \dagger universal bundle for $K(\pi, n-1)$ in the s.s. category in the following sense: Let L be an s.s. complex, and let $f: L \rightarrow K(\pi, n)$ be an s.s. mapping. We define $f^* W(\pi, n-1)$ to be the subcomplex of $W(\pi, n-1) \times L$ generated by simplexes $(\sigma_q \times \tau_q) \times \rho_q$ such that $\tau_q = f(\rho_q)$, where $\sigma_q \times \tau_q \in W(\pi, n-1)_q$ and $\rho_q \in L_q$. Let $p: f^* W(\pi, n-1) \rightarrow L$ be the natural projection. Then $(f^* W(\pi, n-1), p, L)$ is called the principal fiber bundle induced from $W(\pi, n-1)$ by f . Any principal bundle over L with group $K(\pi, n-1)$ can be expressed as an induced bundle. This property means that $(W(\pi, n-1), p, K(\pi, n))$ is universal. On the other hand, we have an algebraic analog of the universal bundle for the chain group of $K(\pi, n-1)$, called the **bar construction** [12]. Both these concepts were defined by Eilenberg and MacLane in order to determine the structure of the (co)homology of $K(\pi, n)$, which is denoted by $(H^*(\pi, n))H_*(\pi, n)$. This object was later achieved by H. Cartan, who introduced an improved notion called Cartan construction (\rightarrow Appendix A, Table 6.III). Let $\pi(L, K(\pi, n))$ be the set of s.s. homotopy classes of s.s. map-

pings from L to $K(\pi, n)$. If π is Abelian, there exists a one-to-one correspondence $\pi(L, K(\pi, n)) \rightarrow H^n(L; \pi)$ given by the assignment $[f] \rightarrow f^*u$, where $u \in H^n(\pi, n; \pi)$ is the fundamental class of $K(\pi, n)$. By virtue of this correspondence, $k = f^*u \in H^n(L; \pi)$ determines an induced bundle $f^*W(\pi, n-1)$ uniquely up to equivalence, which is denoted by $K(\pi, n-1) \times_k L$.

Let X be an arcwise connected topological space. Let X^n be the Cartesian product of n copies of X . Clearly, the symmetric group \mathfrak{S}_n of degree n operates on X^n . The n -fold **symmetric product** $SP^n X$ of X is defined to be the quotient space of X^n under the action of \mathfrak{S}_n . If we specify a reference point of X , we have a natural inclusion $SP^{n-1} X \subset SP^n X$ and can consider the inductive limit space $\bigcup_{1 \leq n} SP^n X$, denoted by $SP^\infty X$. Then the Dold-Thom theorem [15] shows that $M(SP^\infty X) \cong \prod_{i=1}^\infty K(H_i(X), i)$. In particular, we have $M(SP^\infty S^n) \cong K(\mathbb{Z}, n)$ for $n \geq 1$. This result can be applied to obtain a direct relationship between the axiomatic definition of t cohomology operations using $K(\pi, n)$ due to Eilenberg and Serre and the constructive definition using the symmetric groups due to Steenrod (A. Dold [16], T. Nakamura [17]). For a detailed study of the (co)homology of $SP^n X \rightarrow [18]$.

G. Postnikov Complex

Let X be an arcwise connected topological space. For the sake of simplicity, throughout this section we assume that X is t simple (\rightarrow 202 Homotopy Theory). Then the t Postnikov system of X can be defined as an inverse system (X_n, p_n) ($n=0, 1, 2, \dots$) consisting of topological spaces X_n , continuous mappings $p_n: X_n \rightarrow X_{n-1}$, and a system (X, q_n) ($n=0, 1, 2, \dots$) consisting of continuous mappings $q_n: X \rightarrow X_n$ such that $p_n \circ q_n = q_{n-1}$ and satisfying the following three properties: (1) X_0 is one point. (2) (X_n, p_n, X_{n-1}) is a t fiber space induced from a standard contractible fiber space over an Eilenberg-MacLane space of type $(\pi_n(X), n+1)$ by a mapping corresponding to a cohomology class $k^{n+1} \in H^{n+1}(X_{n-1}; \pi_n(X))$. (3) $q_{n*}: \pi_i(X) \rightarrow \pi_i(X_n)$ gives an isomorphism for $0 \leq i \leq n$. These cohomology classes k^{n+1} are called **Eilenberg-Postnikov invariants** (or simply **k-invariants**). Corresponding to the above facts, the minimal complex $M(X)$ can be obtained as the inverse limit of a certain inverse system $(K(n), p(n))$ consisting of Kan complexes $K(n)$ and s.s. mappings $p(n): K(n) \rightarrow K(n-1)$ defined by $K(0) = K(0, 0)$ and $K(n) = K(\pi_n, n) \times_{k^{n+1}} K(n-1)$ for $n \geq 1$ with natural

projections $p(n)$, where $\pi_n = \pi_n(X)$ and $k^{n+1} \in H^{n+1}(K(n-1); \pi_n)$. This system is determined uniquely up to s.s. homotopy equivalence by its limit, called the **Postnikov complex** and denoted by $K(\pi_1, k^3, \pi_2, \dots, k^{n+1}, \pi_n, \dots)$. As yet we are ignorant of an effective method of computing the cohomology of a Postnikov complex from π_n and k^{n+1} .

71 (XVI.9) Complexity of Computations

A. Measures for Complexity of Computation

Intuitively, **complexity of computation** means the amount of computing efforts measured on some suitable scale. When a problem can be solved by means of any one of several algorithms, it is highly desirable to compare the complexities of those algorithms. For example, the power x^{10} can be evaluated with a pocket calculator by using either of the algorithms

$$x^{10} = x \times x \times x \times x \times x \times x \times x \times x \times x \times x, \quad (A)$$

$$u = x \times x, \quad v = u \times u, \quad w = v \times v,$$

$$x^{10} = u \times w. \quad (B)$$

The complexities of these algorithms can be measured by various quantities: (*T1*) time in seconds, (*T2*) the number of times keys and buttons are touched, (*T3*) the number of basic operations (here, multiplications), and (*S*) the number of values to be stored in the calculator. The quantities (*T1*), (*T2*), and (*T3*) are called **time complexities**, and (*S*) is called the **space complexity**. Obviously, algorithm (B) is preferable with respect to time complexity, although (A) is better with respect to space complexity. (If the calculator has only one memory register, then only (A) can be executed without recording numbers by hand.) For many calculators, the following algorithm is best with respect to both time and space complexities:

$$x^{10} = ((x^2)^2 \times x)^2. \quad (C)$$

In the general theory of complexity, the number of basic operations (*T3*) is often taken as the basis of time complexity, since it represents the intrinsic complexity of the algorithm, rather than of extrinsic factors such as human skill or mechanical performance.

For the evaluation of a power x^n in general, the complexity depends on the value of n : such a parameter dominating the complexity is called the **size** of the problem. Let $T_X(n)$ be the number of multiplications required for evaluating x^n by an algorithm X . Let \mathcal{F} be the set of all algorithms for evaluating x^n . The time complexity $T(n)$ for evaluation of the power is then defined by

$$T(n) = \min_{X \in \mathcal{F}} T_X(n).$$

This is satisfied when [6]

$$\log_2 n \leq T(n) \leq 2 \log_2 n$$

and

$$\lim_{n \rightarrow \infty} \frac{T(n)}{\log_2 n} = 1.$$

In a problem concerning a ^{*}graph, the number m of nodes in the graph, the number n of its edges, or their sum $m+n$ are chosen as the size of the graph. However, the complexity is not determined by such a size, because there are many different instances (particular graphs) of the same size. So the complexity of this problem is defined in the following manner. Let $T(I)$ be the complexity of solving an instance I of the problem and $L(n)$ be the set of all possible instances of size n . Then

$$W(n) = \max_{I \in L(n)} T(I)$$

and

$$A(n) = \sum p(I) T(I),$$

where $p(I)$ denotes the relative frequency of the instance I . The value $W(n)$ is called the **worst-case complexity**, and $A(n)$ is called the **average complexity** of the problem.

In some cases the complexity of a circuit is measured by the number of its building blocks [1], and the complexity of a program is measured by its length [2, 3].

B. Complexity of a Decision Problem

A decision problem and its complexity are rigorously formulated in terms of ^{*}Turing machines. Let Σ be a finite set of symbols and Σ^+ be the whole set of nonempty strings of symbols in Σ . Every instance of the problem is assumed to be represented by a string in Σ^+ . A **decision problem** is a triple (Σ, L, P) of the set Σ of symbols, a subset L of Σ^+ , and a mapping P from L to $\{0 \text{ (false), } 1 \text{ (true)}\}$. The set L represents the set of all possible instances of the problem. The problem is said to be **solvable** if and only if there exists a Turing machine M satisfying the following condition for every string α in the set L : When a tape containing the string α is given to the machine M whose head is initially put on the leftmost symbol of α , the machine writes the value of $P(\alpha)$ on the tape and stops after a finite number of steps. Such a Turing machine is said to **compute** the function P . The number $T_M(\alpha)$ of steps is the time complexity of solving the instance α by the machine M , and the length $S_M(\alpha)$ of the used area of the tape is the space complexity. The worst-case complexity $T_M(n)$ is defined by

$$T_M(n) = \max_{\alpha \in L, |\alpha|=n} T_M(\alpha).$$

The space complexity $S_M(n)$ for the size n is defined in a similar way. The complexities $T(n)$ and $S(n)$ of the problem are not defined, because improvement by a constant factor is always possible for any Turing machine [5].

A problem is said to be solved in **linear** or **polynomial time** if its time complexity $T_M(n)$ is bounded by a linear or polynomial function of the size n .

C. Objectives of Complexity Theory

The objectives of complexity theory are as follows:

- (i) Analyze an algorithm X for a problem P and evaluate its complexity. When exact evaluation is hard, the order of magnitude $O(T_X(n))$ is investigated.
- (ii) Construct better algorithms for the problem P . This gives a better upper bound to the complexity $T(n)$ of the problem.
- (iii) Make clear the limitation of improving algorithms for the problem P . This is done by establishing a lower bound to the complexity $T(n)$ of the problem.

A common approach to constructing better algorithms is to partition the problem into smaller parts, apply algorithms to the parts, and then combine the solutions for the parts into a solution for the whole (divide and conquer, [5]). This approach often yields an efficient algorithm for the problem, especially when the partitioning can be repeated recursively. For demonstrating the limitations of algorithms of a certain class, diagonalization [5], determination of information-theoretic lower bounds [6], or the oracle method [6] are often utilized.

D. Elementary Results on Time Complexity

(1) **Number of arithmetic operations.** A polynomial of degree n with one variable can be evaluated in about $3n/2$ arithmetic operations if preconditioning on coefficients is allowed. Otherwise, $2n-1$ operations are necessary and sufficient for evaluating a polynomial of degree n . For computing the product of two square matrices of degree n , $O(n^2)$ operations are necessary and $O(n^{2.5})$ operations are sufficient. The inverse matrix and the value of the determinant of a square matrix of degree n are computed with the same order of operations as the product. Discrete Fourier transformation of n points is executed in $O(n \log n)$ arithmetic operations (fast Fourier transformation).

(2) **Number of comparisons and data transfers.** Rearrangement of n items in increasing order is realized in $O(n \log n)$ comparisons and

data transfers. Selection of the k th largest item among n items is done in $O(n)$ operations. The position of an item in a list containing n items is found in $O(n)$ comparisons by linear search, in $O(\log n)$ comparisons by binary chopping, and in $O(1)$ comparisons on average by the hashing method.

Many other results can be found in [5]–[7].

E. NP-Completeness

A problem is easily solved if its complexity is $O(n)$ or less. The problem is very hard if its complexity is $O(2^n)$, unless the size n is small. Between these types of problems there is a class of problems, each of which can be solved in polynomial time by a Turing machine.

A **nondeterministic Turing machine** is said to **solve** a decision problem (Σ, L, P) if it can detect the case when $P(\alpha) = 1$ by exercising good choices; more precisely, if it can stop after a finite number of steps and write the value 1 of $P(\alpha)$ on the tape, starting from an initial state with the head on the leftmost symbol of a string α on the tape, provided that $P(\alpha) = 1$. If $P(\alpha) = 0$, then the machine may never stop. For a string α such that $P(\alpha) = 1$, $NT_M(\alpha)$ and $NS_M(\alpha)$ represent the minimum number of steps and the minimum length of tape used in computing $P(\alpha)$. Nondeterministic complexities $NT_M(n)$ and $NS_M(n)$ for the size n are defined in a similar way as before. A problem is said to be solvable in **NP-time** or **NP-space** if it can be solved by a nondeterministic Turing machine M whose time complexity $NT_M(n)$ or space complexity $NS_M(n)$ is bounded by a polynomial function of size n . The class of all problems solvable in NP-time is denoted by **NP**, while that of the problems solvable in polynomial time by ordinary (deterministic) Turing machines is denoted by **P**. Obviously, the class **NP** contains the class **P**. Nevertheless, whether **NP** = **P** or not remains one of the biggest unsolved problems.

A decision problem (Σ, L, P) is **polynomially transformable** to a problem (Σ', L', P') if there exists a mapping h from Σ^+ to Σ'^+ satisfying the following conditions: (1) $h(L) \subseteq L'$; (2) for every string α in L , $P(\alpha) = P'(h(\alpha))$; (3) the mapping h is computed by a Turing machine in polynomial time. If a problem C is polynomially transformable to another problem C' in **P** or **NP**, then the problem C is also in **P** or **NP**. A problem C is said to be **NP-hard** if every problem in **NP** is polynomially transformable to C . It is called **NP-complete** if it is in **NP** and NP-hard. Many problems that have been known empirically to be very hard have recently been shown to be NP-complete [8]. For instance, integer linear programming is

NP-complete. Linear programming has recently been shown to be in **P**. The satisfiability problem of a conjunctive normal form was proven to be NP-complete in 1971 [9].

The **complement** of a decision problem (Σ, L, P) is the problem (Σ, L, P') , where $P'(x) = 1 - P(x)$. If a problem C is in **P**, then its complement C' is also in **P**. When C is in **NP**, it is not guaranteed that C' is in **NP**. The class of all problems whose complements are in **NP** is denoted by **co-NP**. The intersection of **NP** and **co-NP** contains the class **P**, but it is an open problem whether this containment is proper or not. The problem **PRIME**, which asks whether a number N is prime or not, the size n being the number of digits for representing the number N , belongs to both **NP** and **co-NP** [10]. However, it is not known whether it is in **P**.

F. Other Topics

The notion of completeness is introduced in many other classes of problems solvable in linear space, polynomial space, exponential time, etc. Comparisons among these classes have been done, although many problems still remain open. The fundamental conjecture in this field is the nonequality $\mathbf{NP} \neq \mathbf{P}$, the proving of which seems to be extremely difficult. This conjecture can be relativized in ways such that it can be either true or false, so that it is not provable in some formal system.

Some tricks may be used for hard problems. For decision problems, some algorithms have been proposed for guessing the correct answer with high probability [11]. Some algorithms give nearly optimal solutions efficiently, instead of constructing optimal ones over too long a time [7].

A general theory of computational complexity would include investigations on relations among various complexity measures, the complexity hierarchy, and an axiomatic approach independent of any machine models [12].

72 (VII.9) Complex Manifolds

A. Definitions

A Hausdorff topological space X is called a **complex manifold** (or **complex analytic manifold**) of **complex dimension** n if there are given an open covering $\{U_i\}_{i \in I}$ and a family $\{\varphi_i\}_{i \in I}$ of homeomorphisms of U_i onto open sets in the n -dimensional complex affine space \mathbb{C}^n such that in case $U_i \cap U_j \neq \emptyset$, the mapping $\varphi_i \circ \varphi_j^{-1}: \varphi_j(U_i \cap U_j) \rightarrow \varphi_i(U_i \cap U_j)$ is biholomorphic (i.e., $\varphi_i \circ \varphi_j^{-1}$ and its inverse are both holomorphic functions when expressed in terms of coordinate functions in \mathbb{C}^n). We call X the **underlying topological space** of this complex manifold, and we say that an open covering $\{U_i\}_{i \in I}$ and a family $\{\varphi_i\}_{i \in I}$ define a **complex analytic structure** (or simply **complex structure**) on X .

A complex-valued function f defined on an open set U in X is called a **holomorphic function** on U if for any i the function $f \circ \varphi_i^{-1}$ on $\varphi_i(U \cap U_i)$ is holomorphic. When we express the mapping φ_i as $\varphi_i(p) = (z^1(p), \dots, z^n(p))$ on U_i in terms of the coordinates in \mathbb{C}^n , each z^a is a holomorphic function on U_i . We call (z^1, \dots, z^n) a **holomorphic local coordinate system** on U_i . Given two complex manifolds Y, X , a mapping $\varphi: Y \rightarrow X$ is said to be **holo-**

morphic if for any open set U in X and any holomorphic function f on U , $f \circ \varphi$ is holomorphic on $\varphi^{-1}(U) \subset Y$. When a mapping $\varphi: Y \rightarrow X$ is bijective and both φ and φ^{-1} are holomorphic, we say Y and X are **isomorphic** by φ as complex manifolds.

As in the case of \dagger differentiable manifolds of class C^∞ , we can define concepts such as **complex analytic submanifolds**, **holomorphic tangent vectors**, **holomorphic vector fields**, and **holomorphic differential forms of degree k** (or simply **holomorphic k -forms**). **Meromorphic functions** on complex manifolds can also be defined as in the theory of analytic functions of several complex variables (\rightarrow 23 Analytic Spaces D).

Let X be a complex manifold and p a point of X . Take a holomorphic local coordinate system (z^1, \dots, z^n) with center p (i.e., $z^\alpha(p) = 0$ for all α). A holomorphic function defined on a neighborhood of p can be expressed as a holomorphic function in (z^1, \dots, z^n) , hence as a power series in (z^1, \dots, z^n) absolutely convergent in a neighborhood of p . If we denote by $\mathcal{O} = \mathcal{O}_X$ the \dagger sheaf of germs of holomorphic functions on X , the \dagger stalk \mathcal{O}_p of \mathcal{O} at p is isomorphic to the \dagger local ring of convergent power series in n variables z^1, \dots, z^n . At a point p , $(\partial/\partial z^1)_p, \dots, (\partial/\partial z^n)_p$ form a basis of the holomorphic tangent vector space at p . A holomorphic k -form ω defined on a neighborhood of p can be expressed as $\omega = \sum_{i_1 < \dots < i_k} f_{i_1, \dots, i_k} dz^{i_1} \wedge \dots \wedge dz^{i_k}$, where f_{i_1, \dots, i_k} is a holomorphic function for each (i_1, \dots, i_k) .

B. Almost Complex Structures

Let X be a complex manifold, and let $\{U_i, \varphi_i\}_{i \in I}$ be its complex analytic structure, i.e., a covering of X by holomorphic local coordinate systems with $\varphi_i = (z_i^1, \dots, z_i^n)$. Express z_i^α in the form $z_i^\alpha = x_i^\alpha + \sqrt{-1} y_i^\alpha$, where x_i^α and y_i^α are the real and imaginary parts of z_i^α , respectively. Then x_i^α and y_i^α real-valued functions on the open set U_i of X , and the mapping $\psi_i: U \rightarrow \mathbf{R}^{2n}$ defined by $\psi_i(p) = (x_i^1(p), y_i^1(p), \dots, x_i^n(p), y_i^n(p))$ is a homeomorphism of U_i onto an open set of \mathbf{R}^{2n} . This $\{U_i, \psi_i\}_{i \in I}$ defines on X a \dagger differentiable structure of class C^∞ (in fact, a \dagger real analytic structure). Thus a complex manifold of complex dimension n admits canonically a C^∞ -structure of real dimension $2n$. For every point p of X there is a real coordinate system on a neighborhood of p , such as $(x^1, y^1, \dots, x^n, y^n)$, where (z^1, \dots, z^n) ($z^\alpha = x^\alpha + \sqrt{-1} y^\alpha$, $\alpha = 1, \dots, n$) forms a holomorphic coordinate system in X . The real tangent vector space at a point p of X has $\{(\partial/\partial x^1)_p, (\partial/\partial y^1)_p, \dots, (\partial/\partial x^n)_p, (\partial/\partial y^n)_p\}$ as its basis. Define a linear endomorphism J_p by $(\partial/\partial x^\alpha)_p$

$\rightarrow (\partial/\partial y^\alpha)_p$, $(\partial/\partial y^\alpha)_p \rightarrow -(\partial/\partial x^\alpha)_p$ ($\alpha = 1, \dots, n$); then $J_p^2 = -1$, and J_p does not depend on the choice of holomorphic coordinate system at p . Considering J_p as a tensor of type $(1, 1)$, we thus obtain a tensor field J of type $(1, 1)$ of class C^∞ on X , which is called the **tensor field of almost complex structure** induced by the complex structure of X .

More generally, when a real differentiable manifold X is provided with a tensor field J of type $(1, 1)$ of class C^∞ such that $J^2 = -1$ (considering J as a linear transformation of vector fields), we say that X admits an **almost complex structure** or that X is an **almost complex manifold**. In this case, for contravariant vector fields x and y on X , we define a tensor field S of type $(1, 2)$ by $S(x, y) = -[x, y] + [J(x), J(y)] - J([J(x), y]) - J([x, J(y)])$. S is called a **Nijenhuis tensor**. An almost complex structure J is induced by a complex analytic structure if and only if its Nijenhuis tensor S vanishes identically [49]. A differentiable manifold X of dimension $2n$ admits an almost complex structure if and only if the structure group $GL(2n, \mathbf{R})$ of the bundle of \dagger tangent $2n$ -frames of X can be \dagger reduced to $GL(n, \mathbf{C})$. Almost complex manifolds are \dagger orientable.

C. Types of Differential Forms

Let X be a complex manifold, and let (z^1, \dots, z^n) be a holomorphic local coordinate system in a neighborhood of a point p with $z^\alpha = x^\alpha + \sqrt{-1} y^\alpha$ ($\alpha = 1, \dots, n$). On the complexified real tangent vector space $T_p(X) \otimes \mathbf{C}$ at p , we define $\partial/\partial z^\alpha, \partial/\partial \bar{z}^\alpha$ by

$$(\partial/\partial z^\alpha)_p = (1/2) \{ (\partial/\partial x^\alpha)_p - \sqrt{-1} (\partial/\partial y^\alpha)_p \},$$

$$(\partial/\partial \bar{z}^\alpha)_p = (1/2) \{ (\partial/\partial x^\alpha)_p + \sqrt{-1} (\partial/\partial y^\alpha)_p \}.$$

It is easy to see that the operation $\partial/\partial z^\alpha$ on holomorphic functions coincides with that of the holomorphic tangent vector $\partial/\partial z^\alpha$ defined in Section A. A function f is holomorphic at p if and only if $(\partial/\partial \bar{z}^\alpha)f = 0$ ($\alpha = 1, 2, \dots, n$). $T_p(X) \otimes \mathbf{C}$ is the direct sum of the subspace spanned by $\{\partial/\partial z^1, \dots, \partial/\partial z^n\}$ and the subspace spanned by $\{\partial/\partial \bar{z}^1, \dots, \partial/\partial \bar{z}^n\}$. Moreover, this decomposition is independent of the choice of holomorphic coordinate system. Elements of the two subspaces are respectively called **tangent vectors of type $(1, 0)$** and **tangent vectors of type $(0, 1)$** . Similarly, the complexified space of real differentiable 1-forms can be decomposed into the direct sum of two subspaces spanned by $\{dz^1, \dots, dz^n\}$ and $\{d\bar{z}^1, \dots, d\bar{z}^n\}$, where $dz^\alpha = dx^\alpha + \sqrt{-1} dy^\alpha$ and $d\bar{z}^\alpha = dx^\alpha - \sqrt{-1} dy^\alpha$. We say that the elements of the former subspace are of type $(1, 0)$ and those of the latter are of type $(0, 1)$. Thus the space of differential forms of arbitrary degree can be written as

the direct sum of subspaces of type (r, s) . Here the subspace of **differential forms of type (r, s)** has as a basis $\{dz^{\alpha_1} \wedge \dots \wedge dz^{\alpha_r} \wedge d\bar{z}^{\beta_1} \wedge \dots \wedge d\bar{z}^{\beta_s} \mid (1 \leq \alpha_1 < \dots < \alpha_r \leq n, 1 \leq \beta_1 < \dots < \beta_s \leq n)\}$. This decomposition is independent of the choice of a local coordinate system, hence the concept of type can be defined globally on X .

D. $\bar{\partial}$ -Cohomology

In the rest of this article we consider only complex differential forms. For every differential form ω of type (r, s) on X , its \dagger exterior derivative $d\omega$ decomposes into a sum of differential forms of types $(r+1, s)$ and $(r, s+1)$, which we denote by $\partial\omega$ (or $d'\omega$) and $\bar{\partial}\omega$ (or $d''\omega$), respectively. We have $d = \partial + \bar{\partial}$, $(d')^2 = 0$, $(\bar{\partial})^2 = 0$, and $\partial\bar{\partial} + \bar{\partial}\partial = 0$. In terms of a local coordinate system, we write

$$\begin{aligned}\partial\omega &= \sum_{\gamma} \frac{\partial f}{\partial z^{\gamma}} dz^{\gamma} \wedge dz^{\alpha_1} \wedge \dots \\ &\quad \wedge dz^{\alpha_r} \wedge d\bar{z}^{\beta_1} \wedge \dots \wedge d\bar{z}^{\beta_s}, \\ \bar{\partial}\omega &= (-1)^r \sum_{\gamma} \frac{\partial f}{\partial \bar{z}^{\gamma}} dz^{\alpha_1} \wedge \dots \\ &\quad \wedge dz^{\alpha_r} \wedge d\bar{z}^{\gamma} \wedge d\bar{z}^{\beta_1} \wedge \dots \wedge d\bar{z}^{\beta_s},\end{aligned}$$

for $\omega = f dz^{\alpha_1} \wedge \dots \wedge dz^{\alpha_r} \wedge d\bar{z}^{\beta_1} \wedge \dots \wedge d\bar{z}^{\beta_s}$. A differential k -form ω is holomorphic if and only if ω is of type $(k, 0)$ and $\bar{\partial}\omega = 0$.

For the operator $\bar{\partial}$ **Dolbeault's lemma** holds: Let ω be a differential form on a neighborhood U of a point p . If $\bar{\partial}\omega = 0$, there is a neighborhood V of p contained in U and a differential form θ on V such that $\omega = \bar{\partial}\theta$ on V .

Let $A^{(r,s)}$ and Ω^p be the \dagger sheaf of germs of differential forms of type (r, s) and the sheaf of germs of holomorphic p -forms on X , respectively, and let $\Gamma(X, A^{(r,s)})$ be the set of \dagger sections of $A^{(r,s)}$ on X . $\Gamma(X, A^{(r,s)})$ is the set of differential forms of type (r, s) on X , and $\sum_i \Gamma(X, A^{(p,i)})$ forms a \dagger cochain complex with respect to $\bar{\partial}$. This complex is called the **$\bar{\partial}$ -complex** or the **Dolbeault complex**, and its \dagger cohomology groups are called the **$\bar{\partial}$ -cohomology groups** or the **Dolbeault cohomology groups**. The q th cohomology group is denoted by $H^{p,q}(X, \bar{\partial})$. It follows easily from Dolbeault's lemma that $0 \rightarrow \Omega^p \rightarrow A^{(p,0)} \xrightarrow{\bar{\partial}} A^{(p,1)} \rightarrow \dots$ is an \dagger exact sequence of sheaves. From this we get **Dolbeault's theorem**: $H^q(X, \Omega^p) \cong H^{p,q}(X, \bar{\partial})$,

where the left-hand side is the cohomology group with coefficient sheaf Ω^p .

More generally, for any \dagger complex analytic (holomorphic) vector bundle E on X , we can define the $\bar{\partial}$ cohomology groups of the differential forms on X with values in E , and they can be shown to be isomorphic to the coho-

mology groups with coefficient sheaves of germs of holomorphic forms with values in E (\rightarrow 194 Harmonic Integrals E).

E. Analytic Coherent Sheaves

The structure of a complex manifold X is determined by the \dagger sheaf \mathcal{O} of germs of holomorphic functions on X , and \mathcal{O} is a \dagger coherent sheaf (of rings) (**Oka's theorem**). Sheaves of \mathcal{O} -modules are called **analytic sheaves**, and coherent sheaves of \mathcal{O} -modules are called **coherent analytic sheaves**. Many properties of X can be expressed in terms of coherent analytic sheaves and their cohomology groups; some examples appear later in this article (also \rightarrow 366 Riemann-Roch Theorems B).

It is important to know whether an analytic sheaf on a complex manifold is coherent. To this question, not only does Oka's theorem apply but so does **Cartan's theorem**: The \dagger sheaf of ideals defined by an analytic subset of a complex manifold is coherent. (We say that a subset Y of X is an **analytic subset** if it is a closed subset and each point of Y has a neighborhood U such that $U \cap Y$ is the set of common zeros of a finite number of holomorphic functions on U .) Also relevant is **Grauert's theorem**: If $\pi: X \rightarrow Y$ is a \dagger proper holomorphic mapping of complex manifolds (i.e., the inverse image of any compact subset of Y for a holomorphic mapping π is also compact), then for any coherent analytic sheaf F on X its \dagger direct images $R^q \pi_*(F)$ ($q=0, 1, 2, \dots$) are also coherent [16]. (In fact, this theorem holds for analytic spaces; \rightarrow 23 Analytic Spaces.)

For an analytic coherent sheaf F on a \dagger Stein manifold X , we have the following **fundamental theorems of the Stein manifold**. **Theorem A**: $H^0(X, F)$ generates the stalk F_x (as an \mathcal{O}_x -module) at every point x of X . **Theorem B**: $H^q(X, F) = 0$ for all $q > 0$. Conversely, a Stein manifold X is characterized by the following property: For any coherent analytic sheaf F of ideals of \mathcal{O} , $H^1(X, F) = 0$. If a complex manifold X is compact and F is a coherent analytic sheaf on X , then $H^q(X, F)$ is a complex vector space of finite dimension. If X is an open submanifold of another complex manifold and its closure is compact, then $H^q(X, F)$ is finite-dimensional for some q that depends on various properties (convexity or concavity) of the boundary of X [3].

Let E be a \dagger complex analytic (holomorphic) vector bundle on a complex manifold X of dimension n , and let E^* be the \dagger dual vector bundle of E . Then $H^q(X, \mathcal{O}^p(E))$ and $H^{n-q}_*(X, \mathcal{O}^{n-p}(E^*))$ (where H_* denotes the cohomology group with compact support) are dual as topological vector spaces under suit-

able conditions. The duality is given by the integration on X of the exterior products of the differential forms representing the respective elements of the cohomology groups. The duality holds, for example, when $\dim H^q(X, \mathcal{O}^p(E)) < \infty$. If X is compact, we need not distinguish H_* from H (**Serre's duality theorem**) [50].

F. Compact Complex Manifolds

On a compact and connected complex manifold X , there are no holomorphic functions except constants (by the †maximum principle of holomorphic functions). The field $K(X)$ of meromorphic functions on X is finitely generated over the complex number field, and its †transcendence degree d does not exceed the complex dimension n of X . d is said to be the **algebraic dimension** of X and is denoted by $a(X)$. For elements of $K(X)$, functional independence and algebraic independence are equivalent [52]. When $n=1$, X is a compact †Riemann surface and the classical theory of algebraic functions shows that $K(X)$ is an †algebraic function field of one variable and X is a †projective algebraic variety. When $n=2$, $a(X)=2, 1$, and 0 can all occur. If $a(X)=2$, X is a projective †algebraic surface (**Chow-Kodaira theorem**). If $a(X)=1$, there exist an †algebraic curve Δ and a surjective holomorphic mapping $\varphi: X \rightarrow \Delta$ such that $K(\Delta)$ is isomorphic to $K(X)$ under φ^* , and $\varphi^{-1}(x)$ is an †elliptic curve for all but a finite number of $x \in \Delta$. K. Kodaira investigated the structure of compact complex surfaces in detail [34, III].

On a compact complex manifold X , the free Abelian group generated by the set of irreducible analytic subsets of codimension 1 is called the **divisor group** of X , and an element of it is called a **divisor** of X . For an analytic subset Y of codimension 1, the sheaf of ideals $\mathfrak{I}(Y)$ defined by Y is a sheaf of locally principal ideals of \mathcal{O} . For a divisor $D = \sum a_\alpha Y_\alpha$, the sheaf of locally principal fractional ideals $\mathfrak{I}(D) = \prod_\alpha \mathfrak{I}(Y_\alpha)^{a_\alpha}$ is called the **sheaf of ideals of D** . The set of nonzero coherent sheaves of locally principal fractional ideals corresponds bijectively to the set of divisors. An element $f \neq 0$ of $K(X)$ generates a sheaf of principal fractional ideals and therefore defines a divisor, which is denoted by (f) . The divisor group has an ordering defined by $D = \sum a_\alpha Y_\alpha > 0$ if and only if all $a_\alpha \geq 0$, under which it becomes an †ordered group. For a divisor D , let

$$L(D) = \{f \in K(X) | f \neq 0, (f) + D \geq 0\} \cup \{0\}.$$

Then $L(D)$ is a \mathbb{C} -module of finite dimension. This submodule of $K(X)$ is easy to handle and exhibits various analytic properties of D . The

†Riemann-Roch theorem is used to calculate the dimension of $L(D)$ in terms of other factors (\rightarrow 366 Riemann-Roch Theorems C). Here is an example of how $L(D)$ exhibits a property of D : We call two divisors D and D' **linearly equivalent** if there is a $0 \neq F \in K(X)$ such that $(F) = D - D'$. This is an equivalence relation finer than †homological equivalence. If D and D' are linearly equivalent, then $L(D)$ and $L(D')$ are isomorphic by the mapping $L(D) \ni f \rightarrow fF \in L(D')$; therefore $\dim L(D) = \dim L(D')$. (The latter equation does not follow from the homological equivalence.) A holomorphic vector bundle with fiber \mathbb{C} and structure group \mathbb{C}^* is called a **complex line bundle**. For the sheaf of ideals $\mathfrak{I}(D)$ of a divisor D , we can take a suitable open covering $\{U_j\}$ of X such that for each U_j there is an $R_j \in \Gamma(U_j, \mathfrak{I}(D))$ which generates $\mathfrak{I}(D)_x$ for any $x \in U_j$. Also $g_{jk} = R_j/R_k$ is a holomorphic function nowhere vanishing on $U_j \cap U_k$. With $\{g_{jk}\}$ as the system of †coordinate transformations, we define the **complex line bundle determined by D** and denote it by $[D]$. It is easy to see that $[D]$ is independent of the choice of $\{U_j\}$ or $\{R_j\}$. Moreover, $[D]$ is determined only by the linear equivalence class of D . If we denote by $\mathcal{O}([D])$ the sheaf of germs of holomorphic sections of $[D]$, the mapping $H^0(X, \mathcal{O}([D])) \ni \varphi = \{\varphi_j\} \rightarrow f = \varphi_j/R_j = \varphi_k/R_k \in L(D)$ is an isomorphism of these modules. On an algebraic variety in a projective space, any complex line bundle comes from a divisor (i.e., it can be expressed in the form $[D]$ for some divisor D) [35, 51], but this is not necessarily true on general compact complex manifolds. However, the importance of complex line bundles in the theory of complex manifolds lies in the relation $L(D) \cong H^0(X, \mathcal{O}([D]))$, which replaces “things with poles” with “things holomorphic.”

Any analytic subvariety X of the projective space \mathbb{P}^N is an algebraic variety (**Chow's theorem**) [51]. Suppose that X is an analytic submanifold of \mathbb{P}^N , and let Y be a general †hyperplane section of X . Then Y is a divisor on X , and the †Chern class of the complex line bundle $[Y]$ corresponds to the canonical Hodge metric on X (\rightarrow 232 Kähler Manifolds D). When $[Y]$ is represented by the system of coordinate transformations $\{g_{jk}\}$ with respect to an open covering $\{U_i\}$, we can associate with a coherent analytic sheaf F sheaves $F(n)$ ($n=0, \pm 1, \pm 2, \dots$) as follows. Denoting by F_j the restriction of F to U_j , we glue F_j and F_k together on $U_j \cap U_k$ with the relation $f_j \sim f_k \Leftrightarrow f_j = g_{kj}^{-n} f_k$ (where $f_j \in F_j \subset F$, $f_k \in F_k \subset F$) and obtain a sheaf (denoted by $F(n)$) that is locally isomorphic to F . The following theorems for $F(n)$ hold. For each coherent analytic sheaf F there exists an integer n_0 such that for any $n \geq n_0$ the following **fundamental theorems A, B of projec-**

tive algebraic varieties hold [17]. **Theorem A:** $\Gamma(X, F(n))$ generates F_x (as an \mathcal{O}_x -module) for every $x \in X$. **Theorem B:** $H^q(X, F(n)) = 0$ for all $q > 0$. This means that if we permit "poles" on Y of sufficiently high order, then F has sufficiently many sections and the higher cohomology groups vanish.

On a (nonsingular) algebraic variety X in \mathbf{P}^N we have the sheaf \mathcal{O} of germs of holomorphic functions (the \dagger structure sheaf as a complex manifold) and the sheaf \mathcal{O}_{alg} of germs of holomorphic rational functions (the structure sheaf as an algebraic variety). Therefore we have two kinds of coherent sheaves, coherent analytic sheaves and **coherent algebraic sheaves**. In fact, the cohomology theories derived from them are isomorphic. More precisely, for any coherent algebraic sheaf F , $\tilde{F} = F \otimes_{\mathcal{O}_{\text{alg}}} \mathcal{O}$ is a coherent analytic sheaf. The correspondence $F \rightarrow \tilde{F}$ gives an equivalence between the \dagger category of coherent algebraic sheaves and that of coherent analytic sheaves, thus giving an isomorphism of their cohomology groups. In other words, as far as the properties that can be expressed by cohomology-theoretic terms of coherent sheaves are concerned, there is no difference between the analytic and algebraic theories of projective algebraic varieties [51].

G. Deformations of Complex Structures

The deformation theory of complex structures was initiated by Kodaira and Spencer [36] in order to explain various phenomena in the theory of (compact) complex manifolds. A triple (X, π, S) is called a **family of compact complex manifolds** if X and S are connected \dagger analytic spaces and π is a \dagger proper holomorphic mapping of X onto S such that (i) it is smooth, i.e., is locally identified with the projection $S' \times U \rightarrow S'$, where S' and U are open in S and \mathbf{C}^n , respectively, and (ii) every fiber $V_s = \pi^{-1}(s)$ of π is connected. V_s is then a compact complex manifold. We sometimes write $\{V_s\}_{s \in S}$ instead of (X, π, S) . S is called the **parameter space of the family**. Take a point $o \in S$ and fix it. We say that V_s is a **deformation** of V_o for any $s \in S$. There are a neighborhood S' of o in S and a diffeomorphism $\pi^{-1}(S') \rightarrow S' \times V_o$ (Kuranishi [39]). Thus every $V_s, s \in S'$, determines a \dagger complex structure on a fixed differentiable manifold. We say that the complex structure of $V_s, s \in S'$, is a **deformation** of that of V_o .

Now $(X, \pi, S) = \{V_s\}_{s \in S}$ is said to be **complete at o** if for any family $(Y, \mu, T) = \{W_t\}_{t \in T}$ with a point $o' \in T$ and a holomorphic isomorphism $\iota: W_{o'} \rightarrow V_o$, there is a neighborhood T' of o' in T and holomorphic mappings $f: T' \rightarrow S$ and $h: \mu^{-1}(T') \rightarrow X$ such that (i) $f\mu = \pi h$, (ii) $f(o') = o$,

and (iii) $h = \iota$ on $W_{o'}$. In this case, if T' is sufficiently small, then h induces a holomorphic isomorphism $h_t: W_t \rightarrow V_{f(t)}$, for any $t \in T'$. Hence $\{V_s\}_{s \in S}$ contains all small deformations of V_o . On the other hand, $\{V_s\}_{s \in S}$ is said to be **effectively parametrized at o** if the **Kodaira-Spencer mapping (Kodaira-Spencer map)** $\rho_o: T_o S \rightarrow H^1(V_o, \Theta)$ is injective, where $T_o S$ is the Zariski tangent space to S at o and Θ is the sheaf of germs of holomorphic vector fields on V_o . Here, the linear mapping ρ_o is defined by $\rho_o(\partial/\partial s) = \{(\partial g_{jk}/\partial s)_{(z_k, o)}\}$, where $\partial/\partial s \in T_o S$ and g_{jk} are the coordinate transformations $(z_j, s) = (g_{jk}(z_k, s), s)$, using the smoothness of π . $\rho_o(\partial/\partial s)$ is called the **infinitesimal deformation to the direction $\partial/\partial s$** .

Kuranishi's fundamental theorem [39, 40] states: For any compact complex manifold V , there exists a family $\{V_s\}_{s \in S}$ with a point $o \in S$ such that (i) it is complete at every point of S , (ii) it is effectively parametrized at o , and (iii) $V_o = V$.

The parameter space S in the theorem is called the **Kuranishi space** or the **local moduli space of V** . It is given as the zeros of a holomorphic mapping $f: U \rightarrow H^2(V, \Theta)$ with $f(0) = 0$, where U is a neighborhood of 0 in $H^1(V, \Theta)$. Hence (1) if $H^2(V, \Theta) = 0$, then $S = U$ is nonsingular (Kodaira, Nirenberg, and Spencer [37]; (2) if $H^1(V, \Theta) = 0$, then $S = \{0\}$, i.e., one point (e.g., $V = \mathbf{P}^n(\mathbf{C})$, the complex projective space).

Kuranishi's theorem was generalized to a compact analytic space V by Grauert [18] and A. Douady [8].

There are Kuranishi-type theorems in the deformation theory of other objects: (1) compact analytic subvarieties of an analytic space (Douady [9]; → 23 Analytic Spaces G), (2) holomorphic mappings (Y. Miyajima [41]), (3) germs of analytic spaces with isolated singularities [7], etc.

So far, only the local theory of deformations has been developed. The global theory is not yet in a satisfactory state. Its final purpose is to construct moduli spaces and to understand them. For a compact differentiable manifold V , we denote by $M(V)$ the set of all isomorphism classes of complex structures on V . It is difficult in general to determine the set $M(V)$. As yet unsolved problems are: (1) Is $M(S^6)$ nonempty? (2) Does $M(\mathbf{P}^n(\mathbf{C}))$ ($n \geq 3$) consist of one point? ($M(\mathbf{P}^2(\mathbf{C}))$ is known to consist of one point (S. T. Yau; → 232 Kahler Manifolds C).

If $M(V)$ has a reasonable structure (e.g., an analytic space structure) and a universal property, then we call it the **moduli space** (→ 11 Algebraic Functions F, 16 Algebraic Varieties W). Kodaira [34, III] constructed the moduli space of Hopf surfaces. Only a few examples of moduli spaces are known. It is to be noted that moduli spaces cannot in general exist.

One of the reasons for this is that there may exist **jumpings of structures** (Kodaira and Spencer [36]).

As for algebraic manifolds (varieties), there are two known methods for the moduli problem: (1) Griffiths' period mapping (\rightarrow 16 Algebraic Varieties V) and (2) Mumford's geometric invariant theory (\rightarrow 16 Algebraic Varieties V, W).

H. Monoidal Transformations

Let Y be an analytic subspace of a complex manifold X , which is defined by a nonzero coherent sheaf of ideals \mathfrak{I} . Then X has an open covering such that for each member U of the covering, there are elements $\varphi_1, \dots, \varphi_m \in \Gamma(U, \mathfrak{I})$ that generate the stalks \mathfrak{I}_x at all $x \in U$. Let W' be the graph of the holomorphic mapping $x \mapsto (\varphi_1(x) : \varphi_2(x) : \dots : \varphi_m(x))$ from $U - U \cap Y$ to \mathbf{P}^{m-1} , and denote by W the closure of W' in $U \times \mathbf{P}^{m-1}$. Then W is an analytic space, possibly with singularities, which is independent of the choice of the generators $\{\varphi_i\}$ and is determined uniquely by U and \mathfrak{I} . Therefore all the W 's can be glued together to form an analytic space \tilde{X} and to determine a holomorphic mapping $p: \tilde{X} \rightarrow X$. We call p the **monoidal transformation** (or **blowing-up**) of X with center \mathfrak{I} or with center Y . When Y is a point, p is also called a **locally quadratic transformation** or a **σ -process**. When Y is an analytic submanifold, \tilde{X} also is a manifold, $\tilde{Y} = p^{-1}(Y)$ is a nonsingular divisor on \tilde{X} , and $p^{-1}(y) \cong \mathbf{P}^{k-1}$ for all $y \in Y$, where k is the codimension of Y . Moreover, the line bundle $[\tilde{Y}]$ restricted to each fiber $p^{-1}(y)$ is isomorphic to the Hopf bundle L on \mathbf{P}^{k-1} , i.e., the line bundle associated to the natural \mathbf{C}^* bundle $\mathbf{C}^k \rightarrow \mathbf{P}^{k-1}$. Conversely, suppose that we are given $\tilde{Y} \subseteq \tilde{X}$ and a holomorphic mapping $p_0: \tilde{Y} \rightarrow Y$ with the property as above so that, in particular, $p_0^{-1}(y) \cong \mathbf{P}^{k-1}$ and $[\tilde{Y}] \cong L$ on $p_0^{-1}(y)$ for all $y \in Y$. Then there exists a complex manifold containing Y as a submanifold such that \tilde{X} is obtained by the monoidal transformation of X with center Y as above (S. Nakano [47]). Let $f: X \rightarrow Y$ be a proper modification of complex manifolds (or analytic spaces). Then there exists a proper holomorphic mapping $h: Y' \rightarrow Y$ such that $f^{-1} \circ h: Y' \rightarrow X$ is holomorphic, where over any relatively compact subdomain of Y , h is obtained by a finite succession of monoidal transformations with nonsingular centers (Hironaka). The result is called **Chow's lemma**.

I. Fiber Spaces

A triple of compact complex manifolds V , W , and a surjective holomorphic mapping $f:$

$V \rightarrow W$ is called a **fiber space** if general fibers $f^{-1}(w)$ are irreducible. In addition, if both V and W are algebraic, it is called an **algebraic fiber space**.

For a compact complex manifold V , letting K_V denote the canonical line bundle of V , define a subfield $\mathfrak{K}(V)$ to be $\{\omega_1/\omega_2, \text{ where } \omega_1, \omega_2 \in H^0(V, \Omega) \text{ for some } m > 0\}$. The transcendental degree of \mathfrak{K} over \mathbf{C} is denoted by $\kappa(V)$, which we call the **Kodaira dimension** of V .

If $\mathfrak{K} = 0$, then define $\kappa(V) = -\infty$. If $\kappa(V) = \dim V$, then V is said to be of **general type**, and there exist a projective manifold X and a bimeromorphic holomorphic mapping $\mu: X \rightarrow V$. If $\kappa(V) \geq 0$, there exists a fiber space $f: V^* \rightarrow W$ such that (1) V^* is bimeromorphically equivalent to V , (2) $\dim W = \kappa(V)$, and (3) some general fibers $f^{-1}(w)$ satisfy $\kappa(f^{-1}(w)) = 0$. In general, for a fiber space $f: V \rightarrow W$, we have $\kappa(V) \leq \kappa(f^{-1}(w)) + \dim W$, where $f^{-1}(w)$ is a general fiber. Moreover, if it is algebraic, an inequality of the form $\kappa(V) \geq \kappa(f^{-1}(w)) + \kappa(W)$ is called the **conjecture** C_n , n being $\dim V$. C_n has been verified by K. Ueno, E. Viehweg, T. Fujita, and Y. Kawamata [13, 14, 32, 33, 54–57] in the following cases: (1) $n \leq 3$, (2) when general fibers are curves, (3) $\dim w = 1$, $\kappa(w) = 1$, (4) $\kappa(V) \geq 0$, and W is of general types, etc. By using the results of case (4), Kawamata proves that an algebraic compact complex manifold V is birationally equivalent to an Abelian variety if and only if $\kappa(V) = 0$ and the irregularity of V equals the dimension of V [32].

J. Analytic Surfaces

In what follows, an analytic surface means a 2-dimensional compact complex manifold. For an analytic surface S , an exceptional curve on S and a (relatively) minimal model, etc., are defined with respect to bimeromorphic mappings in analogy with the corresponding concepts for an algebraic surface (\rightarrow 15 Algebraic Surfaces). Let $C \subset S$ be an irreducible curve on S . Then there exists a holomorphic mapping φ from S onto another surface S' such that $\varphi(C)$ is a point and such that φ induces the isomorphism $S - C \xrightarrow{\sim} S' - \varphi(C)$ if and only if $C^2 = -1$ and C is a nonsingular rational curve (Grauert [17]). S has a minimal model if and only if S is not a ruled surface (Kodaira [34, III]). The irregularity $q = h^{0,1}$, the geometric genus p_g , i -genus P_i , etc., are also defined in the same way as in the case of algebraic surfaces. Note that, in general, $h^{0,1} \neq h^{1,0}$. The Riemann-Roch theorem and M. Noether's formula are valid also for an analytic surface (Atiyah and Singer; \rightarrow 366 Riemann-Roch Theorems C).

K. Classification of Surfaces

The classification of analytic surfaces by the aid of their numerical invariants was completed by Kodaira and includes as a special case Enriques's classification of algebraic surfaces [34, III]. By an **elliptic surface** we mean a surface from which there exists a surjective holomorphic mapping φ onto an algebraic curve Δ , such that for a general point p on Δ , $\varphi^{-1}(p)$ is an irreducible nonsingular elliptic curve. If $a(S)=1$ or $\kappa(S)=1$, S has a unique structure as an elliptic surface. The image by φ of the points on S at which φ is not of maximal rank is a finite subset $\{a_1, \dots, a_r\}$ of Δ . Let t_i be a local coordinate on Δ around a_i with $t_i(a_i)=0$. We call a singular fiber of φ the divisor on S defined by $\{t_i \circ \varphi = 0\}$. The structure and the construction of singular fibers of elliptic surfaces have been completely determined by Kodaira. By an elliptic surface of general type we mean a surface with Kodaira dimension 1. If $\kappa(S)=2$, S is projective algebraic and is called a **surface of general type**. If $a(S)=0$, then there exists only a finite number of irreducible curves on S . By a **Hopf surface** we mean a surface whose universal covering is $\mathbb{C}^2 - (0,0)$. If an analytic surface S is homeomorphic to $S^1 \times S^3$, S is a Hopf surface. Let $b_v(S)$ be the v th Betti number of S . If $a(S)=0$, $b_1(S)=1$, $b_2(S)=0$, and S contains a curve, then S is a Hopf surface (Kodaira). By a surface of class VII_0 we mean a minimal surface S with $b_1(S)=1$. M. Inoue [26] constructed three families of surfaces of class VII_0 with $b_2=0$ which contain no curves. These are $S_M^{(\pm)}$ ($M \in \text{SL}(3, \mathbb{Z})$) and $S_{N,p,q,r,t}^{(+)}$ and $S_{N,p,q,r,t}^{(-)}$ ($N \in \text{SL}(2, \mathbb{Z})$, $p, q, r \in \mathbb{Z}$, $t \in \mathbb{C}$) which have $H \times \mathbb{C}$ as their universal covering surfaces, H being the complex upper half-plane. These have a line bundle L such that $H^0(\Omega^1 \otimes \mathcal{O}(L))=0$. This property characterizes these Inoue surfaces among VII_0 surfaces with $b_2=0$ which contain no curves. A couple of new surfaces of class VII_0 with $b_2>0$ were constructed and studied by Inoue, Ma, Kato, T. Oda, I. Nakamura, and I. Enoki [10, 27–29, 46]. Some of these have close connections with cusp singularities of Hilbert modular surfaces, torus embeddings, and global spherical shells. Enoki's surface is denoted by $S_{n,\alpha,t}$ ($n>0$, $0<|\alpha|<1$, $t \in \mathbb{C}^n$) and has the following properties: (1) class VII_0 and $b_2=n$, (2) there exists a connected curve D with $D^2=0$, (3) $S_{n,\alpha,t} - D$ is an affine bundle over an elliptic curve. Properties (1) and (2) characterize $S_{n,\alpha,t}$ (Enoki).

Let K_S denote the canonical line bundle of an analytic surface S . An analytic surface S is said to be a **K3 surface**, if K_S is trivial, i.e., if there exists a nonvanishing holomorphic 2-

form ω and if $q=0$. K3 surfaces are simply connected and are deformations of a nonsingular quartic surface in \mathbb{P}^3 (Kodaira). We shall define the period mapping of K3 surfaces. Let L be a free Abelian group of rank 22 with the pairing $\langle \rangle$ which is the direct sum of the two copies of $-E_8$ and three copies of $U = \mathbb{Z}e_1 + \mathbb{Z}e_2$ with $\langle e_1, e_1 \rangle = \langle e_2, e_2 \rangle = 0$, $\langle e_1, e_2 \rangle = \langle e_2, e_1 \rangle = 1$, where $-E_8$ denotes the lattice with the pairing corresponding to the Dynkin diagram E_8 with the opposite signs. $H^2(S, \mathbb{Z})$ with the intersection form is such a pair, consisting of S and $\langle \rangle$. A **marked K3 surface** is defined to be a pair (S, ψ) , where S is a K3 surface and $\psi: H^2(S, \mathbb{Z}) \rightarrow L$ is an isomorphism preserving $\langle \rangle$. The class $[\omega]$ of ω is a base of $H^{2,0}$ and satisfies $\langle [\omega], [\omega] \rangle = 0$ and $\langle [\omega], [\bar{\omega}] \rangle > 0$. Let $\mathbf{P}(L_{\mathbb{C}})$ denote the 21-dimensional projective space associated with $L_{\mathbb{C}} = L \otimes_{\mathbb{Z}} \mathbb{C}$. $\mathcal{D} = \{(a) \in \mathbf{P}(L_{\mathbb{C}}) | \langle a, a \rangle = 0, \langle a, \bar{a} \rangle > 0\}$ is an open set of the quadric $\mathcal{Q}_{\mathbb{C}} = \{(a) \in \mathbf{P}(L_{\mathbb{C}}) | \langle a, a \rangle = 0\}$. \mathcal{D} is the set of all Hodge structures on $L_{\mathbb{C}}$. The **period** of a marked K3 surface (S, ψ) is defined to be $(\psi_{\mathbb{C}}[\omega])$. Every point of \mathcal{D} is the period of some marked Kähler K3 surface. If the periods of two marked Kähler K3 surfaces (S, ψ) and (S', ψ') , coincide then S is isomorphic to S' .

An analytic surface with $p_g = q = 0$ and $K_S^{\otimes 2} \cong 0$ is called an **Enriques surface**, which has a K3 surface as its universal covering. An Enriques surface is an algebraic elliptic surface. An analytic surface with $q=1$ and $K_S^{\otimes 12} \cong 0$ is said to be a **hyperelliptic surface**, which has an Abelian surface as an unramified covering. It is an algebraic surface and is an elliptic bundle over an elliptic curve. The classification of minimal surfaces is given in Table 1. The following relations hold among these invariants: Let b^+ (b^-) be the number of positive (negative) eigenvalues (counted with multiplicities) of the intersection matrix on $H^2(S, \mathbb{R})$ and c_i be the i th Chern class of S . Then

(1) $b^+ - b^- = \frac{1}{3}(c_1^2 - 2c_2)$ (**Hirzebruch signature theorem**);

(2) if b_1 is even, $q = h^{1,0} = \frac{1}{2}b_1$ and $b^+ = 2p_g + 1$;

(3) if b_1 is odd, $q = h^{1,0} + 1 = \frac{1}{2}(b_1 + 1)$ and $b^+ = 2p_g$.

Let c_1^2 and c_2 denote the Chern numbers of an analytic surface S , i.e., $c_1^2 = (K_S^2)$ and c_2 is the Euler number of S . Then $3c_2 \geq c_1^2$ [43], and if equality holds, then K_S is ample (Y. Miyaoka) (\rightarrow 232 Kähler Manifolds C). If S is a surface of general type which is minimal, then $c_1^2 > 0$, the bigenus $P_2 \geq 2$ and the m -genus P_m is $m(m-1)c_1^2/2 + 1 - q + p_g$ for $m \geq 2$. For each $m \geq 5$, the m th canonical mapping of S is a birational holomorphic mapping onto its image (Kodaira, E. Bombieri [5]). In general, $c_1^2 \geq 2p_g - 4$, and if the canonical mapping, i.e., the

rational mapping associated with K_S , is birational, then $c_1^2 \geq 3p_g - 7$. For certain kinds of surfaces of general type, E. Horikawa succeeded in determining completely the structure of surfaces obtained as deformations of a given surface. Among others, every minimal surface with $p_g = 4$, $q = 0$, and $c_1^2 = 5$ is a deformation of a nonsingular quintic surface [22, 23].

Table 1. Classification of Minimal Surfaces

κ	p_g	P_{12}	q	b_1	Structure
2		> 0			algebraic surface of general type
1					elliptic surface of general type
0	1	1	2	4	complex torus
	1	1	2	3	elliptic surface with a trivial canonical bundle
	0	1	1	2	hyperelliptic surface
	0	1	1	1	elliptic surface belonging to class VII_0
	1	1	0	0	K3 surface
	0	1	0	0	Enriques surface
$-\infty$	0	0	0	0	rational surface
			≥ 1	$2q$	ruled surface of genus q
			1	1	surface of class VII_0

For $a, b > 0$, let Σ_{ab} be the set of isomorphism classes of all minimal surfaces with $c_1^2 = a$ and $1 - q + p_g = b$. D. Gieseker [15] proved the existence of N and constructed the mapping $h: \Sigma_{ab} \rightarrow \mathbf{P}^N$ so that the following hold: (1) h is injective; (2) if $f: X \rightarrow Y$ is a smooth holomorphic mapping such that all $h^{-1}(y)$ represent some classes $\in \Sigma_{ab}$, then the set-theoretic mapping $f: Y \rightarrow \mathbf{P}^N$ induced from h is a morphism of schemes; (3) $h(\Sigma_{ab})$ is a locally closed subvariety of \mathbf{P}^N . Hence, $h(\Sigma_{ab})$ is a moduli variety of surfaces of general type with $c_1^2 = a$ and $1 - q + p_g = b$.

For each m with $1 \leq m \leq 9$, there exists a minimal surface of general type with $p_g = q = 0$ and $c_1^2 = m$.

If there exist a compact analytic surface S and a curve C on S such that $S - C$ is biholomorphic to a complex manifold M , then we say that S is a **compactification** of M with boundary C . Every compactification of \mathbf{C}^2 is a rational surface (Kodaira, J. Morrow [45]). Every compactification of $\mathbf{C} \times (\mathbf{C} - \{0\})$ is also rational (T. Ueda [53]). However, all compac-

tifications of $(\mathbf{C} - \{0\})^2$ are rational surfaces, certain kinds of Hopf surfaces, or \mathbf{P}^1 -bundles over elliptic curves as constructed by Serre (Ueda).

73 (V.15) Complex Multiplication

A. Classical Theory

If the ratio ω_1/ω_2 of two periods ω_1, ω_2 of an \dagger elliptic function f belongs to an imaginary \dagger quadratic field K , then there exists an algebraic relation between $f(z)$ and $f(\lambda z)$ for any λ in K , and such an f is said to have **complex multiplication**. This phenomenon for the \dagger sn function with modulus $\sqrt{-1}$ was discovered by C. F. Gauss and was applied to the problem of dividing a \dagger lemniscate into five arcs of equal length. More generally, N. H. Abel showed that the *special dividing equation* of an sn function with complex multiplication is algebraically solvable. From a number-theoretic point of view, L. Kronecker conjectured that every \dagger Abelian extension of an imaginary quadratic number field K is determined by a *transform equation* of an elliptic function with complex multiplication by a number of K (1880). This is an analog of the fact, announced by Kronecker and proved by H. Weber, that every Abelian extension of the rational number field is a subfield of a \dagger cyclotomic field. Kronecker's work was continued by Weber [2], and his conjecture was proved by T. Takagi (1903) for $K = \mathbf{Q}(\sqrt{-1})$, by T. Takenouchi (1916) for $K = \mathbf{Q}(e^{2\pi i/3})$, and by Takagi (1920) for the general case using \dagger class field theory. H. Hasse [5] and M. Sugawara simplified the theory of complex multiplication, and Hasse noticed a relationship between complex multiplication and \dagger congruence zeta functions. Working from Hasse's idea, M. Deuring constructed the theory of complex multiplication purely algebraically

and determined \dagger Hasse's zeta function of an elliptic curve with complex multiplication.

For the rest of this article, K always stands for an imaginary quadratic field. Let L be a \dagger lattice group on the complex plane \mathbf{C} generated by ω_1, ω_2 , and let z be a complex variable. Define functions \wp, g_2, g_3 as follows: $\wp(z, L) = \wp(z; \omega_1, \omega_2) = z^{-2} + \sum ((z - \omega)^{-2} - \omega^{-2})$, $g_2(L) = g_2(\omega_1, \omega_2) = 60 \sum \omega^{-4}$, $g_3(L) = g_3(\omega_1, \omega_2) = 140 \sum \omega^{-6}$, where the sum \sum is over the elements ω of L except 0. Let \wp' be the derivative of \wp ; then $z \rightarrow (1, \wp(z), \wp'(z))$ is a one-to-one correspondence between the points on the complex torus \mathbf{C}/L and those on the \dagger elliptic curve E ; $X_0 X_2^2 = 4X_1^3 - g_2 X_1^2 X_0 - g_3 X_0^3$ in the projective plane. If the quotient ω_1/ω_2 generates K , then the ring of analytic endomorphisms of \mathbf{C}/L (i.e., the ring of endomorphisms of E) is isomorphic to a subring of the \dagger principal order \mathfrak{o} of K . In particular, if the lattice group L is an \dagger ideal of K (for $K \subset \mathbf{C}$; \rightarrow 347 Quadratic Fields), then the ring of endomorphisms coincides with \mathfrak{o} . The function $J(\tau) = J(E) = J(L) = 2^6 3^3 g_2(L)^3 / \Delta(L)$ ($\Delta(L) = g_2(L)^3 - 27g_3(L)^2$) of $\tau = \omega_1/\omega_2$, $\text{Im } \tau > 0$, is a \dagger modular function of level 1, and $J(E)$ is called the **invariant** of the elliptic curve E . If E has a complex multiplication, then $J(E)$ is an algebraic integer. Then the three main theorems of the classical theory of complex multiplication can be stated.

Theorem 1. Let h be the \dagger class number of K , and let $\mathfrak{a}_1, \dots, \mathfrak{a}_h$ be a set of representatives of ideal classes of K . Then $J(\mathfrak{a}_1), \dots, J(\mathfrak{a}_h)$ are exactly the conjugates of $J(\mathfrak{a}_1)$ over K , and $K(J(\mathfrak{a}_1))$ is the maximal unramified Abelian extension (the \dagger absolute class field) of K (\rightarrow 59 Class Field Theory).

Next we define the function f by

$$\begin{aligned} f(z; L) &= g_2 g_3 \Delta^{-1} \cdot \wp(z; L), \\ K &\neq \mathbf{Q}(\sqrt{-1}), \quad \mathbf{Q}(e^{2\pi i/3}), \\ &= g_2^2 \Delta^{-1} \cdot \wp(z; L)^2, \quad K = \mathbf{Q}(\sqrt{-1}), \\ &= g_3 \Delta^{-1} \cdot \wp(z; L)^3, \quad K = \mathbf{Q}(e^{2\pi i/3}). \end{aligned}$$

Theorem 2. Let \mathfrak{o} be the \dagger principal order of K , \mathfrak{m} be an integral ideal of K , and \mathfrak{a} be an arbitrary ideal of K . Choose a number ξ of K such that $\mathfrak{m} = \{\lambda \in \mathfrak{o} \mid \lambda \xi \in \mathfrak{a}\}$. Then $K(J(\mathfrak{a}), f(\xi; \mathfrak{a}))$ is the \dagger class field for the \dagger ray modulo \mathfrak{m} .

The number ξ in this theorem is obtained by $\mathfrak{a}^{-1} \mathfrak{m}(\xi) = \mathfrak{b}$, where \mathfrak{b} is an integral ideal belonging to the ideal class of $\mathfrak{a}^{-1} \mathfrak{m}$. Thus $f(\xi; \mathfrak{a})$ is a "special value" of an elliptic function as well as of a modular function.

The \dagger general law of reciprocity, the \dagger principal ideal theorem, and the ramification in the class field in theorem 2 can also be described

in terms of elliptic functions or elliptic curves. In general, the ring of endomorphisms of an elliptic curve defined over a field k of characteristic 0 is either \mathbf{Z} or an order of an imaginary quadratic field. On the other hand, if the characteristic of k is not zero, then the ring of endomorphisms may be an order in a definite \dagger quaternion algebra.

B. Complex Multiplication of an Abelian Variety

Following Kronecker's idea, D. Hilbert posed in his lecture at Paris (1900) the so-called 12th problem: to find an analytic function whose special values generate Abelian extensions over a given algebraic number field (\rightarrow 196 Hilbert). E. Hecke constructed unramified Abelian extensions of an imaginary biquadratic field using \dagger Hilbert modular functions [10]. After this, there was no notable development concerning the problem until the theory of complex multiplication was generalized to the case of \dagger Abelian varieties, which was made possible by progress in algebraic geometry, in particular A. Weil's geometric theory of Abelian varieties (G. Shimura and Y. Taniyama [11]). The following results have been obtained: Consider a triple (A, \mathfrak{X}, t) , consisting of an Abelian variety A defined over \mathbf{C} , a \dagger polarization \mathfrak{X} of A , and a point t of A . Call two such triples (A, \mathfrak{X}, t) and (A', \mathfrak{X}', t') isomorphic if an isomorphism of A onto A' maps \mathfrak{X} onto \mathfrak{X}' and t onto t' . Then there exists one and only one subfield k_0 of \mathbf{C} with the following property: In order for (A, \mathfrak{X}, t) and $(A^\sigma, \mathfrak{X}^\sigma, t^\sigma)$ to be isomorphic for an automorphism σ of \mathbf{C} , it is necessary and sufficient that σ fix all elements of k_0 . We call k_0 the **field of moduli** of (A, \mathfrak{X}, t) . If A is an elliptic curve E and if $t=0$, then $k_0 = \mathbf{Q}(J(E))$. In the higher-dimensional case, the field of moduli is generated by special values of a \dagger Siegel modular function.

If F is a totally imaginary number field that is a quadratic extension of a totally real field F_0 of degree n , then there exists a set $\{\varphi_1, \dots, \varphi_n\}$ of n different isomorphisms of F into \mathbf{C} such that $\bar{\varphi}_i = \varphi_j$ never occurs for $i \neq j$, where the bar denotes complex conjugation. We call $(F; \{\varphi_\lambda\})$ a **CM-type**.

If \mathfrak{a} is an ideal of F , then $L = \{(\varphi_1(\alpha), \dots, \varphi_n(\alpha)) \in \mathbf{C}^n \mid \alpha \in \mathfrak{a}\}$ is a lattice group in the n -dimensional complex linear space \mathbf{C}^n , and \mathbf{C}^n/L is analytically isomorphic to an Abelian variety A of dimension n in a complex projective space. The \dagger endomorphism ring $\mathfrak{A}(A)$ of A contains a ring that is isomorphic to the principal order \mathfrak{o} of F . Conversely, every

Abelian variety of dimension n such that $\mathfrak{A}(A)$ contains a ring isomorphic to \mathfrak{o} can be constructed in this way.

Let M be a normal extension of \mathbf{Q} containing F . Denote the Galois group of M by G and the subgroup of G corresponding to F by H , and put $S = \bigcup_\lambda \varphi_\lambda H$, where φ_λ stands for a prolongation of the previous φ_λ to G . Then the following three conditions are equivalent: (i) $\mathfrak{A}(A) \cong \mathfrak{o}$; (ii) A is simple; (iii) $H = \{\gamma \in G \mid S\gamma = S\}$. If $H^* = \{\delta \in G \mid \delta S = S\}$, then we can choose $\psi_\mu \in G$ such that $S = \bigcup_\mu H^* \psi_\mu$. If F^* is the subfield of M corresponding to H^* , then $(F^*; \{\psi_\mu\})$ is also a CM-type, and $F^* = \mathbf{Q}(\sum_\lambda \varphi_\lambda(\alpha) \mid \alpha \in F)$. Moreover, for an ideal \mathfrak{r} of F^* , $\prod_\mu \psi_\mu(\mathfrak{r})$ is an ideal of F .

Now let H_m be the group of ideals \mathfrak{r} of F^* that are relatively prime to the norm $N(\mathfrak{m})$ of an integral ideal \mathfrak{m} of F^* and for which there exists a number ξ of F with

$$\prod_\mu \psi_\mu(\mathfrak{r}) = (\xi), \quad N(\mathfrak{r}) = |\xi|^2, \quad \xi \equiv 1 \pmod{\mathfrak{m}}.$$

Then H_m is an \dagger ideal group modulo \mathfrak{m} in F^* .

Theorem 3. Assume that $\mathfrak{A}(A) \cong \mathfrak{o}$, and let \mathfrak{X} be an arbitrary polarization of A . Denote a point of A with $\mathfrak{m} = \{\lambda \in \mathfrak{o} \mid \lambda t = 0\}$ by t , and let k_m be the field of moduli of (A, \mathfrak{X}, t) . Then $k_m F^*$ is the \dagger class field over F^* corresponding to H_m .

The point t in theorem 3 always exists. In particular, if $\mathfrak{m} = \mathfrak{o}$, then $t=0$. When A is an elliptic curve E , F is an imaginary quadratic field and we have $F^* = K$, and theorem 3 coincides essentially with the content of theorems 1 and 2. If $n > 1$, $F = F^*$ holds only in special cases.

The theory of complex multiplication of A is closely related to the \dagger Hasse zeta function of A (\rightarrow 450 Zeta Functions).

74 (II.11) Complex Numbers

A. Algebraic Properties of Complex Numbers

A **complex number** is an expression of the form $a + ib$ with arbitrary real numbers a and b and the **imaginary unit** i . Writing $\alpha = a + ib$, $\beta = c + id$, we define $\alpha = \beta$ if and only if $a = c$ and $b = d$. As regards algebraic operations with complex numbers, we define $\alpha + \beta = (a + c) + i(b + d)$, $\alpha - \beta = (a - c) + i(b - d)$, $\alpha\beta = (ac - bd) + i(ad + bc)$, and for $\beta \neq 0$, i.e., $c^2 + d^2 \neq 0$, $\alpha/\beta = (ac + bd)/(c^2 + d^2) + i(bc - ad)/(c^2 + d^2)$. Then the addition and multiplication thus defined obey commutative, associative, and distributive laws, and complex numbers form a \dagger commutative field with $0 = 0 + i0$ and $1 = 1 + i0$ as its zero element of addition and identity element of multiplication, respectively. The set of all complex numbers is usually denoted by \mathbf{C} .

By assigning to each real number a a complex number $a + i0$, algebraic operations on real numbers are carried into those of the corresponding complex numbers. That is to say, the field \mathbf{R} of all real numbers is mapped isomorphically into the field \mathbf{C} of all complex numbers. By identifying a with $a + i0$, we are taking \mathbf{R} as a subfield of \mathbf{C} . Also, $0 + i1$ will be denoted simply by i . From the previous definition of algebraic operations, it follows that $i^2 = -1$. Furthermore, since $\alpha = a + ib = (a + i0) + (b + i0)(0 + i1)$, $a + ib$ is not a mere symbolic expression but can also be regarded as the outcome of algebraic operations on a, b, i in \mathbf{C} . The **real** and **imaginary parts** of a complex number $\alpha = a + ib$ are, by definition, a and b , denoted by $\operatorname{Re} \alpha$ and $\operatorname{Im} \alpha$, respectively. A complex number that is not a real number is sometimes called an **imaginary number**; in particular, a complex number α with $\operatorname{Re} \alpha = 0$ is called a **purely imaginary number**. For each complex number $\alpha = a + ib$, we define its **conjugate complex number** as $a - ib$, and denote it by $\bar{\alpha}$. We then have $\overline{\alpha + \beta} = \bar{\alpha} + \bar{\beta}$ and $\overline{\alpha\beta} = \bar{\alpha}\bar{\beta}$. The mapping $\alpha \rightarrow \bar{\alpha}$ is an \dagger automorphism of \mathbf{C} which leaves each element of \mathbf{R} invariant. Also, the following relations hold: $\operatorname{Re} \alpha = (\alpha + \bar{\alpha})/2$ and $\operatorname{Im} \alpha = (\alpha - \bar{\alpha})/(2i)$.

Regarded as an overfield of \mathbf{R} , \mathbf{C} is an \dagger extension field of \mathbf{R} of degree 2 obtained by the adjunction of i , which is a root of an irreducible equation $x^2 + 1 = 0$. The important algebraic property of \mathbf{C} is that it is \dagger algebraically closed. Namely, for any polynomial $f(x)$ with coefficients in \mathbf{C} , the equation $f(x) = 0$ possesses at least one root in \mathbf{C} (\dagger Gauss's fundamental theorem of algebra).

B. Topology of \mathbf{C}

The **absolute value** (or **modulus**) of a complex number $\alpha = a + ib$, denoted by $|\alpha|$, is by definition $|\alpha| = \sqrt{a^2 + b^2} = \sqrt{\alpha\bar{\alpha}}$. If α is real, then the absolute value of α in the sense of complex numbers is identical to the one in the sense of real numbers. It always holds that $|\alpha| \geq 0$ and $|\alpha| = 0 \Leftrightarrow \alpha = 0$. It follows further that $|\alpha + \beta| \leq |\alpha| + |\beta|$, $|\alpha\beta| = |\alpha||\beta|$, and $|\alpha| = |\bar{\alpha}|$.

For each pair of complex numbers α and β , define $\rho(\alpha, \beta) = |\alpha - \beta|$. Then with $\rho(\alpha, \beta)$ as the \dagger distance function, \mathbf{C} satisfies the axioms for a \dagger metric space, and in particular, $\lim_{n \rightarrow \infty} \alpha_n = \alpha_0 \Leftrightarrow \lim \rho(\alpha_n, \alpha_0) = 0 \Leftrightarrow \lim |\alpha_n - \alpha_0| = 0 \Leftrightarrow (\lim \alpha_n = a_0 \text{ and } \lim \beta_n = b_0) \text{ (where } \alpha_n = a_n + ib_n, a_0 = a_0 + ib_0)$. From this it is easily seen, as in the case of the set \mathbf{R} of all real numbers, that \mathbf{C} also becomes a \dagger locally compact and \dagger complete metric space.

With respect to this topology, the four oper-

ations (except for division by zero) are continuous: $\alpha_n \rightarrow \alpha_0$ and $\beta_n \rightarrow \beta_0$ imply $\alpha_n + \beta_n \rightarrow \alpha_0 + \beta_0$; $\alpha_n - \beta_n \rightarrow \alpha_0 - \beta_0$; $\alpha_n \beta_n \rightarrow \alpha_0 \beta_0$; and $\alpha_n / \beta_n \rightarrow \alpha_0 / \beta_0$ (where in the last case we assume $\beta_n \neq 0$ and $\beta_0 \neq 0$). Thus \mathbb{C} becomes a topological field. Furthermore, the assignment $\alpha \rightarrow \bar{\alpha}$ gives a continuous mapping $\mathbb{C} \rightarrow \mathbb{C}$, a homeomorphic automorphism of \mathbb{C} .

C. The Complex Plane

If in a plane to which is assigned rectangular coordinate axes a complex number $\alpha = a + ib$ is represented by a point (a, b) , then the plane is called the **complex (number) plane** (**Gauss-Argand plane** or **Gaussian plane**) (Fig. 1), and the point representing α is called simply the point α . The abscissa and ordinate axes are called the **real** and **imaginary axes**, respectively. A point $\alpha = a + ib$ can be represented by † polar coordinates r, θ with the origin and the real axis as the pole and the generating line, respectively, where $r = \sqrt{a^2 + b^2}$ is the absolute value $|\alpha|$ of α and θ is the **argument** (or **amplitude**), denoted by $\arg \alpha$, of α . The argument of α is uniquely determined mod 2π if $a \neq 0$ and is an arbitrary real number if $\alpha = 0$.

Fig. 1

The absolute value $|\alpha|$ of a complex number α , regarded as a vector from the origin to the point α , is the length of this vector. For complex numbers α and β , to the sum of the vectors α and β corresponds the sum $\alpha + \beta$ of the complex numbers. A complex number α , in terms of its absolute value r and argument θ , is expressed as $\alpha = r(\cos \theta + i \sin \theta)$, which is called the **polar form** of α . For polar forms the following hold: $\bar{\alpha} = r(\cos \theta - i \sin \theta) = r(\cos(-\theta) + i \sin(-\theta))$; $\alpha^{-1} = \bar{\alpha} / |\alpha|^2 = r^{-1}(\cos(-\theta) + i \sin(-\theta))$ ($\alpha \neq 0$); and $\alpha_1 \alpha_2 = r_1 r_2 (\cos(\theta_1 + \theta_2) + i \sin(\theta_1 + \theta_2))$, where $|\alpha_j| = r_j$ and $\arg \alpha_j = \theta_j$ for $j = 1, 2$. This last relation when $r_1 = r_2 = 1$ is called **De Moivre's formula**. The n th roots of unity in \mathbb{C} are given by $\rho_j = \cos 2\pi j/n + i \sin 2\pi j/n$ ($j = 0, 1, \dots, n-1$) (Fig. 2).

In the complex plane, the mapping $\alpha \rightarrow \bar{\alpha}$ corresponds to the † reflection of the plane in the real axis, $\alpha \rightarrow \alpha + \beta$ to the parallel † translation along a vector β , $\alpha \rightarrow \alpha\beta$ ($\beta \neq 0$) to the † rotation through the angle $\arg \beta$ followed by

a † homothetic transformation with center 0 and constant ratio $|\beta|$, and $\alpha \rightarrow \bar{\alpha}^{-1}$ to the † inversion with respect to the **unit circle** $\{\alpha \mid |\alpha| = 1\}$.

The distance $\rho(\alpha, \beta) = |\alpha - \beta|$ between α and β in \mathbb{C} coincides with their Euclidean distance, provided that α and β are regarded as points in the Euclidean plane, so that the complex plane is † isometric, and accordingly homeomorphic, to the Euclidean plane.

Fig. 2

D. The Complex Sphere

In the rest of this article, P denotes the complex plane and Σ denotes the sphere of radius 1, with 0, the origin of P , as its center. The points $N(0, 0, 1)$ and $S(0, 0, -1)$ of Σ will be called the **north** and **south pole**, respectively (Fig. 3), where the 1st and 2nd coordinate axes are the real and imaginary axes of P , respectively, and the 3rd coordinate axis is orthogonal to P . A straight line from N through a point z (a complex number) in P intersects Σ at a point $Z = (x_1, x_2, x_3)$ different from N , where $z = (x_1 + ix_2)/(1 - x_3)$, $x_1 = (z + \bar{z})/(1 + |z|^2)$, $x_2 = (z - \bar{z})/(i(1 + |z|^2))$, and $x_3 = (|z|^2 - 1)/(|z|^2 + 1)$. The mapping $z \rightarrow Z$ is called a **stereographic projection** from N , by means of which P and $\Sigma - \{N\}$ become † conformally equivalent to each other. Consequently z can be represented by a point Z of $\Sigma - \{N\}$, and Σ thus used is called a **complex sphere** (or **Riemann sphere**). Let us adjoin to the complex plane P a new element, denoted by ∞ , called the **point at infinity**, which corresponds to the only exceptional point N of Σ . The topology of the complex plane with ∞ can be introduced by the corresponding topology of the Riemann sphere. Indeed, the family of all the sets $\{z \mid |z| > M\} \cup \{\infty\}$ for $M > 0$ forms a † local base around ∞ . By introducing local complex coordinates $\zeta = 1/z$ into the neighborhoods of ∞ , each element of this local base is represented as $\{\zeta \mid |\zeta| < M^{-1}\}$, in which the

convention $\zeta = 0$ is adopted for $z = \infty$. The complex sphere thus defined can be regarded as a \dagger Riemann surface (i.e., a 1-dimensional \dagger complex manifold).

The complex plane (complex sphere) whose points are represented by a variable z or w is called a **z-plane** or a **w-plane** (a **z-sphere** or a **w-sphere**).

Fig. 3

E. Linear Fractional Functions

Given complex numbers a, b, c , and d with $ad - bc \neq 0$, we define a **linear fractional function** (or simply **linear function**) by

$$w = \frac{az + b}{cz + d}. \quad (1)$$

As a mapping from the z -sphere into the w -sphere, this linear function is called a **Möbius transformation** (**linear fractional** or simply **linear transformation**). The usual linear transformation, i.e., the one with $c = 0$ in the present case, is sometimes distinguished as an **entire linear transformation**. Since (1) depends only on the proportion $a:b:c:d$, we can assume $ad - bc = 1$ without loss of generality.

The transformation (1) is \dagger holomorphic and \dagger univalent on the whole z -sphere with only one exceptional \dagger pole at $-d/c$ (∞ if $c = 0$) of order 1, and the inverse of (1) is also a linear fractional function. The set of all linear transformations forms a \dagger group with composition of transformations as the group operation. One of its subgroups is the \dagger modular group.

Linear transformations carry any circle of the complex plane (or of the Riemann sphere) into a circle of the same plane (or of the same sphere) if we adopt the convention that straight lines are a special kind of circle. (In the case of a Riemann sphere, no such convention is necessary.) Given on a plane a circle with center o and radius r and two points p and p' on a half-line issuing from o satisfying $op \cdot op' = r^2$, the points p and p' are called **symmetric points** (or **reflection points**) with respect to the circle. The transformation $p \rightarrow p'$ is called the **inversion** with respect to this circle. In the complex plane, let z and z' be symmetric points with respect to a circle C . Suppose that by a linear transformation, z, z' and

C are carried to points w, w' and a circle D , respectively; then w and w' become symmetric with respect to the circle D (**principle of reflection**). Thus symmetricity is invariant under linear transformations. Also the \dagger anharmonic ratio of any four points z_1, z_2, z_3 , and z_4 , $(z_1, z_2; z_3, z_4) = (z_1 - z_3)/(z_1 - z_4) : (z_2 - z_3)/(z_2 - z_4)$, is invariant under a linear transformation; i.e., $(z_1, z_2; z_3, z_4) = (w_1, w_2; w_3, w_4)$ holds, where w_j is the image of z_j under a linear transformation ($j = 1, 2, 3, 4$).

F. Normal Forms of Linear Transformations

There exist fixed points of the transformation (1) on the Riemann sphere, i.e., points satisfying $z = (az + b)/(cz + d)$. The number of fixed points is 2 or 1, except when $w = z$. If the transformation has two fixed points, they will be denoted here by p and q . The natural convention $p = q$ is adopted if the transformation has one fixed point. If $c = 0$, then p or q is ∞ , and furthermore if $c = a - d = 0$, then p and q are both ∞ .

For unequal finite p and q , (1) can be rewritten in the following normal form:

$$\frac{w-p}{w-q} = \alpha \frac{z-p}{z-q}, \quad \alpha = \frac{a-cp}{a-cq} \neq 1,$$

in which, according as $\arg \alpha = 0$, $|\alpha| = 1$, or otherwise, (1) is called a **hyperbolic** (Fig. 4), **elliptic** (Fig. 5), or **loxodromic transformation**, respectively. This classification can be applied also for finite p and infinite q , i.e., to the transformation $w - p = \alpha(z - p)$. Furthermore, for $p = q \neq \infty$, (1) is rewritten in the following form:

$$\frac{1}{w-p} = \frac{1}{z-p} + \beta, \quad \beta = \frac{c}{a-cp}.$$

Fig. 4
Hyperbolic transformation.

Fig. 5
Elliptic transformation.

In this case (1) is called a **parabolic transformation** (Fig. 6). For $p = q = \infty$, i.e., if $w = z + \beta$, (1) is also called parabolic. We can easily determine to which class (1) belongs from the discriminant $D = (a + d)^2 - 4$ of the quadratic equation $cz^2 - (a - d)z - b = 0$ obtained from $z = (az + b)/(cz + d)$ with $ad - bc = 1$ by multiplying both sides by $cz + d$. If $a + d$ is real, then according as $D > 0$, < 0 , or $= 0$, (1) is hyperbolic, elliptic, or parabolic, respectively, and if $a + d$ is not real, then the transformation is loxodromic.

Fig. 6
Parabolic transformation.

Let D and D' be two arbitrary circular disks. Then there always exists a linear transformation which gives a one-to-one conformal mapping from D onto D' . Conversely, any mapping with this property is given only by linear transformations (provided that the half-plane having a straight line together with the point at infinity as its boundary is regarded as a closed disk), which are uniquely determined by giving three points a, b, c from the boundary of D and as their corresponding points, three arbitrary points a', b', c' from the boundary of D' .

G. The Poincaré Metric

Since conformal mappings from the domain $|z| < 1$ onto $|w| < 1$ are given by the transformations $w = \varepsilon(z - z_0)/(1 - \bar{z}_0 z)$ ($|\varepsilon| = 1$, $|z_0| < 1$) (\rightarrow Appendix A, Table 13), for corresponding z and w it holds that

$$\frac{|dw|}{1 - |w|^2} = \frac{|dz|}{1 - |z|^2}. \quad (2)$$

$|dz|/(1 - |z|^2)$ is called **Poincaré's differential invariant**. With a metric having $ds = |dz|/(1 - |z|^2)$ as its line element, the unit disk $|z| < 1$ becomes a non-Euclidean space in the sense of Lobachevskii, and the metric is called the **Poincaré metric**. Furthermore, since the transformations (2) leave the length of curves invariant, they can be regarded as motions in this space, where the geodesic through two points z_1 and z_2 is the circular arc orthogonal to the unit circle. If we denote the intersections of the arc with the unit circle by z_3 and z_4 , then the non-Euclidean distance between two points

z_1 and z_2 along the geodesic is given by $(1/2)\log(z_1, z_2; z_3, z_4)$, provided that the points z_4, z_1, z_2, z_3 are arranged on the arc in this order (\rightarrow 285 Non-Euclidean Geometry).

75 (XVI.2) Computers

A. History

Since the beginning of civilization, people have utilized tools for aiding computation. In Japan, bamboo computing rods were used in the 7th century; before the close of the 16th century, the **abacus** was imported from China (\rightarrow 230 Japanese Mathematics (Wasan)). The first **calculator** capable of performing the four arithmetic operations automatically was designed by W. Schickard of Tübingen University (1623). After that, B. Pascal independently made his famous adding machine; this was improved by G. W. Leibniz so that it was able to execute multiplications and divisions.

Most calculators manufactured today are electronic; however, many of these machines are not "programmable" and hence require at every step of computation a manual operation for specifying the machine operations to be executed. On the other hand, modern automatic computers can execute automatically a sequence of operations according to a given program without any manual intervention.

The automatic computer was conceived by the English mathematician C. Babbage in the 19th century, but mechanical engineering at that time was not advanced enough to allow the construction of such a computer. His idea was first realized by the relay computers Z3 of K. Zuse (1941) and Mark I of Harvard University (1944). In 1947, the first **electronic computer**, ENIAC, appeared, in which vacuum

tubes were utilized instead of mechanical components. Since then, the capabilities of computers have increased rapidly and it can be said that we now live in the "computer age."

B. Principles of Modern Computers

Information processing in a computer is based on communication among its constituents by electric signals. In **digital computers**, information is encoded as a sequence of binary numbers 0, 1, whereas continuous values are allowed in **analog computers**. The minimum quantity of information in digital computers is therefore a binary digit, called a **bit**. Since continuous values fluctuate on account of electric noise in the circuits, digital computers have the advantage of maintaining high precision during computation.

The binary numbers 0, 1 are represented in practice by two distinct electric signals: two distinct voltages, two distinct phases of alternating current, the existence or nonexistence of a pulse, etc. A system of circuits is called **synchronous** when it contains a clock, a generator of periodic pulses, which synchronizes the transmission and transformation of information. In an **asynchronous** system, circuits execute each step of information processing independently and advance to the next step after verifying the termination of the preceding step.

In ENIAC, a program was inserted into the computer by carefully connecting many control lines on plugboards. Since this caused much trouble in inserting the different programs needed for different jobs, J. von Neumann proposed encoding programs in sequences of binary digits and storing these programs in the memory unit of the computer. His principle, the **stored program principle**, was realized by EDSAC (1949) and has since been widely used.

An automatic computer in general consists of the following five units: the arithmetic unit, memory, control, input, and output (Fig. 1). These units are interconnected by wires that exchange information in the course of computation.

Fig. 1
Construction of electronic computers.

The **arithmetic unit** consists mainly of several memory registers and operational circuits associated with them. Each register stores a binary number of n bits (usually $16 \leq n \leq 64$). An important building block of the operational circuit is the basic adder of 1-bit numbers. A parallel adder of n -bit numbers can be obtained by connecting n copies of the basic adder. Alternatively, a sequential adder can be composed of a single basic adder which is utilized repeatedly to sum up bit by bit two binary numbers from the lowest bit. Subtraction is usually carried out by adding the complement of the subtrahend. Multiplication is realized by shifting the multiplicand to the left and adding it to the intermediate sum; this addition may be omitted, depending on the relevant bit of the multiplier. In division, we shift the dividend to the left and if possible subtract the divisor from it. By recording at each step whether or not the subtraction is possible, we obtain the quotient.

The **memory unit** stores the instructions and given data as well as the necessary data obtained in the course of computation. It is divided into many registers, each of which contains a number and is referred to by means of a serial number called an **address**. At present, high-speed memory units are usually made up of magnetic cores or integrated circuits. As auxiliary large-scale memory, there are also magnetic drums, disks, and magnetic tapes, etc. Other elements under investigation are extreme-low-temperature elements, chemical elements, optical elements, etc.

The **control unit** repeats the following operations consecutively: (1) takes an instruction from the memory location indicated by the sequential control counter, (2) gets a data word from the memory according to the address part of the instruction, (3) decodes the function part of the instruction and sends control signals to appropriate circuits, and (4) increases the content of the sequential control counter by 1 and, after receiving *end* signals from the arithmetic unit, returns to step (1). For these purposes the control unit contains a counter, a decoder, an encoder to send control signals, and a register to store the instruction to be executed.

The arithmetic, control, and memory units form the **central processor** of the computer. In contrast to the central processor, the input and output units are called **peripheral devices**. An input device receives the necessary information (a program and data); a card reader reads punched cards, and a teletypewriter sends signals directly into the computer. An output device presents the results obtained by the computer. The results are usually printed by a teletypewriter or line printer. Magnetic tape

units can be considered as auxiliary input-output devices, since tape reels are removable. The tape units can accept prepared input data as well as record the results, the output.

These devices are operated according to given input-output instructions under the control of the central processor. However, since every input-output device contains mechanical components and is extremely slow in comparison with the central processor, a large-scale computer is often accompanied by satellite computers which undertake the control of input-output devices.

C. Instructions and Programming

In stored-program operation, a computer performs a sequence of calculations according to given instructions. There are various types of instructions, but those most frequently used are **single-address instructions**, each of which contains a single-address part designating an operand.

A **program** is a finite sequence of instructions arranged suitably for the required computation. **Programming**, or making a program, is therefore the task of decomposing the required computation into elementary steps each of which corresponds to an instruction.

Every instruction is represented in a computer by a number, a numeric code, which is determined in a definite way by the construction of the control unit. Before starting computation, instructions thus encoded are stored in the memory. In this sense, a program is a sequence of numbers. This sequence is called a **machine-language program**.

A program is usually divided into several blocks, called subprograms or **subroutines**. Some subroutines are made in advance, especially those for frequently required jobs such as evaluating elementary functions and manipulating input-output devices, etc. The system of these ready-made programs is called **software**, in contrast to the **hardware** (i.e., mechanico-electronic equipment) of the computer. Quite often basic routines are **microprogrammed**, i.e., written in a simple code and stored in a fast read-only memory (ROM). In this case the set of built-in programs is called **firmware**. The handiness of a computer depends mainly on close matching of the software and hardware.

Programs are usually written in certain forms called **external languages** which are easy to master. A problem-oriented language is an advanced external language in which ordinary arithmetic expressions are available with slight modifications. Programs written in these languages are translated into machine languages by program input routines. The translator for

a problem-oriented language is called the **compiler**.

A compiler accepts several macroinstructions. Moreover, it is equipped with the following facilities: (i) the ability to translate arithmetic expressions into machine language; (ii) the ability to generate linkages to various ready-made subroutines according to certain simple indications; (iii) the ability to automatically allocate programs, subroutines, and data in the memory; (iv) the ability to check automatically the syntactic correctness of programs. Thus it accepts an external form such as

```
if  $x \geq 0$  then printreal (SQRT( $x$ ))
```

```
    else printstring ('negative').
```

Another important translator is the **assembler**, which translates mnemonic codes of instructions (*add* for addition, etc.) into their numeric codes according to a given table. It allows us to utilize symbols for specifying addresses. It also converts decimal numbers into binary and generates certain segments of the program from rather simple indications. Compilers and assemblers are important constituents of software.

The large-scale high-speed computers that have recently appeared have made software systems inevitably more complex. There is now software, so-called monitors or **operating systems**, that supervises the uninterrupted processing of many programs. Some operating systems coordinate several assemblers and compilers so that several languages can be mixed in writing a program. Examples of other important software are mathematical (numerical) software and database management systems.

D. Mathematical Models of Computers

An operational circuit in the arithmetic unit is usually constructed from basic elements (logical gates), each of which performs a certain operation on the binary signals. Thus the construction of a circuit from basic elements is represented by a composition of a logical function defined over the set $\{0, 1\}$ from a given set of basic functions. Post [3] considered functional composition without feedback loops and established a general criterion for a given set of logical functions to be complete, i.e., to be capable of generating the whole set of logical functions. Strictly, however, a logical gate takes a definite time delay to perform its operation. Therefore Kudryavtsev [4] proposed as a model of a logical gate a pair (f, d) of a logical function f and a non-

negative integer d : f represents the operation of the gate and d represents its delay. He defined the feedback-free composition of such functions with delays and gave a completeness criterion for a set of logical functions with delays. His study has been extended in various directions by Loomis [5], Nozaki [6], and Rosenberg [7].

When a circuit contains memory elements or feedback loops, its function is suitably represented by an \dagger automaton. Hence the design and analysis of circuits with memory elements, state-minimization, and equivalence checking [8], decomposition into simpler components [9, 10], verification of completeness [11], etc., can be studied in terms of automata (\rightarrow 31 Automata). A computer itself can be considered to be a finite automaton, since it has a finite number of memory elements and its behavior is completely determined by the content of the memory (its internal state) and the inputs. However, since a modern computer has an enormous memory and contains replaceable parts, such as magnetic tapes, it is more adequately represented by an infinite model, such as a \dagger Turing machine.

Turing machines are capable of simulating many intellectual activities governed by formal rules. It is believed that any well-defined finite algorithm can be simulated by a Turing machine (Church's thesis.) Thus any computer can be simulated by a Turing machine, and hence it is unable to resolve those decision problems which are unsolvable for Turing machines. For instance, no program can decide in finite steps whether a given program written in a computer language, say FORTRAN or PASCAL, eventually stops or not. On the other hand, a modern computer can simulate a universal Turing machine provided that its memory can be extended unboundedly by supplying magnetic tapes. Hence any well-defined finite algorithm can be simulated by a computer unless the limitation of memory capacity hampers its accomplishment.

E. Mathematical Theory of Programming Languages

Along with the development of software, programming techniques have gradually accumulated. For instance, we now have an almost satisfactory method of translating arithmetic expressions into machine language. However, we still lack a general theory to cover effectively a wide array of programming problems. The design of an adequate metalanguage

is still an important problem, if the word "adequate" implies complete description of syntax and semantics of problem-oriented languages. An interesting problem is to define and suitably classify grammars with respect to their capabilities of forming languages. Such research is an important branch of **mathematical linguistics**. N. Chomsky [12] has investigated this problem, starting from research on natural languages, and has given formal definitions of the grammars (\rightarrow 31 Automata D).

\dagger Context-free grammars (type-2 languages) play an important role in the theory of software as well as in Chomsky's syntax, since they are powerful enough to describe the parenthesis structure and simple and easy to manipulate. Some variants of context-free grammar have been proposed for attaining high efficiency in the automatic appraisal of programs [13, 14] or for increasing the programs' generative power [15].

F. Branches of Information Science

Many fields related to computers now make up the **information sciences** or **informatiques**.

Important mathematical theories born or developed in the information sciences are:

(1) Design and analysis of hardware devices:

\dagger Boolean algebra [16], switching theory [17], and theory of \dagger automata [18, 19].

(2) Design and analysis of programming language; theory of formal languages [14, 21].

(3) Design and analysis of algorithms; \dagger numerical analysis, theory of \dagger complexity of computation, theory of \dagger data processing.

(4) Mathematical foundation of programming; logical verification of correctness and equivalence of programs [22], \dagger recursive function theory, \dagger decision problems.

Applications of the information sciences are found in diversified fields, such as statistics, operations research, mathematical psychology, econometrics, jurimetrics, and behaviorimetrics.

76 (VI.17) Conformal Geometry

A. Möbius Geometry

We represent an n -dimensional sphere S^n as the \dagger quadric hypersurface $S^n: x_1^2 + x_2^2 + \dots + x_n^2 - 2x_0x_\infty = 0$ in an $(n+1)$ -dimensional real \dagger projective space \mathbf{P}^{n+1} , where the (x_α) are

\dagger homogeneous coordinates in \mathbf{P}^{n+1} . We denote by $M(n)$ the group of all \dagger projective transformations of \mathbf{P}^{n+1} that leave S^n invariant. Then the transformation group $M(n)$ acts on S^n . The pair $(S^n, M(n))$ is called the **conformal geometry** or **Möbius geometry**. We call S^n an n -dimensional **conformal space**, a transformation belonging to $M(n)$ a **Möbius transformation**, and $M(n)$ the **Möbius transformation group**. Every point of the projective space \mathbf{P}^{n+1} corresponds to a **hypersphere** on S^n . For example, if a point A lies outside of S^n , then the intersection of S^n and the \dagger polar hyperplane of A with respect to S^n is an $(n-1)$ -dimensional sphere S^{n-1} , and the point A corresponds to this **real hypersphere** S^{n-1} . Similarly, if a point A lies on S^n , it corresponds to a **point hypersphere**, and if a point A lies inside of S^n , then A corresponds to an **imaginary hypersphere**. We sometimes identify the point A with the corresponding hypersphere. For any two points $A=(a_\alpha)$ and $B=(b_\alpha)$, we put $AB=a_1b_1+a_2b_2+\dots+a_nb_n-(a_0b_\infty+a_\infty b_0)$ and call it the **inner product** of the two hyperspheres A and B . The **angle** θ between two intersecting real hyperspheres A and B is defined by $\cos \theta = AB/(\sqrt{A^2} \cdot \sqrt{B^2})$. This angle is invariant under the Möbius transformation.

In the projective space \mathbf{P}^{n+1} , we take a \dagger frame $(A_0, A_1, \dots, A_n, A_\infty)$ that satisfies the conditions

$$A_0^2 = A_0A_j = A_iA_\infty = A_\infty^2 = 0, \quad A_0A_\infty = -1,$$

$$A_iA_j = g_{ij}, \quad i, j = 1, 2, \dots, n,$$

where (g_{ij}) is a positive definite matrix. We see that A_0 and A_∞ are points on S^n and each A_i is a real hypersphere passing through these two points. Every hypersphere X of S^n can be written as a linear combination of the A_i : $X = u_0A_0 + u_1A_1 + \dots + u_nA_n + u_\infty A_\infty$. That is, X is represented by \dagger projective coordinates (u_α) with respect to the above frame. We call these homogeneous coordinates (u_α) $(n+2)$ -**hyperspherical coordinates** of the hypersphere X . If we use these coordinates, the inner product of two hyperspheres $X=(u_\alpha)$ and $Y=(v_\alpha)$ is given by $XY = \sum_{i,j=1}^n g_{ij}u_iv_j - (u_0v_\infty + u_\infty v_0)$.

The Möbius transformation group $M(n)$ is a topological group with two \dagger connected components. If we denote by $M_0(n)$ the maximal connected subgroup of $M(n)$ and by H the subgroup of $M(n)$ that leaves invariant a real hypersphere of S^n , then the set E of all real hyperspheres of S^n can be identified with the \dagger homogeneous space $M_0(n)/H$. The group H also consists of two connected components. If we denote by H_0 the maximal connected subgroup of H , the homogeneous space $\tilde{E} = M_0(n)/H_0$ is a two-fold \dagger covering space of E .

For each real hypersphere $A \in E$, an element $\tilde{A} \in \tilde{E}$ over A is called an **oriented real hypersphere**. The Möbius transformation group contains as its subgroups ones that are isomorphic to the group of congruent transformations of a Euclidean space and ones that are isomorphic to the group of congruent transformations of a non-Euclidean space. That is, the subgroup of $M(n)$ that leaves a point hypersphere invariant is isomorphic to the group generated by congruent transformations and homotheties of the Euclidean space E^n . The subgroup of index 2 (the factor group by a cyclic subgroup of order 2) of the subgroup of $M(n)$ that leaves invariant a real (imaginary) hypersphere is isomorphic to the group of congruent transformation of n -dimensional hyperbolic (elliptic) non-Euclidean space.

In the n -dimensional Euclidean space E^n , consider a hypersphere of radius r with center O . For each point P of E^n , mark a point Q on the ray OP such that $\overline{OP} \cdot \overline{OQ} = r^2$. We call the point transformation that sends P to Q an **inversion** with respect to the hypersphere. A symmetry with respect to a hyperplane, considered as an extreme case of inversions, is also called an inversion. We adjoin a point at infinity to the space E^n to construct an n -dimensional sphere S^n . Each inversion can be extended to a transformation of S^n , which we also call an inversion. Then each Möbius transformation is generated by a finite number of inversions. By a Möbius transformation of S^n , each hypersphere is transformed to a hypersphere. Any angle between two curves that intersect at a point of E^n is invariant under Möbius transformations. Conversely, if $n \geq 3$, each local transformation of E^n that leaves invariant the angle of each pair of intersecting curves is a restriction of a Möbius transformation. However, for $n = 2$ this is not true in general; any transformation that leaves angles invariant is called a conformal mapping. Any Möbius transformation $z \rightarrow w$ on the complex sphere $S^2 = \mathbb{C} \cup \{\infty\}$ can be expressed by an equation of the form $w = (\alpha z + \beta) / (\gamma z + \delta)$ or $w = (\alpha \bar{z} + \beta) / (\gamma \bar{z} + \delta)$, where α, β, γ , and δ are complex numbers such that $\alpha\delta - \beta\gamma \neq 0$ and \bar{z} denotes the complex conjugate of z .

B. Laguerre Geometry

Let Γ be an oriented smooth curve in a Euclidean plane E^2 . The tangent line at a point p of Γ is supplied with an orientation that is induced by the orientation of the curve Γ in an obvious manner. The oriented line l thus obtained is called the **oriented tangent line** of Γ at p .

Let S be the set of oriented lines in E^2 and T be a given set of oriented smooth curves in E^2 . Consider a bijection γ of the direct product $S \times T$ to itself satisfying the following condition: If l is an oriented tangent line of a curve Γ belonging to T and γ sends (l, Γ) to (l', Γ') , then l' is an oriented tangent of the curve Γ' . The set of such bijections forms a group G . Suppose that we have $l \in S$ for which there exist two curves Γ_1 and Γ_2 in T such that l is a common tangent line of Γ_1 and Γ_2 at p_1 and p_2 , respectively. Further suppose that the element $\gamma \in G$ sends (l, Γ_i) to (l', Γ'_i) ($i = 1, 2$). Then the element γ of G is called an **equilong transformation** if the following conditions (i) and (ii) are satisfied: (i) l' is tangent to Γ'_i at points p'_i ($i = 1, 2$), (ii) the distance between p_1 and p_2 is equal to the distance between p'_1 and p'_2 . The set of equilong transformations forms a subgroup H of G . In particular, if T is the set of oriented circles (including point circles), the elements of H are called **Laguerre transformations**. In an obvious manner, we can divide the set of oriented circles into two classes, those with "positive" and those with "negative" orientations. With an oriented circle Γ we associate the pair $\varphi(\Gamma) = (P, r)$, where P is the origin of the circle and r is a real number whose absolute value is equal to the radius of the circle and whose signature coincides with that of the orientation of Γ . The mapping $\varphi: T \rightarrow E^2 \times E^1$ thus defined is called **Lie's minimal projection**. An example of a Laguerre transformation, called a **dilatation**, is given by a bijection γ of $S \times T$ to itself satisfying the following condition: Let $\gamma(l, \Gamma) = (l', \Gamma')$; then l' is parallel to l , the distance between l and l' is a given number, and $\varphi(\Gamma') = (P, r + c)$, where $\varphi(\Gamma) = (P, r)$ and c is a given constant. We note here that the action of a Laguerre transformation $\gamma: (l, \Gamma) \rightarrow (l', \Gamma')$ is determined by its action on S (γ acts on S by $\gamma(l) = l'$). Another example of a Laguerre transformation γ , called a **Laguerre inversion**, is determined by means of a given oriented circle O and a line p that is not tangent to O ; given an oriented line l , its image l' under the action of γ is determined as follows (here we describe the case where l is not parallel to p). There exists a uniquely determined oriented tangent line g of the circle O parallel to l . Now we have a uniquely determined oriented tangent line g' of O that passes through the point of intersection of the lines g and p such that $g' \neq g$. The image l' is the line parallel to g' and passing through the point of intersection of the lines l and p (Fig. 1). Each Laguerre transformation can be written as a product of a finite number of Laguerre inversions. We denote the group of Laguerre transformations by L . The pair (L, S) is, by defini-

tion, a model of **Laguerre geometry**. Notions such as Laguerre inversions, dilatations, and transformations can be generalized to cases of higher dimension by utilizing oriented hyperspheres and oriented hyperplanes.

Fig. 1

C. Sphere Geometry

Let S be the set of oriented circles (including point circles and oriented lines) in the Euclidean plane E^2 . Two oriented circles C_1 and C_2 are said to be in contact with each other if they have a point p and an oriented tangent line passing through p in common. (An oriented circle C and an oriented line l are in contact with each other if and only if l is an oriented tangent line of C .) In this case, we call the pair (C_1, C_2) a **contact pair**. A bijection γ of S to itself is called a **Lie transformation** if it sends any contact pair to another. (The Lie transformation is a special case of the **contact transformations**.) An inversion with respect to a circle determines in an obvious manner a Lie transformation, which is also called an **inversion**. We denote the group of Lie transformations by G . Any element γ of G can be written as the product of a finite number of inversions and Laguerre inversions, and G contains the group of Möbius transformations and the group of Laguerre transformations as subgroups. The pair (G, S) is called a model of **circle geometry**. The notion of circle geometry can be generalized to that of **hypersphere geometry** for the case of higher dimensions. Specifically, when we replace E^2 by E^3 and circles by spheres, we have **sphere geometry**.

Let V be a complex 3-dimensional space, and let M, N be the sets of oriented lines and oriented spheres in V , respectively. Then M, N have the structure of 4-dimensional complex manifolds that are homeomorphic to each other. The homeomorphism is given by the **Lie line-sphere transformation** that induces a bijection from the set of pairs of intersecting oriented lines onto the set of pairs of oriented spheres that are in contact with each other.

D. Group-Theoretic Considerations

Here we discuss the preceding three kinds of geometries from the group-theoretic point of view (\rightarrow 137 Erlangen Program). Let us consider the quadratic form Q defined by $Q(x) = -x_0^2 + x_1^2 + x_2^2 + x_3^2 - x_4^2$ in a real projective space P^4 , where $x = (x_0, x_1, x_2, x_3, x_4)$ are homogeneous coordinates. We denote by G the set of all projective transformations of P^4 that leave Q invariant. The group G consists of the set of matrices A of order 5 such that $\det A = 1$ and $Q(Ax) = Q(x)$ holds for all x in P^4 ; we denote by L^3 the set of all points x in P^4 that satisfy $Q(x) = 0$. Then G acts transitively on L^3 . Hence if we denote by H_a the set of all elements of G that fix a point a in L^3 , for example $a = (-1, 1, 0, 0, 0)$, we may assume that $L^3 = G/H_a$. The circle geometry that belongs to the group of Lie transformations of circles is exactly the geometry of the homogeneous space G/H_a . The group G_b of all transformations of G that leave the hyperplane $x_4 = 0$ invariant acts transitively on $L^3 \cap \{x_4 = 0\}$ (G_b is isomorphic to $M(2)$). The geometry of the homogeneous space $G_b/H_a \cap G_b$ is plane conformal geometry. Next, the group G_a of all transformations of G that leave invariant $x_0 + x_1 = 0$ coincides with H_a and acts transitively on $L^3 \cap \{x_0 + x_1 = 0\}$. The geometry of the homogeneous space $L^3 \cap \{x_0 + x_1 = 0\}$ (on which G_a acts transitively) is plane Laguerre geometry. In this sense, the circle geometry that belongs to the group of Lie transformations contains the other circle geometries as subgeometries.

We now describe how plane Laguerre geometry can be realized as the geometry of the space $L^3 \cap \{x_0 + x_1 = 0\}$. Let E^2 be a plane in a Euclidean space E^3 . We fix a Cartesian coordinate system (y_0, y_1, y_2) in E^3 so that E^2 is given by $y_0 = 0$. To each point y of E^3 we can associate an oriented circle in E^2 with center $(0, y_1, y_2)$, radius $|y_0|$, and positive (negative) orientation if y_0 is positive (negative). If y lies on E^2 , the corresponding circle is the point circle y itself. Now let us consider the group G'_a of all affine transformations of E^3 whose rotation parts leave the quadratic form $Q'(y) = -y_0^2 + y_1^2 + y_2^2$ invariant. (G'_a is an isometry with respect to the metric defined by Q' .) Each element of G'_a induces a transformation of the set of oriented circles in E^2 (including the oriented lines and point circles) onto itself. The mappings of E^3 into L^3 defined by $x_0 = (1 + Q'(y))/2$, $x_1 = (1 - Q'(y))/2$, $x_2 = y_1$, $x_3 = y_2$, $x_4 = y_0$ is a one-to-one correspondence of E^3 onto the subset of L^3 such that $x_0 + x_1 \neq 0$. This correspondence induces an isomorphism of G'_a onto G_a . In Laguerre geometry, there are

no essential distinctions between points and oriented circles on E^2 ; and the group G_a acts on a 3-dimensional space of oriented circles (including point circles).

77 (XI.14) Conformal Mappings

A. General Remarks

Let a function $w = f(z)$ that maps a \dagger domain D on the \dagger complex z -sphere homeomorphically onto a domain Δ on the complex w -sphere satisfy the following two conditions: (1) Every curve $C_z: z(t) (0 \leq t \leq 1)$ that starts at any point z_0 in D and possesses a tangent there has an image curve $C_w: w = w(t) = f(z(t)) (0 \leq t \leq 1)$ that also possesses a tangent at the image point $w_0 = f(z_0)$. (2) The angle between any two curves $C_z^{(1)}$ and $C_z^{(2)}$ possessing tangents at z_0 is equal to the angle between their image curves $C_w^{(1)}$ and $C_w^{(2)}$, where the direction of the angle is also taken into account. Then the mapping from D onto Δ is said to be **conformal**, and Δ is called **conformally equivalent** to D . It has been proved that $w = f(z)$ is necessarily a function \dagger analytic in D (D. Men'shov, 1931).

Consequently, the theory of conformal mapping is a branch of the theory of analytic functions. That a function $w = f(z)$ maps a domain D conformally onto a domain Δ means that it is a \dagger meromorphic function \dagger univalent in D and its range is Δ . Then $f'(z) \neq 0$ holds at every (finite) point in D , and the ratio of the lengths of the segments between two points $w_0 = w(0)$, $w(t)$ on C_w and between two points $z_0 = z(0)$, $z(t)$ on C_z tends to a fixed nonvanishing limit $|f'(z_0)|$ as $t \rightarrow 0$ independently of the choice of C_z . Hence if z_1 and z_2 lie on $C_z^{(1)}$ and $C_z^{(2)}$, respectively, and w_1 and w_2 are their image points lying on the image curves $C_w^{(1)}$ and $C_w^{(2)}$, respectively, then the two triangles $\Delta_{z_1 z_0 z_2}$ and $\Delta_{w_1 w_0 w_2}$ are nearly similar in the positive sense, provided that z_1 and z_2 are near enough to z_0 . This justifies the word "conformal," which means "of the same form" (\rightarrow Appendix A, Table 13).

B. Conformal Mapping onto the Unit Disk

A fundamental theorem in the theory of conformal mapping is **Riemann's mapping theo-**

rem, which states that any \dagger simply connected domain D with at least two boundary points can be mapped conformally onto the interior Δ of the unit circle. This theorem is equivalent to the assertion of the existence of \dagger Green's function of D and can be proved in various ways. B. Riemann (1851) gave a proof, based on an idea of C. F. Gauss, by assuming the existence of a solution for a variational problem minimizing the \dagger Dirichlet integral. The logical incompleteness implied by this assumption was later removed by D. Hilbert and others. The proof that is now regarded as simplest is due to L. Fejér and F. Riesz's method (T. Radó, 1922, 1923), which applies \dagger normal family theory. On the other hand, the **osculating process** due to P. Koebe (1912) is a purely constructive method of proving existence that is also applicable to the case of \dagger multiply connected domains. The mapping function $w = f(z)$ in Riemann's mapping theorem is uniquely determined under the normalization condition $f(z_0) = 0$, $\arg f'(z_0) = \theta_0$ at a point z_0 in D , where θ_0 is a given angle.

The other types of simply connected domains are the Riemann sphere less one point and the sphere itself. In both cases every conformal mapping of these domains is a linear transformation. A simply connected domain is called **hyperbolic**, **parabolic**, or **elliptic** if it is conformally equivalent to the unit disk, the complex plane, or the Riemann sphere, respectively.

Let $w = f(z)$ map a simply connected domain D on the z -sphere conformally onto a simply connected domain Δ on the w -sphere. If a sequence $\{z_v\}$ in D tends to a boundary point ζ of D , then the corresponding sequence $\{w_v\}$ ($w_v = f(z_v)$) has no \dagger accumulation point in Δ and does not necessarily tend to a boundary point of Δ .

If for any sequence $\{z_v\}$ tending to ζ , $\{f(z_v)\}$ tends to a unique point ω on the boundary of Δ , it is said that $f(z)$ possesses a **boundary value** ω at ζ . To investigate the behavior of $\{w_v\}$ on a hyperbolic domain D , we can assume, by using a suitable mapping if necessary, that D is bounded. Then the problem is reduced, in view of Riemann's mapping theorem, to the case where D is a bounded simply connected domain and Δ is the unit disk $|w| < 1$.

C. Correspondence between Boundaries

Concerning the correspondence between boundaries under the conformal mapping $w = f(z)$ of a bounded simply connected domain D onto the unit disk $|w| < 1$, we have the following three theorems:

(1) To any \dagger accessible boundary point z_C of D there corresponds a unique point on $|w|=1$, and to any distinct accessible boundary points z_{C_1} and z_{C_2} of D there correspond distinct points on the unit circumference. Furthermore, the set of all points on $|w|=1$ that correspond to accessible boundary points of D has \dagger angular measure equal to 2π .

(2) There is a one-to-one correspondence between \dagger boundary elements of D and points on $|w|=1$ (C. Carathéodory).

(3) Let $w=f(z)$ map the interior D of a \dagger Jordan curve C conformally onto the unit disk $\Delta: |w|<1$. Then it possesses a boundary value, say $f(\zeta)$, at every point ζ on C that satisfies $|f(\zeta)|=1$. Hence $f(z)$ is continuous on the closed domain $\bar{D}=D\cup C$ and maps \bar{D} bijectively onto the closed disk $\bar{\Delta}: |w|\leq 1$. Similarly, the inverse function $z=\varphi(w)$ has an analogous property and maps $\bar{\Delta}$ bijectively and continuously onto \bar{D} ; that is, a conformal mapping of the interior D of a Jordan curve onto the unit disk Δ can be extended into a homeomorphism of the closure \bar{D} to $\bar{\Delta}$ (Carathéodory).

In this case, if the Jordan curve C contains a \dagger regular analytic arc Γ , then the mapping function $w=f(z)$ can be prolonged analytically beyond Γ (except at the endpoints of Γ). Hence the mapping $w=f(z)$ is conformal at interior points of Γ .

Problems on the correspondence of angles at the boundary are closely related to \dagger angular derivatives. These problems have been attacked by Carathéodory, S. Warschawski, J. Wolff, and others.

D. Schwarz-Christoffel Transformation

The problem of determining the form of an analytic function that maps the interior of a circle or a half-plane conformally onto the interior of a polygon was first dealt with by H. A. Schwarz and E. B. Christoffel (1869) (\rightarrow Appendix A, Table 13).

Let P be a polygon in the complex w -plane with vertices b_μ ($\mu=1, \dots, m$) and interior angles $\alpha_\mu\pi$ at b_μ . Then a function $w=f(z)$ that maps a circular disk or a half-plane in the z -plane conformally onto the interior of P is given by

$$f(z) = C \int \prod_{\mu=1}^m (a_\mu - z)^{\alpha_\mu - 1} dz + C'.$$

Here $b_\mu = f(a_\mu)$, and C, C' are constants depending on the position and magnitude of the polygon P . If instead of a disk we consider a half-plane in the z -plane, and if one of the a_μ is the point at infinity, then, modifying this formula by deleting the factor of the integrand corresponding to $a_\mu = \infty$, we obtain a formula

for $w=f(z)$. This representation is called the **Schwarz-Christoffel transformation formula**. This formula was originally derived by Christoffel to solve a problem of 2-dimensional distribution of stationary temperature. It then found extensive application to several problems of conformal mapping concerning polygonal domains and to problems of determining force lines or stream lines and equipotential lines in 2-dimensional electrostatics or hydromechanics.

An analogous formula is also derived for a function that maps the interior of a circle or a half-plane conformally onto the exterior of a polygon. In connection with these formulas, a third-order differential equation that is satisfied by a function mapping the interior of a circle onto a domain bounded by a circular polygon is found useful in the theory of automorphic functions. Moreover, a representation analogous to the Schwarz-Christoffel transformation formula is obtained for a function that maps the interior of a circle onto a curvilinear polygonal domain bounded by arcs of logarithmic spirals with the origin as asymptotic point.

E. Conformal Mapping of Multiply Connected Domains

It is also important to consider problems concerning one-to-one conformal mapping of a multiply connected domain on the z -sphere onto a suitable multiply connected domain \mathfrak{D} on the w -sphere. The two domains D and \mathfrak{D} are then homeomorphic, but the converse is not true; i.e., there does not necessarily exist a one-to-one conformal mapping between D and \mathfrak{D} even when they are homeomorphic. Now let D and \mathfrak{D} be multiply connected domains on the z - and w -planes, respectively, both possessing at least three boundary points. The \dagger universal covering surfaces \hat{D} and $\hat{\mathfrak{D}}$ of D and \mathfrak{D} are hyperbolic and they can be mapped onto the unit disks. The groups of their \dagger covering transformations form the \dagger Fuchsian groups G and \mathfrak{G} . Then in order for D to be mapped one-to-one and conformally onto \mathfrak{D} , it is necessary and sufficient that the group \mathfrak{G} be transformed into the group G by a suitable linear transformation.

To a domain of finite \dagger connectivity having only continua for its boundary components, we can associate **conformal invariants** (namely, **moduli**) expressed by one real parameter in the doubly connected case and by $3n-6$ real parameters in the $n(>2)$ -connected case. A one-to-one conformal mapping is possible only within a class of domains having the same invariants (\rightarrow 416 Teichmüller Spaces).

While a circular disk is taken as a canonical domain in the simply connected case, an annulus is often taken as a canonical domain in the doubly connected case. In the latter case, the logarithm of the ratio (> 1) of the radii of two concentric boundary circles is usually called the **modulus**. There are various types of n (≥ 2)-connected canonical domains, for instance, the whole plane, a circular disk or annulus slit along concentric circular arcs or radial segments, a parallel slit plane, etc. The possibility of a one-to-one conformal mapping of a given domain onto a canonical domain of such a type was proved by Hilbert, Koebe, and others in a potential-theoretic way and by E. Rengel, R. de Possel, H. Grunsky, and others in a purely function-theoretic way. Such canonical domains are characterized by some extremal properties. For example, the horizontal parallel slit mapping function $p_0(z, z_0) = (z - z_0)^{-1} + a[p_0](z - z_0) + \dots$, $z_0 \in D$, has the extremal property that it is the unique function maximizing $\operatorname{Re} a[f]$ within the family of univalent functions $f(z) = (z - z_0)^{-1} + a[f](z - z_0) + \dots$ in D . For a general domain D , $p_0(z, z_0)$, called the extremal horizontal slit mapping, is defined as the limit function of the sequence of horizontal slit mappings $p_0^{(n)}(z, z_0)$ of D_n , $z_0 \in D_n$. Here $\{D_n\}_{n=1}^\infty$ is a canonical exhaustion of D . It has the same extremal property as in the case of finite connectivity. The boundary components of the image domain of D under $p_0(z, z_0)$ consist of a horizontal slit and a point. The parallel slit mapping $p_\theta(z, z_0)$ in the direction of θ is defined similarly to the one that maximizes $\operatorname{Re} e^{-2i\theta} a[f]$ [8].

For a domain of infinite connectivity, by accumulation of boundary components, a pointlike boundary component can be mapped onto a continuum. A boundary component γ of a domain D is called **weak** if its image $f(\gamma)$ is a point under every conformal mapping f on D . γ is called **strong** if $f(\gamma)$ always consists of more than one point. A boundary component γ that is neither weak nor strong is called **unstable** (L. Sario, *J. Analyse Math.*, 5 (1956)). Criteria of weakness, etc., by means of extremal length are given in [8]. Moreover, in terms of extremal length, a generalization of a boundary element is given by Oikawa and Suita [9]. On the other hand, the existence of one-to-one and conformal mapping of a domain bounded by a finite number of curves onto the whole plane with mutually disjoint circular disks removed was proved by Koebe and later derived by J. Douglas and R. Courant as a particular case of the existence of a solution of \dagger Plateau's problem [10]. M. Schiffer showed that the mapping function is a solution of an extremal problem involving

Fredholm eigenvalues [11]. L. Bieberbach and H. Grunsky showed the possibility of mapping an n -connected domain onto an n -sheeted disk. Concerning doubly connected domains, detailed investigations were made by O. Teichmüller, Y. Komatu, and others. For a domain D bounded by n analytic Jordan curves, as an extension of the Schwarz lemma, Ahlfors showed that there exists a unique extremal function $f_0(z)$ maximizing $\operatorname{Re} f'(z_0)$, $z_0 \in D$, within the family of analytic functions $f(z)$ satisfying $|f(z)| < 1$ in D and that $f_0(z)$ maps D onto the n -sheeted unit disk (1947). $f_0(z)$ is called the **Ahlfors function** at z_0 . For a general domain the uniqueness of the extremal function in nontrivial cases was established first by S. Havinson (1961) and later by L. Carleson (1967) and S. Fisher (1969).

Most \dagger kernel functions of a plane domain D have connections with conformal mappings. For example, the Bergman kernel $U(z, \zeta)$ of exact differentials is equal to $(2\pi)^{-1}(p'_0(z, \zeta) - p'_{\pi/2}(z, \zeta))$. The adjoint kernel $V(z, \zeta)$ is defined by $(2\pi)^{-1}(p'_0(z, \zeta) + p'_{\pi/2}(z, \zeta))$. M. Schiffer showed that the integral of $V(z, \zeta)$, $S(z, \zeta) = \int_\zeta^z V(z, \zeta) dz$, is univalent and maps D onto a domain bounded by n analytic convex curves if D is bounded by n Jordan curves [13]. For a general domain D , this is true in the sense that each boundary component of the image domain under $S(z, \zeta)$ is a convex set (K. Oikawa and N. Suita, *Kôdai Math. Sem. Rep.*, 16 (1964)). It is known that $S(z, \zeta)$ maximizes the area of the complementary set of the image domain under $f(z)$ within the family of univalent functions $f(z) = (\pi(z - \zeta))^{-1} + b_1(z - \zeta) + \dots$. The maximum value multiplied by 4π is called the **span** of the domain D ; it is equal to $a[p_0] - a[p_{\pi/2}]$. For the \dagger Szegő kernel function $k(z, \zeta)$ of a domain D bounded by n analytic curves, the adjoint kernel $l(z, \zeta)$ is defined, and the Ahlfors function $f_0(z)$ at ζ is expressed by $k(z, \zeta)/l(z, \zeta)$ (P. Garabedian, *Trans. Amer. Math. Soc.*, 67 (1949)).

F. Universal Constants

Among various universal constants appearing in the theory of conformal mapping, Bloch's constant is especially famous. A. Bloch (1924) showed that a covering surface over the w -plane obtained from a mapping $w = F(z) = z + \dots$ that is one-to-one, conformal, and holomorphic in $|z| < 1$ always contains a \dagger univalent (schlicht) disk whose radius B is a positive number independent of the function F (**Bloch's theorem**). The supremum \mathfrak{B} of such constants B is called **Bloch's constant**. The true value of \mathfrak{B} is yet unknown, but estimates have

been given by Ahlfors (*Trans. Amer. Math. Soc.*, 43 (1938)) and by Ahlfors and Grunsky (*Math. Z.*, 42 (1937)) in the form

$$\frac{\sqrt{3}}{4} \leq \mathfrak{B} \leq \sqrt{\pi} 2^{1/4} \frac{\Gamma(1/3)}{\Gamma(1/4)} \left(\frac{\Gamma(11/12)}{\Gamma(1/12)} \right)^{1/2} = 0.4719 \dots$$

M. Heins showed that the equality sign can be deleted from the left-hand side (*Nagoya Math. J.*, 21 (1962)) and C. Pommerenke gave a simpler proof for the same fact (*J. London Math. Soc.*, 2 (1970)). It is conjectured that the correct value of \mathfrak{B} is equal to the upper bound of Ahlfors and Grunsky. **Landau's constant** \mathfrak{L} corresponding to the case where the image disks are not necessarily univalent satisfies $0.5 \leq \mathfrak{L} < 0.55$. The lower and upper bounds are due to Ahlfors (cited above) and Landau (*Math. Z.*, 30 (1929)). Pommerenke showed $0.5 < \mathfrak{L}$ (1970, cited above). For the family of univalent functions these constants coincide, and the value is called the **schlicht Bloch constant**, denoted by \mathfrak{A} . Its lower and upper bounds are known to be 0.5705 (J. Jenkins, *J. Math. Mech.*, 10 (1961)) and 0.6565 (R. Robinson, *Bull. Amer. Math. Soc.*, 41 (1935)). (For distortion theorems and coefficient problems \rightarrow 438 Univalent and Multivalent Functions.)

78 (VI.9) Conic Sections

A. General Remarks

Suppose that we are given two straight lines l and m intersecting at V (but not orthogonally) in the 3-dimensional Euclidean space E^3 . By rotating the line m around l , we obtain a surface \mathfrak{F} . We call this surface \mathfrak{F} a **circular cone** with **vertex** V and **axis** l ; a straight line on the surface passing through V is called a **generating line** of \mathfrak{F} .

A section C of \mathfrak{F} by a plane π not passing through V ($C = \pi \cap \mathfrak{F}$) is called a **conic section** (or simply a **conic**). This C is a plane curve on the plane π . The point set $\mathfrak{F} - V$ consists of two †connected components \mathfrak{F}_1 and \mathfrak{F}_2 . Let π_i ($i = 1, 2, 3$) be planes not passing through V . If the conic section $C_1 = \pi_1 \cap \mathfrak{F}$ is †bounded, then C_1 is contained either in \mathfrak{F}_1 or in \mathfrak{F}_2 and is †connected. We call such a C_1 an **ellipse**. When $C_2 = \pi_2 \cap \mathfrak{F}$ is not bounded but is connected, then π_2 is parallel to one of the generating lines of \mathfrak{F} , and C_2 is contained either in \mathfrak{F}_1 or in \mathfrak{F}_2 . We call such a C_2 a **parabola**. When π_3 intersects both of \mathfrak{F}_1 and \mathfrak{F}_2 , then $C_3 = \pi_3 \cap \mathfrak{F}$ has two connected components and is not bounded. We call such a C_3 a **hyperbola**. These three types exhaust all possible types of conic sections. In particular, if the plane π is perpendicular to the axis l , then $C = \pi \cap \mathfrak{F}$ becomes a circle. Thus a circle is a special kind of ellipse.

B. Foci and Directrices

Let $C = \pi \cap \mathfrak{F}_1$ be an ellipse. The Euclidean space E^3 is divided by π into two †half-spaces E_1^3, E_2^3 (two “sides” of π). If we put $\mathfrak{F}_1 \cap E_1^3 = \mathfrak{F}_{11}$, $\mathfrak{F}_1 \cap E_2^3 = \mathfrak{F}_{12}$, we can construct a sphere S that is contained in E_1^3 , tangent to \mathfrak{F}_{11} along a circle K , and tangent to π at a point F . Similarly, we can construct a sphere S' that is in E_2^3 , tangent to \mathfrak{F}_{12} along a circle K' , and tangent to π at a point F' . We call F, F' the **foci** of the ellipse (Fig. 1).

Let κ, κ' be the planes containing K, K' . Straight lines $d = \kappa \cap \pi, d' = \kappa' \cap \pi$ are called **directrices** of C . Unless C is a circle, we have $F \neq F'$, and κ, π (and κ', π) actually intersect; hence d, d' exist. When $C = \pi \cap \mathfrak{F}$ is a parabola or a hyperbola (Figs. 2 and 3), we can similarly define foci (a parabola has only one focus, F , while a hyperbola has two foci, F, F') and directrices (a parabola has only one directrix, d , while a hyperbola has two directrices, d, d').

Fig. 1

Fig. 2

Fig. 3

Let X be a point on the plane π , let $D_F(X)$ be the distance between the point X and a focus F , and let $D_d(X)$ be the distance between X and a directrix d . Then the curve C is the locus of the points X satisfying the condition $D_F(X) = e \cdot D_d(X)$, where e is a constant. We call

e the **eccentricity** of the conic section C . According as C is an ellipse, a parabola, or a hyperbola, we have $e < 1$, $e = 1$, or $e > 1$. A circle is an ellipse whose eccentricity is zero. An ellipse is also characterized as the locus of X such that $FX + F'X = 2a$; a hyperbola is the locus of X such that $|FX - F'X| = 2a$, where a is a positive constant. When there are two foci, the straight line FF' is perpendicular to directrices d and d' .

C. Canonical Forms of Equations

When C is a hyperbola or an ellipse that is not a circle, C has two foci, F and F' . In this case, the midpoint O of the segment FF' is the center of symmetry of C (when C is a circle, its center O is, of course, the center of symmetry of C). We call O the **center** of C ; an ellipse or a hyperbola is called a **central conic**. If we choose a rectangular coordinate system (x, y) having O as the origin and FF' as x -axis, then the equation of C can be expressed in the form

$$x^2/a^2 \pm y^2/b^2 = 1, \quad a, b > 0. \quad (1)$$

According as C is an ellipse or a hyperbola, we take the $+$ or $-$ of the double sign. If C is an ellipse, we have $a > b$. Furthermore, $e = \sqrt{a^2 - b^2}/a$ if C is an ellipse and $e = \sqrt{a^2 + b^2}/a$ if C is a hyperbola. We also have $F = (ae, 0)$ and $F' = (-ae, 0)$; the equations of directrices are $x = \pm a/e$.

On the other hand, if C is a parabola, the straight line that is perpendicular to the directrix d and passes through F becomes the axis of symmetry of C . We call this straight line the **axis** of C ; the intersection O of the axis and C is called the **vertex** of C . If we choose a rectangular coordinate system (x, y) having O as the origin and having the axis of C as the x -axis, the equation of C can be expressed in the form

$$y^2 = 4ax, \quad a > 0. \quad (2)$$

We call (1) and (2) the **canonical** (or **standard**) forms of the equation of C . We call the associated coordinate system the **canonical coordinate system**. Suppose that C is an ellipse (hence $a > b$). Let A, A' be points of intersection of the x -axis and the ellipse and B, B' be the points of intersection of the y -axis and the ellipse. We call AA' the **major axis** of C and BB' the **minor axis** of C . If C is a hyperbola and (x, y) is the canonical coordinate system, we call the x -axis the **transverse axis** and the y -axis the **conjugate axis**. If C is a central conic, the x - and y -axes of the canonical coordinate system are called the **principal axes**; if C is a parabola, the x -axis is sometimes called the **principal axis**.

D. Properties of Ellipses

An ellipse may be considered the image of a circle under a \dagger parallel projection. Consequently, the section of a circular cylinder by a plane is an ellipse. Also, if we are given a circle C and a fixed diameter D of C , an ellipse is obtained as the locus of the points X lying on lines PM , which are perpendicular to D , with $P \in C$, $M \in D$, satisfying the condition that the ratio $PM:XM$ is constant.

Suppose that we are given two concentric circles having the center at the origin O and with radii a , b . Let P , Q be points of intersection of moving half-lines through O and the two circles. Then the locus of points X of intersection of the ordinates (lines parallel to the y -axis) passing through P and the abscissae (lines parallel to the x -axis) passing through Q is an ellipse (Fig. 4). Suppose that the equation of an ellipse is given by $x^2/a^2 + y^2/b^2 = 1$, with $a > b$. Then the lengths of its major axis and minor axis are $2a$ and $2b$, respectively.

Fig. 4

Given an ellipse and its center O , the circle with center O and diameter equal to the major axis of the ellipse is called the **auxiliary circle** of the ellipse. Given an ellipse C and its focus F , the auxiliary circle of C is the locus of the points X satisfying the condition that the line FX is perpendicular to a tangent line to C passing through X . Suppose that X is a point on an ellipse with foci F , F' . Let TT' be the line tangent to the ellipse at X (X lies between T and T'). Then the angle $\angle TXF'$ is equal to $\angle T'XF$ (Fig. 5). Consequently, the rays starting from one focus of an ellipse and “reflected” by the ellipse converge on the other focus of the ellipse. Also, the product of the distances from two foci of an ellipse to an arbitrary tangent is constant and is equal to b^2 .

Fig. 5

The ellipse $C: x^2/a^2 + y^2/b^2 = 1$ is expressed parametrically in the form

$$x = a \cos \theta, \quad y = b \sin \theta. \quad (3)$$

We call the parameter θ the **eccentric angle** of a point (x, y) on C . Consequently, C is a \dagger Jordan curve and divides the plane into two parts, the inside and the outside. The inside is the set of points (x, y) satisfying $x^2/a^2 + y^2/b^2 < 1$, and the outside is the set of points (x, y) satisfying $x^2/a^2 + y^2/b^2 > 1$. The inside is a \dagger convex set.

From a point Q outside C , two tangents to C can be drawn. The locus of points Q such that these two tangents are orthogonal is the circle $x^2 + y^2 = a^2 + b^2$. We call this circle the **direct circle**. The area of the “sector” OAX formed by two points $A(a, 0)$, $X(a \cos \theta, b \sin \theta)$ ($\theta > 0$) and the origin O is $ab\theta/2 = (ab/2) \text{Arcos}(x/a)$; the length of the arc AX of the ellipse is represented by the value of the \dagger elliptic integral

$$a \int_0^\theta \sqrt{1 - e^2 \cos^2 \theta} d\theta = aE(\pi/2 - \theta, e).$$

In particular, the area inside an ellipse is equal to πab , and the whole length of the ellipse is $4aE(0, e)$.

With respect to a polar coordinate system (r, θ) having the focus $F(ae, 0)$ as the origin and the ray directed positively along the x -axis as the initial line, the equation of the ellipse C is

$$r = \frac{l}{1 + l \cos \varphi}, \quad l = \frac{b^2}{a}. \quad (4)$$

Here l is equal to half of the length of the chord that is perpendicular to the major axis and passes through the focus. (This chord is called the **latus rectum** of the ellipse.) Suppose that F is a fixed point and that X is a moving particle attracted toward F by a \dagger central force inversely proportional to the square of the length of FX . Suppose further that X begins with an initial velocity whose direction is tangent to the ellipse C with focus F . Then X always moves on C , and the areal velocity described by the radius FX is constant (Kepler's second law).

E. Properties of Hyperbolas

Two straight lines $x^2/a^2 - y^2/b^2 = 0$, that is, $y/x = \pm b/a$, are \dagger asymptotes of the hyperbola $C: x^2/a^2 - y^2/b^2 = 1$. The hyperbola $C': x^2/a^2 - y^2/b^2 = -1$ is called the **conjugate hyperbola** of C . When $a = b$, the asymptotes are orthogonal to each other, and C , C' are congruent. In this case, we call C a **rectangular hyperbola** (or **equilateral hyperbola**). When we draw parallels to asymptotes from a point X on C , the area of the parallelogram formed by these

lines and two asymptotes is constant. (In particular, when C is a rectangular hyperbola, the equation of C becomes $xy = k^2/2$ if we take two asymptotes as coordinate axes. The segment cut off by the asymptotes on the tangent to C at X is divided equally at X . In the case of the hyperbola as well, the product of the distances from two foci to an arbitrary tangent is constant and is equal to b^2 , and the angle between two straight lines joining two foci to a point X on C is divided equally by the tangent at X .

A hyperbola C is represented parametrically by

$$x = a \sec \theta, \quad y = b \tan \theta. \quad (3')$$

In this case also, we call θ the **eccentric angle** of (x, y) . If we use the hyperbolic functions and the parameter u , the equation of a hyperbola can be written as

$$x = a \cosh u, \quad y = b \sinh u \quad (3'')$$

instead of (3'). The area of a "sector" OAX formed by two points $A(a, 0)$, $X(x, y)$ on the hyperbola and the origin O is, in this case,

$$\frac{abu}{2} = \frac{ab}{2} \operatorname{Arccosh} \frac{x}{a} = \frac{ab}{2} \log \frac{x + \sqrt{x^2 - a^2}}{a}.$$

The length of the arc \widehat{AX} of the hyperbola is given by the elliptic integral

$$\int_0^x \sqrt{\frac{e^2 x^2 - a^2}{x^2 - a^2}} dx.$$

With respect to a polar coordinate system (r, φ) having the focus $F(ae, 0)$ as origin and the ray directed positively along the x -axis as the initial line, the equation of the hyperbola C becomes

$$r = \frac{l}{1 - e \cos \varphi}, \quad l = \frac{b^2}{a}, \quad (4')$$

where l is equal to half the length of the chord passing through the focus and perpendicular to the principal axis. (This chord, too, is called the **latus rectum**.)

F. Properties of Parabolas

The curve described by a particle attracted by "gravitation" in a fixed direction and affected by no other force is a parabola (G. Galilei). The tangent at a point X on a parabola makes equal angles with the straight line joining F and X and the direction of the principal axis (Fig. 6). Consequently, if the rays starting from the focus of a parabola are "reflected" by the parabola, they all become rays parallel to the principal axis. Let X' be

Fig. 6

the point of intersection of the tangent at $X(x_0, y_0)$ and the x -axis, X'' the point of intersection of the normal at X and the x -axis, and X_0 the foot of the perpendicular from X to the x -axis. Then $FX = FX'$, $\triangle FXX'$ is an isosceles triangle, and XX' is divided equally by the y -axis. Consequently, the locus of the foot of a perpendicular from F to a tangent is the y -axis. Also, the length of subtangent $X'X_0 = 2x_0$, and the length of subnormal $X''X_0 = 2a = 2OF$. Conversely, a curve whose length of subnormal is constant is a parabola. The locus of the midpoints of parallel chords of a parabola is a straight line parallel to the principal axis.

With respect to a polar coordinate system having the focus as origin and the ray directed positively along the x -axis as the initial line, the equation of a parabola is

$$r = \frac{l}{1 - \cos \varphi}, \quad l = 2a. \quad (4'')$$

The area bounded by a chord BC and an arc \widehat{BC} of a parabola (Fig. 7) is equal to $4/3$ the area of $\triangle ABC$, where A is the point of contact on the tangent of the parabola parallel to BC (Archimedes). Also, the length of the arc \widehat{OX} of parabola (2) is

$$\frac{y_0}{4a} \sqrt{y_0^2 + a^2} + a \log \frac{y_0 + \sqrt{y_0^2 + a^2}}{2a},$$

X having the coordinates (x_0, y_0) .

Fig. 7

G. Conjugate Diameters

The **diameter** is a straight line passing through the center of a central conic. The locus of the midpoints of the chords parallel to a diameter d is another diameter d' , called **conjugate** to d .

Then the diameter conjugate to d' is d . The x -axis and y -axis of a canonical coordinate system form a set of conjugate diameters. Let $2a'$, $2b'$ be the lengths of the segments (sometimes called conjugate diameters) cut off from d , d' by the curve or by the curve and the conjugate one for hyperbolas and by ω , the angle between d and d' . Then the following relations hold (as to the double signs \pm , we take $+$ in the case of an ellipse and $-$ in the case of a hyperbola): $a'^2 \pm b'^2 = a^2 \pm b^2$, $a'b' \sin \omega = ab$. The product of the slopes of d , d' is equal to $\pm b^2/a^2$. With respect to an oblique coordinate system having d and d' as axes, the equation of the curve is $x^2/a'^2 \pm y^2/b'^2 = 1$.

H. Confocal Conic Sections

The set of ellipses and hyperbolas having two fixed points F , F' as foci is called the **family of confocal central conics** with foci F and F' (Fig. 8). The family of confocal central conics containing the ellipse $x^2/a^2 + y^2/b^2 = 1$ is represented parametrically by

$$\frac{x^2}{a^2 + \lambda} + \frac{y^2}{b^2 + \lambda} = 1.$$

There exist only one ellipse and only one hyperbola that pass through a point inside each quadrant (for example, a point (x_0, y_0) , $x_0 > 0$, $y_0 > 0$, inside the first quadrant) and belong to the family of curves. The ellipses and hyperbolas of the same family cut each other orthogonally. Thus parameters corresponding to ellipses and hyperbolas belonging to a family of confocal central conics define an orthogonal curvilinear coordinate system, called an \dagger elliptic coordinate system (\rightarrow 90 Coordinates).

Fig. 8

The set of parabolas having a fixed point F as focus and a straight line passing through F as axis is called a **family of confocal parabolas** (Fig. 9). The family of confocal parabolas containing $y^2 = 4ax$ is the set of curves

$$y^2 = 4(a + \lambda)(x + \lambda).$$

Such families also give rise to orthogonal curvilinear coordinate systems.

Fig. 9

I. Curves of the Second Order

With respect to a rectangular coordinate system, a curve represented by an equation with real coefficients of the second degree with two variables x , y ,

$$ax^2 + 2hxy + by^2 + 2gx + 2fy + c = 0, \quad (5)$$

where $(a, h, b) \neq (0, 0, 0)$, is called a **curve of the second order**. A curve of the second order is either an empty set, one point, one or two straight lines, or a conic section. For equation (5), we put

$$D_0 = \begin{vmatrix} a & h \\ h & b \end{vmatrix}, \quad D = \begin{vmatrix} a & h & g \\ h & b & f \\ g & f & c \end{vmatrix} \quad (6)$$

and call D the **discriminant** of the curve of the second order. If $D_0 \neq 0$, $D \neq 0$, and the curve is not an empty set, then the curve is a central conic. If $D_0 > 0$, then the curve is an ellipse or an empty set. If $D_0 < 0$, then the curve is a hyperbola. If $D_0 = 0$, $D \neq 0$, then the curve is a parabola. If $D = 0$, $D_0 > 0$, then the curve consists of one point. If $D = 0$, $D_0 < 0$, then the curve is two intersecting straight lines. If $D = D_0 = 0$, then the curve is an empty set, one straight line, or two parallel straight lines.

J. Poles and Polars

Let $F(x, y) = ax^2 + 2hxy + by^2 + 2gx + 2fy + c = 0$ be the equation of a conic C and (x_0, y_0) the coordinates of a point P on the plane. A straight line P^* having the equation

$$ax_0x + h(x_0y + xy_0) + by_0y + g(x + x_0) + f(y + y_0) + c = 0$$

is called the **polar** of P with respect to C (Fig. 10). When the polar of a point P is l , we call P the **pole** of l and denote it by l^* . In general, l^* is uniquely determined by l , and $P^{**} = P$, $l^{**} = l$. If $Q \in P^*$, then $P \in Q^*$. If $P' \in l$, then $l^* \in P'^*$. When a straight line passing through P intersects C at X , Y and intersects P^* at P' , then P , P' are \dagger harmonic conjugate with respect to X , Y . In particular, if $P \in P^*$, then $P \in C$, and P^* becomes the tangent of C at P . Given a

triangle $\triangle PQR$ on the plane of C , we call the triangle with sides P^* , Q^* , R^* the **polar triangle** of $\triangle PQR$. Let $Q^* \cap R^* = P'$, $R^* \cap P^* = Q'$, and $P^* \cap Q^* = R'$. Then the three straight lines $P \cup P'$, $Q \cup Q'$, $R \cup R'$ meet at a point (M. Chasles). When the polar triangle of $\triangle PQR$ coincides with itself, then $\triangle PQR$ is called a **self-polar triangle**. The polar of a focus is a directrix.

Fig. 10

K. Curves of the Second Class

When the coefficients u, v, w of a straight line $ux + vy + w = 0$ satisfy an equation with real coefficients of the second order,

$$Au^2 + 2Huv + Bv^2 + 2Guw + 2Fvw + Cw^2 = 0, \quad (5')$$

where $(A, H, B) \neq (0, 0, 0)$, the curve enveloped by these straight lines is called a **curve of the second class**. Let Δ be the discriminant defined analogously to D in (6) by using A, H, B, \dots instead of a, h, b, \dots . A curve of the second class (with $\Delta \neq 0$) is essentially the same as a curve of the second order with $D \neq 0$. In order for the curve (5') with $\Delta \neq 0$ to coincide with the curve (5) with $D \neq 0$, it is necessary and sufficient that A, B, C, F, G, H be proportional to the \dagger cofactors of a, b, c, f, g, h in the determinant D given by (6). If $\Delta = 0$, then (5') represents either the empty set, or a point (regarded as the set of straight lines passing through the point), or two points.

From a projective point of view, a curve of the second order is defined as a locus of the point of intersection $l \cap l' = X$ of corresponding lines l and l' when two \dagger pencils of lines $A(l, m, \dots)$, $A'(l', m', \dots)$ passing through two different centers A and A' are in correspondence under a \dagger projective mapping f (J. Steiner) (Fig. 11). From this it can be proved that three points of intersection of three pairs of opposite sides (AB, DE) , (BC, EF) , (CD, FA) of a hexagon inscribed in a curve of the second order are on the same straight line (**Pascal's theorem**, Fig. 12). In particular, if the curve of the second order in this theorem consists of two straight lines, the theorem coincides with **Pappus's theorem** (Fig. 13). We call this

straight line l the **Pascal line** of $ABCDEF$.

Given a set of six points A, B, C, D, E, F on a curve of the second order, by considering all possible combinations of the points, we get 60 Pascal lines. A configuration consisting of these 60 lines is called **Pascal's configuration**, and has been studied by Steiner, Kirkman, and others. As a \dagger dual to Pascal's theorem, **Brianchon's theorem** holds: Three diagonals of a hexagon with a curve of the second class inscribed meet at a point (Fig. 14).

79 (II.20) Connectedness

A. General Remarks

A \dagger topological space X is said to be **connected** if there are no proper closed subsets A and B of X such that $A \cap B = \emptyset$ and $A \cup B = X$ (C. Jordan, *Cours d'Analyse* I, 1883). A subset S of X is **connected** if S considered as a \dagger subspace of X is connected.

If a subset S of X is connected, then the \dagger closure \bar{S} is also connected. Let $\{A_\alpha\}$ be a family of connected subsets of X such that either $\bar{A}_\alpha \cap A_\beta \neq \emptyset$ or $A_\alpha \cap \bar{A}_\beta \neq \emptyset$ for any pair A_α and A_β . Then the union $\bigcup_\alpha A_\alpha$ is connected. The continuous image of a connected set is connected. The \dagger product space $\prod_\alpha X_\alpha$ of a family of connected spaces $\{X_\alpha\}$ is also con-

nected. Let $\{A_\alpha\}$ be a family of connected subsets of X and A_0 be a connected subset of X . If $A_0 \cap A_\alpha \neq \emptyset$ for every A_α , then the union $A_0 \cup \bigcup_\alpha A_\alpha$ is also connected. For a point p of a topological space X , the union of all connected subsets containing p is connected and is called the **connected component** of p (F. Hausdorff, 1927).

The n -dimensional Euclidean space E^n ($n \geq 0$) and the n -dimensional unit sphere S^n ($n \geq 1$) are connected, whereas S^0 , consisting of two points, is not connected. $E^n \setminus \{0\}$ is connected for $n \geq 2$, whereas $E^1 \setminus \{0\}$ is not connected. This fact implies that E^1 is not homeomorphic to E^n ($n \geq 2$). A connected open subset of a topological space X is called a **domain** (or **region**) in X .

A topological space X is said to be **locally connected** at a point p if for every open set U containing p , there is an open set V containing p and contained in the connected component of p in U . X is said to be **locally connected** if it is locally connected at each point of X . A space X is locally connected if and only if every connected component of every open subset is open in X .

There are connected spaces that are not locally connected. For example, the **comb space** $\{(x, y) \in \mathbb{R}^2 \mid x = 1/n \text{ and } 0 \leq y \leq 1 \text{ (} n = 1, 2, 3, \dots) \text{ or } 0 \leq x \leq 1 \text{ and } y = 0\}$ is not locally connected at $(0, 1)$ (see Fig. 1).

Fig. 1
Comb space.

B. Arcwise Connectedness

Two points a and b of a topological space X are said to be **joined by an arc** in X if there is a continuous map $f(t)$ of the closed interval $I = [0, 1]$ into X such that $f(0) = a$ and $f(1) = b$. A topological space X is said to be **arcwise connected** (or **path-connected**) if every two points of X are joined by an arc in X . For a point p of X , the union of all arcwise-connected subsets in X containing p is arcwise connected and is called the **arcwise-connected component** (or **path-component**) of p . A topological space X is said to be **locally arcwise connected** at a point p if for every open subset U containing p , there is an open subset V

containing p such that every two points in V are joined by an arc in U . X is said to be **locally arcwise connected** if it is locally arcwise connected at each point of X .

An arcwise-connected space is connected, but the converse is not true. The \dagger sinusoid $\{(x, y) \in \mathbb{R}^2 \mid y = \sin 1/x \text{ and } 0 < x \leq 1 \text{ or } x = 0 \text{ and } -1 \leq y \leq 1\}$ is connected but not arcwise connected. A complete metric space is arcwise connected if it is connected and locally connected.

C. Simple Connectedness and n -Connectedness

Denote by S^n the n -dimensional unit sphere and by D^{n+1} the $(n+1)$ -dimensional unit disk. A topological space X is said to be **n -connected** if every continuous map f from S^m to X is extendable over D^{m+1} ($m = 0, 1, 2, \dots, n$). 0-Connectedness is equivalent to arcwise connectedness. A 1-connected space is also called **simply connected**. (For simple connectedness and n -ply connectedness of plane domains → 333 Plane Domains) A topological space X is said to be **locally n -connected** at a point p if for every open subset U containing p , there is an open subset V containing p and contained in U such that any continuous map $f: S^m \rightarrow V$ is extendable to a continuous map $\tilde{f}: D^{m+1} \rightarrow U$ ($m = 0, 1, 2, \dots, n$). X is said to be **locally n -connected** if it is locally n -connected at each point of X . A space X is said to be **ω -connected** (or **locally ω -connected**) if X is n -connected (or locally n -connected) for every n .

S^n is $(n-1)$ -connected but not n -connected. Similarly for $E^{n+1} \setminus \{0\}$. If X is n -connected ($n \geq 1$), then the \dagger suspension SX is $(n+1)$ -connected and the \dagger loop space ΩX is $(n-1)$ -connected. The **Hawaiian earring** $\{(x, y) \in \mathbb{R}^2 \mid (x - 1/n)^2 + y^2 = 1/n^2 \text{ (} n = 1, 2, 3, \dots) \}$ is arcwise connected but not locally simply connected. The \dagger cone over the Hawaiian earring is simply connected, but not locally simply connected (Fig. 2).

Fig. 2
Hawaiian earring and its cone.

A topological space X is said to be **contractible** if the identity map 1_X is \dagger homotopic to a constant map c_{x_0} to a point x_0 of X (K. Borsuk, *Fund. Math.*, 24, 1935). A topological space X is said to be **locally contractible** at a

point p of X , if for every open subset U containing p , there is an open subset V containing p and contained in U such that the inclusion $i: V \subset U$ is homotopic to a constant map to a point in U . X is said to be **locally contractible** if it is locally contractible at each point of X .

A contractible or locally contractible space is ω -connected or locally ω -connected, respectively. The n -dimensional simplex, the n -dimensional disk D^n , and the n -dimensional Euclidean space E^n are contractible. More generally, a \ast convex set in E^n is contractible. \ast Topological manifolds and \ast polyhedra are locally contractible.

D. Continua and Discontinua

A topological space is said to be **totally disconnected** if each connected component consists of one point. Divide the closed interval $I = [0, 1]$ into three equal parts, and let I_{11} and I_{12} be the closed intervals obtained from I by removing the middle open interval. As the next step, divide I_{11} and I_{12} into three equal parts, respectively, and remove the middle open intervals. Inductively we obtain 2^{n+1} closed intervals $I_{n+1,i}$ ($i = 1, \dots, 2^{n+1}$) from 2^n closed intervals $I_{n,j}$ by removing open intervals lying in their middles. Let $C^{(n)} = \bigcup_{i=1}^{2^n} I_{n,i}$ and $C = \bigcap_{n=1}^{\infty} C^{(n)}$. Then C is called the **Cantor discontinuum** or simply the **Cantor set** or the **ternary set** (G. Cantor, *Math. Ann.*, 21 (1883)) (Fig. 3).

Fig. 3
Cantor discontinuum.

C is a subset of I consisting of points with coordinates $t = (n_1/3) + (n_2/3^2) + \dots + (n_i/3^i) + \dots$, where $n_i = 0$ or 2 . As a topological space C is homeomorphic to the Cartesian product of countably many copies of the discrete space $D = \{0, 1\}$. C has the power of the continuum c and is a compact, totally disconnected, \ast perfect set. The Cartesian product of infinitely many (countably or not) copies of D is called the **general Cantor set**. The continuous image of a general Cantor set is called a **dyadic compactum**. Compact metric spaces and compact groups are examples of dyadic compacta.

A **continuum** is by definition a connected compact metric space consisting of more than one point. A metric space X is said to be **well-chained** if for every two points a, b and $\varepsilon > 0$ there are points x_1, x_2, \dots, x_{n-1} such that $d(x_i, x_{i+1}) < \varepsilon$ ($x_0 = a, x_n = b$). A well-chained compact metric space is a continuum.

Let K be a continuum containing two

points a and b . Then K is said to be **irreducible** between a and b if there is no proper subcontinuum of K containing a and b (L. Zoratti, *Ann. Sci. Ecole Norm. Sup.*, 26 (1909)) (\rightarrow 93 Curves).

A continuum K is said to be **indecomposable** if there are no proper subcontinua K_1, K_2 such that $K = K_1 \cup K_2$ (L. E. J. Brouwer, *Math. Ann.*, 66 (1910)). Simple examples of indecomposable continua have been given by A. Denjoy, *C. R. Acad. Sci. Paris*, 151 (1910); K. Yoneyama, *Tôhoku Math. J.*, 12 (1917); and B. Knaster, *Fund. Math.*, 3 (1922).

C. Kuratowski conjectured the following: If a plane continuum K is homogeneous (that is, for any two points $a, b \in K$ there exists a homeomorphism $h: K \rightarrow K$ with $h(a) = b$) then K is homeomorphic to the circle. A counterexample for this conjecture has been found by R. H. Bing and E. E. Moise. It is an indecomposable, homogeneous, plane continuum and is called the **pseudo-arc** [8].

80 (VII.4) Connections

A. History

The geometric notion of connections originated with T. Levi-Civita's parallelism (*Rend. Circ. Mat. Palermo*, 42 (1917)) and was later generalized to the notion of connections of differentiable fiber bundles. Notions such as affine connections, Riemannian connections, projective connections, and conformal connections can be described in terms of bundles

constructed from the tangent bundles of differentiable manifolds. They are also standard examples of the Cartan connections formulated by E. Cartan and C. Ehresmann.

B. Connections in Principal Bundles

Let $P = (P, \pi, M, G)$ be a differentiable \dagger principal fiber bundle. (For the sake of convenience, we assume that differentiability always means that of class C^∞ .) The total space P and the base space M are \dagger differentiable manifolds, and the projection π is a differentiable mapping. The \dagger structure group G is a \dagger Lie group and acts on P from the right as a transformation group. On each fiber, G acts transitively without fixed points. For elements a, x in G, P , we write $R_a(x) = xa$. The mappings induced on \dagger tangent vector spaces by R_a and π will be denoted by the same letters, namely $R_a: T_x(P) \rightarrow T_{xa}(P), \pi: T_x(P) \rightarrow T_{\pi(x)}(M)$. The tangent vector space $T_x(P)$ at each point x of P is mapped by the projection π onto the tangent vector space $T_p(M)$ at the point $p = \pi(x)$ of M . The kernel of this mapping is denoted by $V_x(P)$, and each vector in $V_x(P)$ is said to be **vertical**. The kernel $V_x(P)$ is the totality of elements of $T_x(P)$ that are tangent to the fiber.

C. Connections

We say that a **connection** is given in P if for each point $x \in P$, a subspace Q_x of the tangent space $T_x(P)$ is given in such a way that the following three conditions are satisfied: (i) $T_x(P) = V_x(P) + Q_x$ (direct sum); (ii) $R_a(Q_x) = Q_{xa}$ (Q is invariant under G); and (iii) the mapping $x \rightarrow Q_x$ is differentiable. A vector in Q_x is said to be **horizontal**.

Now suppose that X is an arbitrary \dagger vector field on P . By condition (i), the value X_x of X at each point x of P can be expressed uniquely as $X_x = Y_x + Z_x$, where $Y_x \in V_x(P)$ and $Z_x \in Q_x$. The vector fields Y and Z defined by Y_x and Z_x ($x \in P$) are called the **vertical** and **horizontal components** of X , respectively. Condition (iii) implies that if X is a differentiable vector field, then its horizontal and vertical components are also differentiable vector fields. Let X be a vector field on the base space M . Since π defines an isomorphism of Q_x and $T_p(M)$ ($p = \pi(x)$), we have a unique vector field X^* on P such that (a) $\pi(X^*) = X$ and (b) $X_x^* \in Q_x$. We call X^* the **lift** of X , and it is invariant under G by condition (ii).

Suppose that a connection is given in P . If C is a piecewise differentiable curve in the base space M , we can define a mapping φ that maps the fiber over the initial point p of C

onto the fiber over the endpoint q of C as follows: Take an arbitrary point x on the fiber at p . Then we have a unique curve C_x^* in P starting at x such that (a) $\pi(C_x^*) = C$, and (b) each tangent vector to C_x^* is horizontal. (C_x^* is called a **lift** of C that starts at x .) The endpoint y of the curve C_x^* belongs to the fiber over q . We set $\varphi(x) = y$. Because $C_{xa}^* = R_a(C_x^*)$, the mapping φ commutes with transformations of G . We call this mapping φ the **parallel displacement** or **parallel translation** along the curve C .

D. Holonomy Groups

Fix a point p in the base space. If C is a closed curve in M starting from p , the parallel displacement along C maps the fiber over p onto itself. So if we fix a point x on the fiber over p , x is transformed by the parallel displacement to a point xa ($a \in G$). Thus each closed curve C starting from p determines an element $a(x, C)$ of G . If C varies over the set of closed curves that start from p , the totality of such elements of G forms a subgroup of G . This subgroup is called the **holonomy group** of the connection defined over P with the reference point x . If M is connected, holonomy groups with different reference points are conjugate. In the above, if we choose as the closed curves C starting from p only those curves that are null-homotopic, the elements $a(x, C)$ form a subgroup of the holonomy group. This is called the **restricted holonomy group**. The holonomy group is a \dagger Lie subgroup of the structure group, and its connected component containing the identity coincides with the restricted holonomy group. Holonomy groups are useful in the study of the behavior of connections.

E. Connection Forms

Let \mathfrak{g} be the Lie algebra (\rightarrow 249 Lie Groups) of the structure group of G of a principal fiber bundle $P = (P, \pi, M, G)$. For each A in \mathfrak{g} , the 1-parameter subgroup $\exp tA$ ($-\infty < t < \infty$) of G defines a \dagger one-parameter group $R_{\exp tA}$ of transformations on P , and it determines a vector field A^* on P (\rightarrow 105 Differentiable Manifolds). Each element of the vector field A^* is vertical at each point x on P , and the A^* ($A \in \mathfrak{g}$) at x generate $V_x(P)$. Moreover, for each element a of G we have $R_a(A^*) = (\text{ad}(a^{-1})A)^*$.

For a connection in P , we define the **connection form** ω on P with values in \mathfrak{g} by the following: (i) $\omega_x(A_x^*) = A$ ($A \in \mathfrak{g}$), and (ii) $\omega_x(X) = 0$ ($X \in Q_x$). The connection form ω thus defined satisfies (iii) $R_a^*(\omega) = \text{ad}(a^{-1})\omega$ ($a \in G$), where $R_a^*(\omega)$ is the \dagger differential form induced by the

transformation R_a from the differential form ω . Conversely, given a 1-form ω with values in \mathfrak{g} that satisfies conditions (i) and (ii), we can define a connection in P by defining vectors X such that $\omega(X)=0$ as the horizontal, and its connection form coincides with ω . Thus giving a connection in P is equivalent to giving a connection form in P .

In particular, when a principal fiber bundle P is trivial, i.e., when $P = M \times G$, we can identify the tangent vector space $T_x(P)$ at a point $x = (p, g)$ of P with the direct sum of $T_p(M)$ and $T_g(G)$. If we set $Q_x = T_p(M)$, then Q defines a connection in $P = M \times G$. Such a connection is called **flat**. When a connection can always be expressed as above locally, it is called **locally flat**. Since each principal fiber bundle is locally a product fiber bundle, we see that locally there exists a connection. If the base space M is \dagger paracompact, we can show the existence of connections on P .

F. Extension and Restriction of Connections

When a principal fiber bundle $P = (P, \pi, M, G)$ has a \dagger reduced fiber bundle P' , we shall consider the relation between the connections of P and of P' . Let G' be a Lie subgroup of G and \mathfrak{g}' its Lie algebra. We shall denote by j both the injection of G' into G and also the injection of \mathfrak{g}' into \mathfrak{g} . If there exist a differentiable principal fiber bundle $P' = (P', \pi', M, G')$ and a differentiable embedding f of P' into P such that $\pi \circ f = \pi'$ and $f \circ R_a = R_{j(a)} \circ f$ ($a \in G'$) are satisfied, then (P', f) is said to be a reduced fiber bundle of P . Then we have $f_*(A_x^*) = j(A)_{f(x)}^*$ for each $A \in \mathfrak{g}'$ and $x \in P'$.

Suppose that a connection is given in P' ; we denote the horizontal space at the point x of P' by Q'_x . At the point $f(x)$ of P , we take $f_*(Q'_x)$ as the horizontal space and transform it by right translations of G . Thus we obtain a connection on P . Let ω' and ω be the corresponding connection forms. Then we have $j \circ \omega' = f^*(\omega)$ on P' . Conversely, suppose that we are given a connection in P with the connection form ω . If the induced form $f^*(\omega)$ on P' has values always in $j(\mathfrak{g}')$, we can write $f^*(\omega) = j \circ \omega'$, and ω' defines a connection in P' . In this case the connection in P is called an **extension** of the connection in P' , and the connection in P' is called the **restriction** of the connection in P .

G. Curvature Forms

Suppose that a principal fiber bundle $P = (P, \pi, M, G)$ has a connection. Let F be a finite-dimensional vector space and α be a differential form of degree k on P with values in F . We

define the **covariant differential** $D\alpha$ of α by

$$(D\alpha)(X_1, \dots, X_{k+1}) = (d\alpha)(hX_1, \dots, hX_{k+1}),$$

where the X_i are vector fields on P and h denotes the projection to the horizontal component. $D\alpha$ is a differential form of degree $k+1$ on P with values in F .

Let $\rho: G \rightarrow GL(F)$ be a \dagger representation of a Lie group G on F . A differential form α on P with values in F is called a **pseudotensorial form** of type ρ if α satisfies $R_a^*(\alpha) = \rho(a^{-1})\alpha$ ($a \in G$). In particular, if a pseudotensorial form α satisfies $\iota(A^*)\alpha = 0$ for any $A \in \mathfrak{g}$ (\rightarrow 105 Differentiable Manifolds Q), it is called a **tensorial form** of type ρ . For each representation ρ of G , we can construct an associated vector bundle E over M with fiber F . A tensorial form of type ρ is identified with a differential form on M with values in E . If α is a pseudotensorial form of type ρ , then $D\alpha$ is a tensorial form of type ρ .

For a connection form ω on P , the covariant differential $D\omega = \Omega$ of ω is called the **curvature form** of the connection. Since ω is a pseudotensorial form of type ad , Ω is a tensorial form of type ad . For the connection form we have the **structure equation** $d\omega = -[\omega, \omega] + \Omega$ [4, 6]. Let X and Y be vector fields on M , and let X^* and Y^* be their lifts, respectively. Then we have $\omega([X^*, Y^*]) = \Omega(X^*, Y^*)$, which shows that the curvature form Ω for X^*, Y^* gives the vertical component of $[X^*, Y^*]$.

It is known that the following three conditions for a connection are equivalent: (i) The connection is locally flat. (ii) The curvature form vanishes. (iii) The restricted holonomy group is trivial (i.e., the identity group).

The following two theorems are fundamental:

(1) Suppose that a connection is given in a principal fiber bundle $P = (P, \pi, M, G)$. Then the structure group of P can be reduced to the holonomy group [4, 6]. In fact, for $x \in P$, let $P(x)$ be the set of points y in P that can be connected to x by a piecewise horizontal curve in P . Then $P(x)$ gives a reduced fiber bundle of P , and the connection in P is an extension of a connection in $P(x)$ [4, 6].

(2) The Lie algebra of the holonomy group with a reference point x in P coincides with the vector subspace of \mathfrak{g} spanned by $\{\Omega_y(X, Y) \mid y \in P(x), X, Y \in T_y(P)\}$ [4, 6].

The curvature form Ω is used to express the \dagger characteristic classes of the bundle P [1, 2] (\rightarrow 56 Characteristic Classes).

In some cases, a connection in the principal fiber bundle induces a connection in an \dagger associated fiber bundle. In particular, when G is $GL(n, \mathbf{R})$ or $GL(n, \mathbf{C})$, we can define a connection in any associated vector bundle. The notion of connections in vector bundles can be

defined more algebraically (M. F. Atiyah, *Trans. Amer. Math. Soc.*, 85 (1957)) and can also be defined as a kind of differential operator on vector bundles [8].

II. Affine Connections

Let M be a differentiable manifold of dimension n and P be the \dagger bundle of tangent n -frames over M . Then P has the structure group $GL(n, \mathbf{R})$, and it is the principal bundle associated with the tangent vector bundle of M , which consists of all tangent vectors of M . A connection in the bundle of tangent n -frames is called an **affine connection** (or **linear connection**) on M . An affine connection on M defines (as well as the curvature form Ω) a new form Θ called the torsion form on P , which is given as follows: Let F be an n -dimensional vector space with a fixed basis $(\xi_1, \xi_2, \dots, \xi_n)$. Since the bundle of tangent n -frames P is the set of all bases (i.e., n -frames) (e_1, \dots, e_n) in $T_p(M)$ at each point p of M , every point $x = (e_1, \dots, e_n)$ of P is given as a mapping \bar{x} of F onto $T_p(M)$ ($p = \pi(x)$) defined by $\bar{x}: \xi_i \rightarrow e_i$. We define differential form θ of degree 1 with values in F on P by $\theta_x(X) = \bar{x}^{-1}(\pi_*(X))$ ($X \in T_x(P)$). θ is called a **canonical 1-form** of the bundle of tangent n -frames of the manifold M and has the following property: Any diffeomorphism φ of M onto itself induces a bundle automorphism $\tilde{\varphi}$ of P onto itself, and $\tilde{\varphi}$ preserves θ , that is, $\tilde{\varphi}^*(\theta) = \theta$. Conversely, we can show that any bundle automorphism of P that preserves θ is induced by a diffeomorphism of the base space M .

For an affine connection on M , we define the **torsion form** Θ by $\Theta = D\theta$. Θ is a differential form of degree 2 on P with values in F and satisfies $R_a\Theta = a^{-1} \cdot \Theta$ ($a \in GL(n, \mathbf{R})$). Furthermore, we have the **structure equation** for Θ , $d\theta = [\omega, \theta] + \Theta$ [2, 4, 6].

For each element ξ in F , there exists a unique horizontal vector field $B(\xi)$ on P such that $\theta(B(\xi)) = \xi$. $B(\xi)$ is called the **basic vector field** corresponding to ξ . At each point $x \in P$, $B(\xi_1)_x, \dots, B(\xi_n)_x$ form a basis of \mathcal{Q}_x . Let $\{A_1, \dots, A_m\}$ ($m = n^2$) be a basis of $\mathfrak{g} = \mathfrak{gl}(n, \mathbf{R})$. Then at each point $x \in P$, $\{(A^*)_1, \dots, (A^*)_m\}$, $B(\xi_1)_x, \dots, B(\xi_n)_x$ is a basis of the tangent vector space $T_x(P)$. Thus the bundle P of frames is a \dagger parallelizable manifold. The projection to M of any \dagger integral curve of a basic vector field is a geodesic, which is defined in Section I [4].

An affine connection on M gives a parallel displacement of the tangent vector space of M as follows: Let $C = p_t$ ($0 \leq t \leq 1$) be a curve in M and $C^* = x_t$ be a lift of C to P . The parallel displacement of the tangent n -frame x_0 at p_0

along the curve C is x_t , and the mapping $\bar{x}_t \circ \bar{x}_0^{-1}: T_{p_0}(M) \rightarrow T_{p_t}(M)$ is called the **parallel displacement** of the tangent space $T_{p_0}(M)$ onto $T_{p_t}(M)$ along C . It is easily seen that the mapping is independent of the choice of lifts.

I. Covariant Differentials

Let $C = \{p_t\}$ ($0 \leq t \leq 1$) be a differentiable curve in M . If we have a vector Y_t in $T_{p_t}(M)$ for each t and the correspondence $t \rightarrow Y_t$ is differentiable, then $\{Y_t\}$ is called a vector field along the curve C . For $\{Y_t\}$ we set

$$Y'_t = \lim_{h \rightarrow 0} (1/h)(\varphi_{t, t+h}^{-1}(Y_{t+h}) - Y_t),$$

where $\varphi_{t, t+h}$ is the parallel displacement of $T_{p_t}(M)$ onto $T_{p_{t+h}}(M)$ along the curve C . The vector field $\{Y'_t\}$ along C thus obtained is called the **covariant derivative** of $\{Y_t\}$. $\{Y_t\}$ is parallel along C ; that is, $Y_t = \varphi_{0, t}(Y_0)$ if and only if $Y'_t \equiv 0$. In particular, if the tangent vectors to a curve C are parallel along C itself, then C is said to be a **geodesic**.

Let X and Y be vector fields on a manifold M with an affine connection. The **covariant derivative** $\nabla_X Y$ of the vector field Y in the direction of the vector field X is defined as follows: Let p_0 be a point in M , $C = \{p_t\}$ ($-\varepsilon \leq t \leq \varepsilon$) be an integral curve of X through p_0 , and $\{\varphi_t\}$ be the parallel displacement along C . We set

$$(\nabla_X Y)_{p_0} = \lim_{t \rightarrow 0} (1/t)(\varphi_t^{-1}(Y_{p_t}) - Y_{p_0}).$$

Then $\nabla_X Y$ is also a vector field on M .

The mapping $(X, Y) \rightarrow \nabla_X Y$ satisfies the following three conditions: (i) $\nabla_X Y$ is linear with respect to X and Y ; (ii) $\nabla_{fX} Y = f \cdot \nabla_X Y$; and (iii) $\nabla_X(fY) = f \cdot \nabla_X Y + (Xf) \cdot Y$, where f is a differentiable function on M . Conversely, if a mapping satisfying conditions (i)–(iii) above is given, then there exists a unique affine connection on M whose covariant derivative coincides with the given mapping [4, 6].

Fix a vector field Y . Then the mapping $X \rightarrow \nabla_X Y$ defines a \dagger tensor field of type $(1, 1)$. This tensor field is called the **covariant differential** of Y and is denoted by ∇Y . Now fix a vector field X . Then the mapping $Y \rightarrow \nabla_X Y$ can be naturally extended to tensor fields of arbitrary type, and it commutes with the \dagger contraction of the tensors. For a tensor field K this is denoted by $K \rightarrow \nabla_X K$. Furthermore, the mapping $X \rightarrow \nabla_X K$ is called the **covariant differential** of K and is denoted by ∇K . We call $\nabla_X K$ the **covariant derivative** of K in the direction of X . A tensor field K is invariant under parallel displacements if and only if $\nabla K = 0$ (\rightarrow 417 Tensor Calculus).

J. Curvature Tensors and Torsion Tensors

For an affine connection on M , the **curvature tensor** R and the **torsion tensor** T are defined by

$$R(X, Y)(Z) = \nabla_X(\nabla_Y Z) - \nabla_Y(\nabla_X Z) - \nabla_{[X, Y]}(Z),$$

$$T(X \cdot Y) = \nabla_X Y - \nabla_Y X - [X, Y],$$

where X, Y , and Z are vector fields on M , and R and T are tensors of types $(1, 3)$ and $(1, 2)$, respectively. Also, in terms of the curvature form Ω and the torsion form Θ on the bundle of tangent n -frames P over M , they can be defined by

$$R_p(X, Y)(Z) = \bar{x}^{-1} \cdot \Omega_x(X^*, Y^*) \cdot \bar{x}(Z),$$

$$T_p(X, Y) = \bar{x}^{-1}(\Theta_x(X^*, Y^*)),$$

where $\pi(x) = p$, $X, Y \in T_p(M)$, and X^*, Y^* are lifts of X, Y , respectively. The curvature tensor and the torsion tensor satisfy the relations $R(X, Y) = -R(Y, X)$, $T(X, Y) = -T(Y, X)$. Moreover, **Bianchi's identities** hold:

$$\begin{aligned} \mathfrak{S}(R(X, Y)(Z)) &= \mathfrak{S}(T(T(X, Y), Z) \\ &\quad + (\nabla_X T)(Y, Z)) \end{aligned}$$

and

$$\mathfrak{S}((\nabla_X R)(Y, Z) + R(T(X, Y), Z)) = 0,$$

where \mathfrak{S} denotes the sum of terms that are obtained by cyclic permutations of X, Y, Z [4]. For instance, in the case of a Riemannian connection (Section K), we have $T=0$, and Bianchi's identities reduce to

$$\begin{aligned} R(X, Y)(Z) + R(Y, Z)(X) + R(Z, X)(Y) &= 0, \\ (\nabla_X R)(Y, Z) + (\nabla_Y R)(Z, X) + (\nabla_Z R)(X, Y) &= 0. \end{aligned}$$

We now consider a system of coordinates (x^1, \dots, x^n) in an n -dimensional linear space $M = \mathbf{R}^n$. The vector fields (X_1, \dots, X_n) ($X_i = \partial/\partial x^i$) form a basis for vector fields on M . If we set $\nabla_{X_i} X_j = 0$, we get an affine connection on \mathbf{R}^n . For such a connection we have $R=0$, $T=0$, and any straight line in \mathbf{R}^n is a geodesic with respect to this connection. The connection is called the **canonical affine connection** on \mathbf{R}^n . An affine connection on a manifold M satisfies $R=0$ and $T=0$ if and only if the connection on M is locally isomorphic to the canonical affine connection of \mathbf{R}^n .

Let φ be a diffeomorphism of a manifold M with an affine connection onto itself. We call φ an **affine transformation** of M if the induced automorphism $\tilde{\varphi}$ on the bundle of tangent n -frames preserves the connection. In terms of covariant differentials, this condition is equivalent to the condition $\nabla_{\varphi(X)} \varphi(Y) = \varphi(\nabla_X Y)$ for any vector fields X, Y . An affine transformation of the canonical affine connection on \mathbf{R}^n

is an ordinary affine transformation. For an affine connection on a manifold M , the set of all affine transformations forms a Lie group and acts on M as a Lie transformation group [4, 5].

Let M be a manifold with an affine connection. M is called an affine **locally symmetric space** if $\nabla R=0$ and $\nabla T=0$ are satisfied. These conditions are satisfied if and only if at each point p of M , there exist a neighborhood U of p and an affine transformation φ of U such that $\varphi^2=1$ and p is the isolated fixed point of φ . If for each point p of M there exists an affine transformation of M such that $\varphi^2=1$ and p is an isolated fixed point, then M is called an **affine symmetric space**. A symmetric Riemannian space is a special case of this type (\rightarrow 413 Symmetric Spaces).

At each point p in a manifold M with an affine connection, we can choose local coordinates (x^1, \dots, x^n) such that $x^i(p)=0$ and the curve $x^i = a^i t$ ($-\delta < t < \delta$) is a geodesic for each (a^1, \dots, a^n) with $\sum (a^i)^2 = 1$. Such local coordinates are called **geodesic coordinates** at p [4]. With respect to geodesic coordinates, we have $(\nabla_{X_i}(X_j))_p = 0$ ($\partial/\partial x^i = X_i$).

K. Riemannian Connections

When a Riemannian metric g (\rightarrow 364 Riemannian Manifolds) is given on a manifold M , it defines a metric on the tangent space $T_p(M)$ at each point p of M , and we can take orthonormal bases in $T_p(M)$. The set P' of all orthonormal bases of tangent spaces is a subset of the bundle P of tangent n -frames of M and forms a subbundle of P ; its structure group is the orthogonal group $O(n)$, and P' gives a reduction of the bundle of tangent n -frames. Conversely, when a reduction of the bundle of frames to $O(n)$ is given, we can define a Riemannian metric on M such that the reduced bundle consists of all orthonormal frames.

For a Riemannian metric g on M , there exists a unique affine connection on M such that (i) $\nabla g=0$, and (ii) the torsion tensor T vanishes [4]. This connection is called the **Riemannian connection** corresponding to g . The first condition is equivalent to the invariance of the Riemannian metric g under parallel displacement. Thus the affine connection transforms orthonormal bases on M to orthonormal bases and induces a connection in the bundle P' . It is known that the restricted holonomy group of any Riemannian connection is a closed subgroup of $O(n)$ [4]. An affine connection on a manifold M is called a **metric**

connection if it preserves a Riemannian metric g on M , i.e., if it satisfies the condition (i).

L. Representations in Local Coordinates

(1) Let (x^1, \dots, x^n) be a local coordinate system in a manifold M and consider vector fields $X_i = \partial/\partial x_i$. For an affine connection on M , the covariant derivative can be expressed as

$$\nabla_{X_j}(X_k) = \sum_i \Gamma_{jk}^i X_i.$$

The Γ_{jk}^i are called **coefficients of the affine connection** with respect to the local coordinate system (x^1, \dots, x^n) . We denote by $\bar{\Gamma}_{jk}^i$ the coefficients of connection with respect to another local coordinate system (y^1, \dots, y^n) . Then on the intersection of their coordinate neighborhoods, we have

$$\bar{\Gamma}_{jk}^i = \sum_{\alpha, \beta, \gamma} \frac{\partial y^i}{\partial x^\alpha} \left(\frac{\partial x^\beta}{\partial y^j} \frac{\partial x^\gamma}{\partial y^k} \Gamma_{\beta\gamma}^\alpha + \frac{\partial^2 x^\alpha}{\partial y^j \partial y^k} \right).$$

Conversely, if the Γ_{jk}^i are given in each local coordinate system of M and satisfy this relation on each intersection of their coordinate neighborhoods, then there exists a unique affine connection such that the coefficients of the connection are given by Γ_{jk}^i .

(2) The **coefficients of the Riemannian connection** corresponding to a Riemannian metric $g = \sum g_{ij} dx^i dx^j$ on a manifold M are given by

$$\Gamma_{jk}^i = \frac{1}{2} \sum_l g^{il} \left\{ \frac{\partial g_{jl}}{\partial x^k} + \frac{\partial g_{lk}}{\partial x^j} - \frac{\partial g_{jk}}{\partial x^l} \right\}$$

and are called the **Christoffel symbols**.

(3) With respect to each local coordinate system (x^1, \dots, x^n) , we express the **torsion tensor** T and the **curvature tensor** R of an affine connection by

$$T = \sum_{ijk} T_{jk}^i dx^j \otimes dx^k \otimes X_i,$$

$$R = \sum_{ijkl} R_{jkl}^i dx^j \otimes dx^k \otimes dx^l \otimes X_i.$$

The components T_{jk}^i and R_{jkl}^i are given by

$$\begin{aligned} T_{jk}^i &= \Gamma_{jk}^i - \Gamma_{kj}^i, \\ R_{jkl}^i &= (\partial \Gamma_{lj}^i / \partial x^k - \partial \Gamma_{kj}^i / \partial x^l) \\ &\quad + \sum_m (\Gamma_{lj}^m \Gamma_{km}^i - \Gamma_{kj}^m \Gamma_{lm}^i). \end{aligned}$$

(4) Let $K = (K_{j_1 \dots j_s}^{i_1 \dots i_r})$ be a tensor field of type (r, s) . Then the **covariant differential** $\nabla K = (K_{j_1 \dots j_s, k}^{i_1 \dots i_r})$ is given by

$$\begin{aligned} K_{j_1 \dots j_s, k}^{i_1 \dots i_r} &= \partial K_{j_1 \dots j_s}^{i_1 \dots i_r} / \partial x^k \\ &\quad + \sum_{\alpha=1}^r \left(\sum_l \Gamma_{kl}^\alpha K_{j_1 \dots j_s}^{i_1 \dots i_{\alpha-1} \alpha i_{\alpha+1} \dots i_r} \right) \\ &\quad - \sum_{\beta=1}^s \left(\sum_m \Gamma_{kj}^m K_{j_1 \dots j_{\beta-1} m j_{\beta+1} \dots j_s}^{i_1 \dots i_r} \right). \end{aligned}$$

(5) A curve $x^i = x^i(t)$ is a **geodesic** if and only if

$$\frac{d^2 x^i}{dt^2} + \sum_{j,k} \Gamma_{jk}^i \frac{dx^j}{dt} \frac{dx^k}{dt} = 0, \quad i = 1, 2, \dots, n$$

(\rightarrow 178 Geodesics, 417 Tensor Calculus).

M. Cartan Connections

Let M be a differentiable manifold of dimension n . Consider a homogeneous space $F = G/G'$ of the same dimension n , where G is a Lie group and G' is a closed subgroup of G (\rightarrow 199 Homogeneous Spaces). Let $B = (B, M, F, G)$ be a fiber bundle over M with fiber F and structure group G , and $P = (P, M, G)$ be the principal fiber bundle associated with B . Suppose that there exists a cross section f over M to B . Then the structure group of P can be reduced to G' . We denote this reduced fiber bundle by $P' = (P', M, G')$ and the injection of P' into P by j (\rightarrow 147 Fiber Bundles).

Suppose that a connection is given in P . Its connection form ω is a differential form of degree 1 on P with values in \mathfrak{g} , and the induced form $\omega' = j^*(\omega)$ is also a differential form of degree 1 on P' with values in \mathfrak{g} . We call the connection in P a **Cartan connection** on M with the fiber $F = G/G'$ if at each point x of P' , ω'_x gives an isomorphism of $T_x(P')$ onto \mathfrak{g} as linear spaces. Such a connection in P is equivalently defined as a 1-form ω' on P' with values in \mathfrak{g} satisfying the following three conditions: (i) $\omega'(A^*) = A$ ($A \in \mathfrak{g}'$ (Lie algebra of G')); (ii) $R_\#^*(\omega') = \text{ad}(a^{-1})\omega'$ ($a \in G'$); and (iii) ω'_x gives an isomorphism of $T_x(P')$ onto \mathfrak{g} at each point $x \in P'$. For such ω' , we can take a connection form ω in P such that $\omega' = j^*(\omega)$; ω defines a Cartan connection.

N. Soudures

A cross section f over M to B gives a vector bundle $T'(B)$ on M defined as follows: For each point p of M , the projection $B \rightarrow M$ defines a mapping $T_{f(p)}(B) \rightarrow T_p(M)$. The kernel of this mapping is denoted by $V_{f(p)}(B)$. Then $T'(B) = \bigcup_p V_{f(p)}(B)$ forms a vector bundle over M , and the dimension of its fibers is equal to $n = \dim F$.

A Cartan connection in P gives a bundle isomorphism between $T'(B)$ and the tangent vector bundle $T(M)$ of M as follows: Let x be an arbitrary point in P' , and put $p = \pi(x)$. The projection $\pi: P' \rightarrow M$ induces an isomorphism of $T_x(P')/V_x(P')$ onto $T_p(M)$. On the other hand, ω'_x gives an isomorphism of $T_x(P')/V_x(P')$ onto $\mathfrak{g}/\mathfrak{g}'$. As a point in P' , x gives a mapping of F

$= G/G'$ onto the fiber in B over p and sends the point $\{G'\}$ in F to $f(p)$. By this mapping, $T_0(F) = \mathfrak{g}/\mathfrak{g}'$ is mapped isomorphically onto $V_{f(p)}(B)$. Combining these isomorphisms, we get an isomorphism between $T_p(M)$ and $V_{f(p)}(B)$ that is independent of the choice of $x \in P'$ over p . The set of such isomorphisms for $p \in M$ defines a bundle isomorphism of $T(M)$ and $T'(B)$. If a fiber bundle B over M has an isomorphism such as above through a cross section, then B is said to have a **soudure** [3].

Conversely, if a fiber bundle B over M has a soudure with respect to a cross section f , then there exists a Cartan connection in P such that the soudure given by the connection coincides with the original one [3]. There are many Cartan connections in P with the given soudure. However, when $F = G/G'$ is a symmetric space of compact type such that G is noncompact and contains the identity component of the group of isometries, we can determine uniquely the so-called **normal** Cartan connection among the Cartan connections which gives rise to the given soudure [10].

For the tangent vector bundle $T(M)$ of M , the fiber F is an n -dimensional linear space and can be expressed as $F = G/G'$, where G is the \dagger affine transformation group of F and $G' = GL(n, \mathbf{R})$. Then $T(M)$ has the 0-section over M , and there exists a natural soudure. Furthermore, an affine connection on M canonically induces a Cartan connection on M with the fiber $F = G/G'$ [3].

For a Cartan connection on M , we can introduce the notion of **development** of a curve in M into the fiber and also the notion of **completeness** [3].

O. Projective Connections

Let $F_1 = G_1/G'_1$ and $F_2 = G_2/G'_2$ be homogeneous spaces with $\dim F_1 = \dim F_2 = n$. Suppose that G_1 is a Lie subgroup of G_2 and G'_1 is contained in G'_2 by the injection. Then we have a canonical injection $F_1 \rightarrow F_2$ (F_1 is an open subset of F_2 by the assumption).

Suppose that a fiber bundle B_1 with fiber F_1 over M has a cross section f_1 . Using f_1 , we can construct a bundle B_2 with fiber F_2 over M which also has a cross section f_2 . The principal bundle of B_2 is given by extending the structure groups from the principal bundle of B_1 . We can show that if B_1 has a soudure with respect to the cross section f_1 , then B_2 also has a soudure with respect to the cross section f_2 . A Cartan connection in the principal fiber bundle P_1 associated with B_1 that is compatible with a given soudure on B_1 induces a Cartan connection in the principal fiber bundle P_2 associated with B_2 , which then

induces a soudure on B_2 . The latter is called a Cartan connection **induced** from the former.

Let F_1 be an n -dimensional linear space and F_2 be the real \dagger projective space of dimension n . Then the affine transformation group of F_1 can be embedded into the projective transformation group of F_2 . Thus the tangent vector bundle of a manifold M induces a fiber bundle over M with the n -dimensional projective space as its fiber. A Cartan connection in this fiber bundle is called a **projective connection** on M . By the argument in this section, we see that every affine connection on M induces a projective connection on M .

Given two affine connections on M , we denote by ∇ and ∇' their corresponding covariant differentials. The two affine connections on M induce the same projective connection on M if and only if there exists a differential form φ of degree 1 on M such that $\nabla'_x Y - \nabla_x Y = \varphi(X)Y + \varphi(Y)X$ for any vector fields X, Y [7]. If a diffeomorphism φ of M preserves the projective connection induced by an affine connection in M , then φ maps geodesics of M into geodesics.

P. Conformal Connections

Let F_1 be an n -dimensional Euclidean space and F_2 an n -dimensional sphere (a \dagger conformal space). We can embed the group of \dagger isometries of F_1 canonically into the group of \dagger conformal transformations of F_2 . A Riemannian metric of the tangent vector bundle of a manifold M of dimension n gives a fiber bundle over M with fiber F_2 . A Cartan connection in this fiber bundle is called a **conformal connection** on M ; a Riemannian connection on M induces a conformal connection on M .

Two Riemannian metrics g_1, g_2 on M induce the same conformal connection on M if and only if there exists a positive function f on M such that $g_2 = fg_1$. Thus for a Riemannian manifold M with metric tensor g_1 , a diffeomorphism φ of M such that $\varphi^*(g) = fg_1$ leaves invariant the conformal connection induced by g_1 . Such a φ is called a **conformal transformation** of M with respect to the given Riemannian metric g_1 .

For a Riemannian manifold M with metric tensor g , we define **Weyl's conformal curvature tensor** W by

$$W_{jkl}^i = R_{jkl}^i + \frac{1}{n-2}(R_{jk}\delta_l^i - R_{jl}\delta_k^i + g_{jk}R_l^i - g_{jl}R_k^i) - \frac{R}{(n-1)(n-2)}(g_{jk}\delta_l^i - g_{jl}\delta_k^i),$$

where the R_{jkl}^i and R_{jk} are components of the curvature tensor and Ricci tensor, respectively,

and R is the scalar curvature (\rightarrow 364 Riemannian Manifolds, 417 Tensor Calculus). When $\dim M \geq 3$, the conformal connection induced by g on M is locally flat if and only if the conformal curvature tensor vanishes [7].

Q. Yang-Mills G -Connection

Let $P = (P, \pi, M, G)$ be a differentiable principal fiber bundle over a compact oriented Riemannian manifold M with group G . Then fiber bundles $G_P = P \times_c G$ and $\mathfrak{g}_P = P \times_{\text{Ad}} \mathfrak{g}$ associated with P are induced naturally from the group conjugation $c: G \rightarrow \text{Aut}(G)$ and the adjoint representation $\text{Ad}: G \rightarrow \text{Aut}(\mathfrak{g})$, respectively. A (local) section of G_P is called a (local) **gauge transformation** of P . The set of all global gauge transformations, which is denoted by \mathcal{G}_P , has a group structure.

A locally faithful representation ρ of G to an n -dimensional complex vector space F with a fixed basis (ξ_1, \dots, ξ_n) defines a differentiable complex vector bundle $E = P \times_\rho F$ associated with P . Every point x of P is identified with a linear mapping \bar{x} of F onto the fiber $E_{\pi(x)}$ defined by $\bar{x}: \xi_i \rightarrow e_i$, where e_i denotes the equivalence class of $\{x, \xi_i\} \in P \times F$, $1 \leq i \leq n$.

In a manner similar to the case of an affine connection, a connection in P with connection form ω gives a notion of parallel displacement of E as follows: Let $c = p_t$ ($0 \leq t \leq 1$) be a curve in M and $c^* = x_t$ be a lift of c to P . The mapping $\bar{x}_t \circ \bar{x}_0^{-1}: E_{p_0} \rightarrow E_{p_t}$ is called the parallel displacement of E_{p_0} onto E_{p_t} along c .

Let X be a vector field on M and φ be a differentiable section of E . The covariant derivative $\nabla_X \varphi$ of φ in the direction of X is defined as follows: Let p_0 be a point of M , $c = p_t$ ($-\varepsilon \leq t \leq \varepsilon$) be an integral curve of X through p_0 and $c^* = x_t$ be a lift of c to P . We set

$$(\nabla_X \varphi)_{p_0} = \lim_{t \rightarrow 0} \frac{1}{t} (\bar{x}_t \circ \bar{x}_0^{-1}(\varphi_{p_t}) - \varphi_{p_0}).$$

Then ∇_X is also a differentiable section of E .

The mapping $(X, \varphi) \rightarrow \nabla_X \varphi$ satisfies the following conditions: (i) $\nabla_X \varphi$ is linear with respect to X and φ ; (ii) $\nabla_{fX} \varphi = f \nabla_X \varphi$; and (iii) $\nabla_X (f\varphi) = (Xf)\varphi + f \nabla_X \varphi$, where f is a differentiable function on M . From these conditions it is seen that the mapping $X \rightarrow \nabla_X \varphi$ for a fixed section φ of E defines a differential form of degree one with values in E , denoted by $\nabla \varphi$. ∇ is called a G -connection on E (induced from the connection in P). A linear operator $d^\nabla: \Gamma(\Lambda^p \otimes E) \rightarrow \Gamma(\Lambda^{p+1} \otimes E)$, defined by $d^\nabla(\alpha \otimes \varphi) = d\alpha \otimes \varphi + (-1)^p \alpha \wedge \nabla \varphi$ for a differential form α of degree p and a differentiable section φ of E is called a covariant exterior differentiation. Here $\Gamma(\Lambda^p \otimes E)$ denotes the set of all differential forms of degree p with values in E .

The curvature form R^∇ of ∇ is defined by $R^\nabla(X, Y)\varphi = \nabla_X(\nabla_Y \varphi) - \nabla_Y(\nabla_X \varphi) - \nabla_{[X, Y]}\varphi$, where X and Y are vector fields on M and φ is a differentiable section of E . In terms of the curvature form Ω of the connection in P , it can be defined also by

$$R_P^\nabla(X, Y)\varphi = \bar{x} \circ \Omega_X(X^*, Y^*) \cdot \bar{x}^{-1}(\varphi),$$

where X and Y are in $T_p M$ and $x \in \pi^{-1}(p)$ and X^*, Y^* are lifts of X, Y to P , respectively, and φ is an element of E_p . Since Ω is a tensorial form of type ad and the differential ρ_* of ρ induces a faithful representation of \mathfrak{g} to $\mathfrak{gl}(F)$, R^∇ can be regarded as a differential form of degree two with values in the bundle $\mathfrak{g}_P = P \times_{\text{Ad}} \mathfrak{g}$.

The curvature form R^∇ satisfies Bianchi's identity: $d^\nabla R^\nabla = 0$, where d^∇ is a covariant exterior differentiation with respect to the G -connection on \mathfrak{g}_P canonically induced from the connection in P .

We denote by \mathcal{C} the set of all G -connections on E . Now let G be a compact semisimple Lie group. A functional $\mathcal{S}: \mathcal{C} \rightarrow \mathbf{R}$ defined by $\nabla \rightarrow \mathcal{S}(\nabla) = -\frac{1}{2} \int_M \text{tr}(R^\nabla \wedge * R^\nabla)$ is called the **action integral (Yang-Mills functional)** of ∇ , where $*$ is Hodge's star operator, given by the fixed orientation of M .

The group \mathcal{G}_P acts on \mathcal{C} by $\nabla \rightarrow f^{-1} \circ \nabla \circ f$ for $f \in \mathcal{G}_P$ and then the curvature form is transformed by this action as $R^\nabla \rightarrow \text{Ad}(f^{-1})R^\nabla$. Thus \mathcal{S} is \mathcal{G}_P -invariant.

A connection ∇ is called a **Yang-Mills G -connection** if ∇ is a critical point of \mathcal{S} . The Euler-Lagrange equation of \mathcal{S} is given by $d^{\nabla*} R^\nabla = 0$ by the aid of the formal adjoint operator $d^{\nabla*}$ of d^∇ . This equation, called the **Yang-Mills equation**, is a system of nonlinear second-order elliptic partial differential equations.

When M is a 4-dimensional vector space \mathbf{R}^4 with Minkowskian metric and G is the Abelian group $U(1)$, the Yang-Mills equation coincides with Maxwell's equations for an electromagnetic field. Thus the Yang-Mills equation for a non-Abelian group G is a natural extension of Maxwell's equations. In fact, the theory of Yang-Mills connections has its origin in the field theory of physics [11].

In the case of $\dim M = 4$, special Yang-Mills G -connections occur. A G -connection ∇ satisfying the condition $*R^\nabla = R^\nabla$ (resp. $*R^\nabla = -R^\nabla$) as a differential form of degree two is called a **self-dual** (resp. **anti-self-dual**) G -connection. From Bianchi's identity and the expression of $d^{\nabla*}: d^{\nabla*} = -* \circ d^\nabla \circ *$, it follows that every self-dual (anti-self-dual) G -connection gives a solution to the Yang-Mills equation. Since the first Pontryagin number $p_1(E)$ is given by $p_1(E) = -(1/4\pi^2) \int_M \text{tr}(R^\nabla \wedge R^\nabla)$ by virtue of the Chern-Weil theorem, the

action integral satisfies $\mathcal{S}(\nabla) \geq 2\pi^2 |p_1(E)|$ for every ∇ in \mathcal{C} and the equality holds if and only if ∇ is self-dual or anti-self-dual.

Explicit forms have been obtained for (anti-) self-dual connections over the 4-sphere S^4 by many interesting methods [12–15]. And it has been shown that moduli space of self-dual G -connections (i.e., the set of all solutions to the Yang-Mills equation modulo \mathcal{G}_P) over S^4 has the structure of a Hausdorff manifold of dimension $p_1(\mathfrak{g}_P) - \dim G$ for every principal bundle P with group G [16, 17]. It is not yet known whether there exists a Yang-Mills G -connection over S^4 whose holonomy group is an open subgroup of G and which is neither self-dual nor anti-self-dual [18]. The following is one of the few known facts concerning the properties of Yang-Mills G -connections: If a Yang-Mills G -connection, $G = SU(2)$, $SU(3)$, or $O(3)$, over S^4 is weakly stable, i.e., if the second variation of \mathcal{S} is positive semidefinite, then it is self-dual or anti-self-dual [19].

81 (I.11) Constructive Ordinal Numbers

A. General Remarks

To extend the theory of \dagger recursive functions to transfinite ordinal numbers, A. Church and S. C. Kleene [1] considered the set of effectively accessible ordinal numbers and defined the concept of constructive ordinal numbers as explained later in this article. Their work became the basis of fruitful research by Kleene, W. Markwald, C. Spector, and others [2–5]. A constructive ordinal number was originally introduced as an “expression” in a \dagger formal system utilizing the λ -notation. Since such a system is “effective,” we can arithmetize it utilizing \dagger Gödel numbers and assume from the outset that each ordinal number is representable by a natural number. The notations, terminology, and theorems mentioned in this article are mainly those for constructive ordinal numbers of the \dagger second number class.

B. Definition and Fundamental Properties

We call a set of natural numbers satisfying conditions (I) and (II) a **system of notations for ordinal numbers**, and an ordinal number a

constructive ordinal number when it is representable by a natural number belonging to such a system of notations: (I) No natural number represents two distinct ordinal numbers. (II) There are three \dagger partial recursive functions $K(x)$, $P(x)$, and $Q(x, n)$ defined as follows: (i) for any natural number x representing X , $K(x)$ takes the value 0, 1, or 2 according as X is zero, an \dagger isolated ordinal number, or a \dagger limit ordinal number, respectively; (ii) when X is the ordinal number \dagger immediately after an ordinal number Y , $P(x)$ represents Y for any natural number x representing X ; (iii) when X is a limit ordinal number, for any natural number x representing X there exists an increasing sequence $\{Y_n\}$ of ordinal numbers such that $X = \lim_n Y_n$ and $Q(x, n)$ represents Y_n for each natural number n .

The system called S_3 by Kleene is the most useful and convenient among systems of notations for ordinal numbers. Let n_0 be a \dagger primitive recursive function of the variable n defined by $0_0 = 1$, $(n+1)_0 = 2^{n_0}$. The fundamental notion $a \in O$ and relation $a <_O b$ of the system S_3 are introduced by the following inductive definition: (1) $1 \in O$; (2) if $y \in O$, then $2^y \in O$ and $y <_O 2^y$; (3) if a sequence $\{y_n\}$ of natural numbers has the property that for each n , $y_n \in O$ and $y_n <_O y_{n+1}$, and if y is a Gödel number that defines y_n recursively as a function of n_0 (i.e., $y_n \cong \{y\}(n_0)$) (\rightarrow 356 Recursive Functions), then $3 \cdot 5^y \in O$, and for each n , $y_n <_O 3 \cdot 5^y$; (4) if $x, y, z \in O$, $x <_O y$, and $y <_O z$, then $x <_O z$; (5) $a \in O$, $a <_O b$ hold only when they follow from (1)–(4).

Now, for brevity, we write $a \leq_O b$ for $(a <_O b) \vee (a = b)$. The following propositions hold for S_3 : (1) If $a <_O b$, then $b \neq 1$; (2) If $a <_O b$, then $a, b \in O$; (3) If $a <_O 2^y$, then $a \leq_O y$; (4) If $a <_O 3 \cdot 5^y$, then there is a natural number n such that $a \leq_O y_n$, where $y_n = \{y\}(n_0)$; (5) If $a \in O$, then $1 \leq_O a$; (6) If $a \in O$, then for any \dagger number-theoretic function α such that $\alpha(0) = a$ and $\forall n(\alpha(n) \neq 1 \rightarrow \alpha(n+1) <_O \alpha(n))$, there is a k such that $\alpha(k) = 1$; (7) For each a , $\neg(a <_O a)$; (8) If $c \in O$, $a \leq_O c$, and $b \leq_O c$, then $a <_O b$ or $a = b$ or $b <_O a$.

Each member a of O represents an ordinal number $|a|$ as follows: $|1| = 0$; $|2^y| = |y| + 1$ for $y \in O$; $|3 \cdot 5^y| = \lim_n |y_n|$ for $3 \cdot 5^y \in O$, where $y_n = \{y\}(n_0)$. Let b be a member of O . Then $|a| < |b|$ when $a <_O b$; and conversely, for each $\alpha < |b|$, there is a number a such that $|a| = \alpha$ and $a <_O b$. Hence the set $\{a | a <_O b\}$ is a \dagger well-ordered set with respect to $<_O$, and its \dagger order type is $|b|$. The least number ξ greater than $|a|$ for every member a of O is the least ordinal number that is not constructive. It is denoted by ω_1^{CK} (Church and Kleene denoted it by ω_1). There is a subsystem of S_3 that is well ordered with respect to \leq_O and contains a

unique notation for each constructive ordinal number α . For such a subsystem we can take a Π_1^1 set K such that K is \dagger recursive in O (S. Feferman and Spector, R. O. Gandy) (\rightarrow 356 Recursive Functions H).

C. Constructive Ordinals and the Kleene Hierarchy

Let $R(x, y)$ be a \dagger predicate on natural numbers. We write $x \leq_R y$ for any natural numbers x, y for which $R(x, y)$ holds. We consider only the case where \leq_R is a \dagger linear ordering on the set $D_R = \{x | \exists y(R(x, y) \vee R(y, x))\}$. If D_R is a well-ordered set with respect to \leq_R , we denote its \dagger order type by $|R|$. (1) For each (constructive) ordinal number $\alpha < \omega_1^{\text{CK}}$, there is a \dagger general recursive (more strictly, \dagger primitive recursive) predicate R such that $|R| = \alpha$ (Markwald, Spector, Kleene [3]). (2) Conversely, if R is a \dagger hyperarithmetical predicate (e.g., R is general recursive), then $|R| < \omega_1^{\text{CK}}$ (Markwald, Spector). The following theorems are the most fruitful ones in the theory of constructive ordinal numbers, and they fully support the validity of Kleene's idea of \dagger analytic hierarchy. (3) The set O is Π_1^1 (\rightarrow 356 Recursive Functions H), and so is the predicate $a <_O b$. Namely, for O , there is a primitive recursive predicate $R(a, x, \alpha)$ such that

$$a \in O \Leftrightarrow \forall x \exists \alpha R(a, x, \alpha)$$

(Kleene [3]). (4) For each ordinal number $\alpha < \omega_1^{\text{CK}}$, the set $\{a | \alpha \geq |a|\}$ is a hyperarithmetical set (Spector). (5) O is a \dagger complete set for Π_1^1 . That is, for any Π_1^1 set E , there is a primitive recursive function φ such that $a \in E \Leftrightarrow \varphi(a) \in O$ (Kleene [3]). Accordingly, O is not a Σ_1^1 set (\rightarrow 356 Recursive Functions H).

D. Relativization and Extension

Given a (number-theoretic) predicate Q of one variable (or a set of natural numbers), we can \dagger relativize to Q the notion of constructive ordinal numbers. The least ordinal that is not constructive relative to Q is denoted by ω_1^Q . The relativization to Q of the fundamental notion $a \in O$ and relation $a <_O b$ of the system S_3 of notations are denoted by $a \in O^Q$ and $a <_{O^Q} b$, respectively. Then we can relativize the results of the preceding paragraphs to Q . For example, as the relativization of (3), we have the following: There is a predicate $R^Q(a, x, \alpha)$ which is primitive recursive \dagger uniformly in Q such that

$$a \in O^Q \Leftrightarrow \forall x \exists \alpha R^Q(a, x, \alpha).$$

When Q is hyperarithmetical, we have no generalization of the constructive ordinal numbers

Constructive Ordinal Numbers

by relativizing them to Q , that is, $\omega_1^Q = \omega_1^{CK}$ holds (Spector). Now by relativizing to O the concept of constructive ordinal numbers, we obtain a proper extension of it ($\omega_1^{CK} < \omega_1^O$), and then, performing such extensions successively, we have a (transfinite) sequence O, O^O, O^{OO}, \dots . On the other hand, we can extend the constructive ordinal numbers to those corresponding to any like higher number class, beyond the second, in which partial recursive functions are used at limit levels to provide an "accessibility" mapping from previously defined number classes. There are several extensions done by Church and Kleene, H. C. Wang, D. L. Kreider and H. Rogers, Jr., H. Putnam, W. Richter, A. Kino and G. Takeuti, and others. Richter [9] has shown that these two ways of extending the constructive ordinals are equivalent, provided the sets of notations for the higher number classes satisfy certain natural conditions. Specifically, the ordinals of the Addison and Kleene [6] constructive third number class are exactly the ordinals less than ω_1^O and the set O_{2^O} of notations for those is recursively isomorphic to O^O (Richter).

E. Constructive Ordinals in Higher Number Classes

Putnum [8] has defined a system C of notations for constructive ordinals of the Cantor higher number classes, improving that of Kreider and Rogers [7], as follows: N_α is the set of notations for the ordinal number α ; if for some α , $x \in N_\alpha$, let $|x| = \mu\xi [x \in N_\xi]$, which is called a **hyperconstructive ordinal**; and let $C_\alpha = \bigcup \{N_\xi \mid \xi < \alpha\}$. Define i to be a Gödel number of the \dagger identity function, and n to be an index in C_α if $3^a \cdot 5^i \in C_\alpha$ for some t . There are four cases:

Case 1. $\alpha = 0$. Then $N_\alpha = \{1\}$.

Case 2. $\alpha = \beta + 1$, where N_β is already defined. Then $N_\alpha = \{2^x \mid x \in N_\beta\}$.

Case 3. α is a limit ordinal such that N_ξ is already defined for all $\xi < \alpha$, and there exists an ordinal $\beta < \alpha$ such that $3^a \cdot 5^i \in N_\beta$ for some a , and a partial recursive function f giving an order-preserving \dagger cofinal mapping (o.p.c.m.) from C_β into C_α . Then N_α is taken to be the set of all numbers $3^a \cdot 5^n$ such that $3^a \cdot 5^i \in N_\beta$ (where β is any ordinal with the above property) and $\{n\}$ is an o.p.c.m. from C_β into C_α .

Case 4. α is a limit ordinal such that N_ξ is already defined for all $\xi < \alpha$, there is no β as in Case 3, but there is a number $a \in C_\alpha$ which is not an index in C_α . Let β_0 be the least β for which such a 's belong to N_β . Then $N_\alpha = \{3^a \cdot 5^n \mid a \in N_{\beta_0} \text{ and } \{n\} \text{ is an o.p.c.m. from } C_\alpha \text{ into } C_\alpha\}$.

We have that $x \in N_\alpha$ only as required by Cases 1–4. Finally, let ω_C be the least ordinal number which is not hyperconstructive, and let $C = C_{\omega_C}$.

Extending Kleene's H_y for $y \in O$ (\rightarrow 356 Recursive Functions H), Putnum has defined a hierarchy H_x for $x \in C$, and shown that hyperconstructive ordinal numbers are uniqueness ordinals, i.e., for $x, y \in C$, if $|x| = |y|$, then H_x and H_y are of the same \dagger degree of (recursive) unsolvability. E_1 is the type-2 object (\rightarrow 356 Recursive Functions F) introduced by T. Tugué such that $E_1(\alpha) = 0$ if $\forall \beta \exists x [\alpha(\beta(x)) = 0]$; otherwise, $E_1(\alpha) = 1$. It is known that $\omega_C = \omega^{E_1}$, where ω^{E_1} is the least ordinal which is not the order type of any well-ordering recursive in E_1 (Richter [10]).

82 (XIII.18) Contact Transformations

A. General Remarks

A transformation of $2n + 1$ variables z, x_j, p_j ($j = 1, 2, \dots, n$),

$$\begin{aligned}
 Z &= Z(z, x_1, \dots, x_n, p_1, p_2, \dots, p_n), \\
 X_j &= X_j(z, x_1, x_2, \dots, x_n, p_1, p_2, \dots, p_n), \\
 &\quad j = 1, 2, \dots, n, \\
 P_j &= P_j(z, x_1, x_2, \dots, x_n, p_1, p_2, \dots, p_n), \\
 &\quad j = 1, 2, \dots, n, \quad (1)
 \end{aligned}$$

is called a **contact transformation** in the $(n+1)$ -dimensional space \mathbf{R}^{n+1} with the coordinate system (z, x_1, \dots, x_n) if the \dagger total differential equation

$$dz - p_1 dx_1 - p_2 dx_2 - \dots - p_n dx_n = 0 \quad (2)$$

is invariant under the transformation, i.e., if the equality

$$\begin{aligned}
 dZ - P_1 dX_1 - P_2 dX_2 - \dots - P_n dX_n \\
 = \rho(dz - p_1 dx_1 - p_2 dx_2 - \dots - p_n dx_n) \quad (3)
 \end{aligned}$$

holds identically for a suitable nonzero function ρ of z, x_j, p_j . Here we assume that (1) has an inverse transformation. Using **Lagrange's bracket**

$$[f, g] = \sum_{j=1}^n \left(\frac{\partial f}{\partial p_j} \left(\frac{dg}{dx_j} \right) - \frac{\partial g}{\partial p_j} \left(\frac{df}{dx_j} \right) \right),$$

$$\left(\frac{df}{dx_j} \right) \equiv \frac{\partial f}{\partial x_j} + p_j \frac{\partial f}{\partial z},$$

we see that (1) is a contact transformation if and only if $[X_j, X_k] = [X_j, Z] = [P_j, P_k] = 0$, $[P_j, X_k] = \rho \delta_{jk}$, $[P_j, Z] = \rho P_j$, where δ_{jk} is \dagger Kronecker's delta.

From this fact it follows that the composite of two contact transformations and the inverse transformation of a contact transformation are also contact transformations. Since the identity transformation $Z = z$, $X_j = x_j$, $P_j = p_j$ is a contact transformation, the set of all contact transformations forms an infinite-dimensional \dagger topological group. Given a set of scalars p_1, \dots, p_n , a pair consisting of a point (z, x_j) and an n -dimensional hyperplane $z^* - z = \sum_{j=1}^n p_j(x_j^* - x_j)$ in an $(n+1)$ -dimensional space is called a **hypersurface element**, and the set of hypersurface elements satisfying (2) is called a **union of hypersurface elements**. Using these concepts, we can state that a transformation (1) of coordinates z, x_j, p_j ($j = 1, 2, \dots, n$) is a contact transformation if it transforms each union of hypersurface elements into another one. Consequently, if two n -dimensional hypersurfaces are tangent at a point (z, x_j) in the $(n+1)$ -dimensional space, their images under a contact transformation, which are again two n -dimensional hypersurfaces, are tangent at the image point of (z, x_j) . The name "contact transformation" is derived from this fact.

For instance, the \dagger correlation with respect to a hypersurface of the second order gives a

contact transformation. In fact, from the relation between \dagger poles and \dagger polar lines with respect to the parabola $x^2 + 2y = 0$ in a plane, we have **Legendre's transformation** $X = -p$, $Y = xp - y$, $P = -x$ ($\rho = -x$).

In general, an invertible transformation defined by the three relations $\Omega(x, y, X, Y) = 0$, $\partial\Omega/\partial X + P\partial\Omega/\partial Y = 0$, $\partial\Omega/\partial x + p\partial\Omega/\partial y = 0$ derived from a function $\Omega(x, y, X, Y)$ is a contact transformation. The function Ω is called the **generating function** of this transformation. In this transformation, to each point (x_0, y_0) there corresponds a curve $\Omega(x_0, y_0, X, Y) = 0$. These results are valid also in the case of several variables. For instance, in an $(n+1)$ -dimensional space, a transformation $Z = z - x_1 p_1 - \dots - x_v p_v$, $X_1 = p_1, \dots, X_v = p_v$, $X_{v+1} = x_{v+1}, \dots, X_n = x_n$; $P_1 = -x_1, \dots, P_v = -x_v$, $P_{v+1} = p_{v+1}, \dots, P_n = p_n$ represents a contact transformation. Here v is an integer between 1 and n . In the case $n=2$, $v=2$, this transformation reduces to a Legendre transformation; and in the case $n=2$, $v=1$, it is called **Ampère's transformation** (\rightarrow Appendix A, Table 15.IV).

B. Canonical Transformations

A transformation of $2n$ variables x_j, p_j ($j = 1, 2, \dots, n$)

$$\begin{aligned}
 X_j &= X_j(x_1, x_2, \dots, x_n, p_1, p_2, \dots, p_n), \\
 P_j &= P_j(x_1, x_2, \dots, x_n, p_1, p_2, \dots, p_n), \\
 &\quad j = 1, 2, \dots, n, \quad (4)
 \end{aligned}$$

is called a **canonical transformation** if the \dagger differential form $\sum_{j=1}^n (P_j dX_j - p_j dx_j)$ is \dagger exact in x_j, p_j , i.e., if there exists a function U of x, p such that

$$\sum_{j=1}^n (P_j dX_j - p_j dx_j) = dU. \quad (5)$$

Let (1) denote a contact transformation, and let λ denote a new variable which is different from zero. Set $\bar{x}_0 = z$, $\bar{p}_0 = \lambda$, $\bar{x}_j = x_j$, $\bar{p}_j = -\lambda p_j$ ($j = 1, 2, \dots, n$) and define a transformation of $(2n+2)$ variables by

$$\begin{aligned}
 \bar{X}_0(\bar{x}, \bar{p}) &= Z(z, x, p), \\
 \bar{P}_0(\bar{x}, \bar{p}) &= \bar{P}_0/\rho(z, x, p), \quad \bar{X}_j(\bar{x}, \bar{p}) = X_j(x, p), \\
 \bar{P}_j(\bar{x}, \bar{p}) &= -\bar{p}_0 P_j(z, x, p)/\rho(z, x, p), \\
 &\quad j = 1, 2, \dots, n, \quad (6)
 \end{aligned}$$

where x, p, \bar{x} , and \bar{p} denote points (x_1, x_2, \dots, x_n) , (p_1, p_2, \dots, p_n) , $(\bar{x}_0, \bar{x}_1, \dots, \bar{x}_n)$, and $(\bar{p}_0, \bar{p}_1, \dots, \bar{p}_n)$, respectively. Then the identity (3) when multiplied by λ on both sides becomes

$$\begin{aligned}
 \bar{P}_0 d\bar{X}_0 + \bar{P}_1 d\bar{X}_1 + \dots + \bar{P}_n d\bar{X}_n \\
 = \bar{p}_0 d\bar{x}_0 + \bar{p}_1 d\bar{x}_1 + \dots + \bar{p}_n d\bar{x}_n. \quad (7)
 \end{aligned}$$

Contact Transformations

Thus the transformation (6) represents a canonical transformation ($U = \text{constant}$). Moreover, from the definition the relation (6) is homogeneous, i.e., for all $\mu \neq 0$,

$$\bar{X}_j(\bar{x}, \mu\bar{p}) = \bar{X}_j(\bar{x}, \bar{p}), \quad \bar{P}_j(\bar{x}, \mu\bar{p}) = \mu\bar{P}_j(\bar{x}, \bar{p}),$$

$$j=0, 1, \dots, n.$$

Conversely, let a transformation of $(2n+2)$ variables

$$\bar{X}_j = \bar{X}_j(\bar{x}, \bar{p}), \quad \bar{P}_j = \bar{P}_j(\bar{x}, \bar{p}),$$

$$j=0, 1, \dots, n, \quad (8)$$

be a **homogeneous canonical transformation**.

Define a transformation of $(2n+1)$ variables z, x_j, p_j ($j=1, 2, \dots, n$) by

$$Z(z, x, p) = \bar{X}_0(z, x_1, \dots, x_n, \lambda, -\lambda p_1, \dots, -\lambda p_n),$$

$$1/\rho(z, x, p)$$

$$= \frac{1}{\lambda} \bar{P}_0(z, x_1, \dots, x_n, \lambda, -\lambda p_1, \dots, -\lambda p_n),$$

$$X_j(z, x, p) = \bar{X}_j(z, x_1, \dots, x_n, \lambda, -\lambda p_1, \dots, -\lambda p_n),$$

$$P_j(z, x, p)$$

$$= -\frac{\rho}{\lambda} \bar{P}_j(z, x_1, \dots, x_n, \lambda, -\lambda p_1, \dots, -\lambda p_n),$$

$$j=1, 2, \dots, n. \quad (9)$$

Since the necessary and sufficient condition for (8) to be a homogeneous canonical transformation is that (7) hold, it follows that

$$\frac{\lambda}{\rho} (dZ - P_1 dX_1 - \dots - P_n dX_n)$$

$$= \lambda(dz - p_1 dx_1 - \dots - p_n dx_n).$$

Thus the transformation (9) represents a contact transformation. Therefore the most general contact transformation of $(2n+1)$ variables and the most general homogeneous canonical transformation are identical concepts, differing only in the choice of notation.

The necessary and sufficient condition for (4) to be a canonical transformation is expressed by the relations

$$(X_j, X_k) = 0, \quad (X_j, P_k) = \delta_{jk}, \quad (P_j, P_k) = 0,$$

$$j, k = 1, 2, \dots, n, \quad (10)$$

where (\cdot, \cdot) is **Poisson's bracket**, i.e., for a pair of functions $f(x, p), g(x, p)$,

$$(f, g) = \sum_{j=1}^n \left(\frac{\partial f}{\partial x_j} \frac{\partial g}{\partial p_j} - \frac{\partial f}{\partial p_j} \frac{\partial g}{\partial x_j} \right).$$

Denote Poisson's bracket in the coordinate system $X_1, X_2, \dots, X_n, P_1, P_2, \dots, P_n$ by $(\cdot, \cdot)'$, and for $f(x, p)$ and $g(x, p)$ denote their transformations by $f'(X, P)$ and $g'(X, P)$. Then the relation (10) is equivalent to

$$(f, g) = (f', g') \quad \text{for all } f \text{ and } g.$$

From this fact it follows that the set of all canonical transformations forms an infinite-dimensional topological group.

Suppose that we can take $x_1, x_2, \dots, x_n, X_1, X_2, \dots, X_n$ as $2n$ independent variables. Denote by $\Omega_1(x, X)$ the function U of (5) represented by x, X . By means of this Ω_1 , $2n$ functions which give a canonical transformation (4) are derived from the relations

$$p_j = -\frac{\partial \Omega_1}{\partial x_j}, \quad P_j = \frac{\partial \Omega_1}{\partial X_j}, \quad j=1, 2, \dots, n.$$

Conversely, for $\Omega(x, X)$ such that $\det \left(\frac{\partial^2 \Omega}{\partial x_j \partial X_k} \right) \neq 0$, a transformation determined by the relations

$$p_j = -\frac{\partial \Omega}{\partial x_j}, \quad P_j = \frac{\partial \Omega}{\partial X_j}, \quad j=1, 2, \dots, n,$$

represents a canonical transformation. For a general canonical transformation, $x_1, x_2, \dots, x_n, X_1, X_2, \dots, X_n$ are not necessarily $2n$ independent variables. But for a canonical transformation there exists n new variables $X_{i_1}, X_{i_2}, \dots, X_{i_k}, P_{j_1}, \dots, P_{j_{n-k}}$ such that $x_1, x_2, \dots, x_n, X_{i_1}, X_{i_2}, \dots, X_{i_k}, P_{j_1}, P_{j_2}, \dots, P_{j_{n-k}}$ are $2n$ independent variables, where $(i_1, i_2, \dots, i_k), (j_1, j_2, \dots, j_{n-k})$ is a partition of the set $(1, 2, \dots, n)$ to two disjoint subsets. Denote by Ω_2 the function $U - \sum_{i=1}^{n-k} X_{i_i} P_{j_i}$. Then the transformation (4) is derived from relations

$$p_j = -\frac{\partial \Omega_2}{\partial x_j}, \quad j=1, 2, \dots, n,$$

$$X_{j_l} = -\frac{\partial \Omega_2}{\partial P_{j_l}}, \quad l=1, 2, \dots, n-k,$$

$$P_{i_l} = \frac{\partial \Omega_2}{\partial X_{i_l}}, \quad l=1, 2, \dots, k.$$

These functions Ω_1, Ω_2 are called the **generating functions** of a canonical transformation.

Consider a transformation of $2n$ variables depending smoothly on a parameter t :

$$X_j = X_j(t, x_1, x_2, \dots, x_n, p_1, p_2, \dots, p_n),$$

$$P_j = P_j(t, x_1, x_2, \dots, x_n, p_1, p_2, \dots, p_n),$$

$$j=1, 2, \dots, n. \quad (11)$$

If (11) represents a canonical transformation of $2n$ variables for each t , then X_j and P_j , $j=1, 2, \dots, n$, satisfy Hamilton's canonical equations

$$\frac{dX_j}{dt} = \frac{\partial H}{\partial P_j}(t, X, P), \quad \frac{dP_j}{dt} = -\frac{\partial H}{\partial X_j}(t, X, P),$$

$$j=1, 2, \dots, n, \quad (12)$$

for some Hamiltonian function $H(t, x, p)$.

Conversely, for any solution X_j, P_j of Hamilton's canonical equations (12) depending on

parameters $x_1, x_2, \dots, x_n, p_1, p_2, \dots, p_n$, if the transformation (11) is a canonical transformation for $t=0$, (11) represents a canonical transformation for each t . By a canonical transformation (4), the solutions of Hamilton's canonical equations

$$\frac{dx_j}{dt} = \frac{\partial H}{\partial p_j}(t, x, p), \quad \frac{dp_j}{dt} = -\frac{\partial H}{\partial x_j}(t, x, p), \quad j=1, 2, \dots, n, \quad (13)$$

are transformed to the solutions of

$$\frac{dX_j}{dt} = \frac{\partial K}{\partial P_j}(t, X, P), \quad \frac{dP_j}{dt} = -\frac{\partial K}{\partial X_j}(t, X, P), \quad j=1, 2, \dots, n, \quad (14)$$

where the new Hamiltonian function is given by $K(t, X, P) = H(t, x, p)$.

C. Applications to the Integration of Differential Equations

Contact transformations have applications to the integration of differential equations since they transform each union of surface elements into another one.

As an example, we shall describe an outline of their application to a partial differential equation of the first order

$$F(x, y, z, p, q) = 0;$$

$$p \equiv \partial z / \partial x, \quad q \equiv \partial z / \partial y. \quad (15)$$

For this purpose, we regard (15) as an equation defining unions of surface elements and transform it into a simpler equation by means of a contact transformation. If the transformed equation can be solved, then the solution of the original equation can be obtained by means of the inverse transformation. Now, let $z = \omega(x, y, a, b)$ be a †complete solution of (15). Then (15) is reduced to $Z - c = 0$ by the transformation generated by the function

$$\Omega \equiv Z - z + \omega(x, y, X, Y) - c = 0,$$

where c is a constant. In this equation the solution $X = a, Y = b, Z = c, \alpha P + \beta Q = 0$ (a, b, c, α, β are constants) plays an important role, and this line element will be called a **characteristic line element**. The characteristic line element satisfies equations that can be transformed by means of the inverse transformation into **Charpit's subsidiary equations** for (15):

$$\begin{aligned} \frac{dx}{\partial F / \partial p} &= \frac{dy}{\partial F / \partial q} = \frac{dz}{p \partial F / \partial p + q \partial F / \partial q} \\ &= \frac{-dp}{\partial F / \partial x + p \partial F / \partial z} = \frac{-dq}{\partial F / \partial y + q \partial F / \partial z}. \end{aligned} \quad (16)$$

Consequently, if we have $p = p(x, y, z; a), q =$

$q(x, y, z; a)$ from the solution $G(x, y, z, p, q) = a$ of (16) and $F = 0$, then the total differential equation $dz = p dx + q dy$ is †completely integrable, and the †general solution of this equation is a complete solution of (15). Also, if we know two independent solutions $G(x, y, z, p, q) = a, H(x, y, z, p, q) = b$ of (16) such that $[G, H] = 0$, we can obtain a complete integral of (15) by eliminating p, q among the three equations $F = 0, G = a, H = b$. This method is called the †Lagrange-Charpit method, which is applicable also to the equation $F(z, x_1, \dots, x_n; p_1, \dots, p_n) = 0$ (\rightarrow 322 Partial Differential Equations (Methods of Integration)).

D. Applications to Analytical Dynamics

Consider Hamilton's canonical equations (13). An example of system (13) is the equation of motion for a dynamical system which is derived from $\delta \int L(x_j, \dot{x}_j) dt = 0$. Here the x_j denote generalized coordinates, $p_j = \partial L / \partial \dot{x}_j$ and $H = \sum_{j=1}^n p_j \dot{x}_j - L$.

Let $S(x_1, x_2, \dots, x_n, X_1, X_2, \dots, X_n)$ be a solution depending on parameters X_1, X_2, \dots, X_n of the †Hamilton-Jacobi equation

$$\begin{aligned} H\left(t, x_1, x_2, \dots, x_n, -\frac{\partial S}{\partial x_1}, -\frac{\partial S}{\partial x_2}, \dots, -\frac{\partial S}{\partial x_n}\right) \\ = K(X_1, X_2, \dots, X_n) \end{aligned} \quad (17)$$

such that $\det \left(\frac{\partial^2 S}{\partial x_j \partial X_k} \right) \neq 0$. Then by a canonical transformation of a generating function S , i.e., by a transformation determined by the relations

$$p_j = -\frac{\partial S}{\partial x_j}, \quad P_j = \frac{\partial S}{\partial X_j}, \quad j=1, 2, \dots, n,$$

the system (13) is transformed to (14). Here

$$K(t, X, P) = H\left(t, x, -\frac{\partial S}{\partial x}\right) = K(X).$$

Then (14) becomes

$$\frac{dX_j}{dt} = 0, \quad \frac{dP_j}{dt} = -\frac{\partial K}{\partial X_j}(X), \quad j=1, 2, \dots, n,$$

and the solutions are

$$X_j(t) = X_j(0), \quad P_j(t) = P_j(0) - t \frac{\partial K}{\partial X_j} \Big|_{X=X(0)}$$

In particular, a transformation that makes $K \equiv 0$ is called a **transformation to an equilibrium system**. Thus solving Hamilton's canonical equations reduces to finding a †general solution of the Hamilton-Jacobi equation (17).

When the variables of the Hamilton-Jacobi equation (17) are totally separable we can obtain a general solution of (17) by †quadra-

tures. Then one can integrate by quadratures the system of equations (13). For many important problems exact solutions are obtained by this method (\rightarrow 271 Mechanics).

Furthermore, every mapping in an optical system is a canonical transformation; in optics, the quantity corresponding to S is called an **eikonal** (\rightarrow 180 Geometric Optics).

83 (V.3) Continued Fractions

A. The Notion of Continued Fractions

Let $\{b_n\}$ ($n=0, \dots, m$) and $\{c_n\}$ ($n=1, \dots, m$) be finite sequences of elements in a \dagger field F . A fraction of the form

$$b_0 + \frac{c_1}{b_1 + \frac{c_2}{b_2 + \dots + \frac{c_{m-1}}{b_{m-1} + \frac{c_m}{b_m}}}}$$

is called a **finite continued fraction**. It expresses an element in the field F unless division by 0 occurs in the process of reduction. Symbolically, it is also written in the forms

$$b_0 + \frac{c_1}{b_1} + \frac{c_2}{b_2} + \dots + \frac{c_{m-1}}{b_{m-1}} + \frac{c_m}{b_m},$$

$$b_0 + \frac{c_1}{|b_1|} + \frac{c_2}{|b_2|} + \dots + \frac{c_{m-1}}{|b_{m-1}|} + \frac{c_m}{|b_m|},$$

$$b_0 + \frac{c_1}{b_1} + \frac{c_2}{b_2} + \dots + \frac{c_{m-1}}{b_{m-1}} + \frac{c_m}{b_m},$$

$$\left[b_0, \frac{c_1}{b_1}, \frac{c_2}{b_2}, \dots, \frac{c_{m-1}}{b_{m-1}}, \frac{c_m}{b_m} \right],$$

etc., or more briefly,

$$b_0 + \left[\frac{c_n}{b_n} \right]_{n=1}^m.$$

If $\{b_n\}$ ($n=0, 1, \dots$) and $\{c_n\}$ ($n=1, 2, \dots$) are infinite sequences, the expression

$$b_0 + \frac{c_1}{b_1 + \frac{c_2}{b_2 + \dots + \frac{c_n}{b_n + \dots}}}$$

is called an **infinite continued fraction**. By analogy with the finite case, it is expressed by

$$b_0 + \frac{c_1}{b_1} + \frac{c_2}{b_2} + \dots + \frac{c_n}{b_n} + \dots$$

$$\text{or by } b_0 + \left[\frac{c_n}{b_n} \right]_{n=1}^{\infty}.$$

For an infinite continued fraction, the quantity

$$k_n = b_0 + \frac{c_1}{b_1} + \dots + \frac{c_n}{b_n}, \quad k_0 = b_0$$

is called its n th **convergent**, b_0 is called the **initial term**, and c_n and b_n ($n \geq 1$) are called the **partial numerator** and **partial denominator**, respectively. If F is a \dagger topological field (e.g., the real or complex number field) and the sequence $\{k_n\}$ of its elements converges, then the infinite continued fraction is said to **converge**, and the limit is called its **value**.

A finite or infinite continued fraction in which c_n ($n \geq 1$) are all equal to 1, b_0 is a rational integer, and b_n ($n \geq 1$) are all positive rational integers is called a **simple continued fraction**. It is expressed by $[b_0, b_1, \dots]$. b_n is often called the n th **partial quotient**. In the following paragraphs we shall mostly discuss simple continued fractions.

For a real number x we mean by $[x]$ the greatest integer not exceeding x . $[]$ is called the **Gauss symbol**. Let ω be any given real number, and put

$$\omega = b_0 + \frac{1}{\omega_1}, \quad b_0 = [\omega];$$

$$\omega_n = b_n + \frac{1}{\omega_{n+1}}, \quad b_n = [\omega_n], \quad n = 1, 2, \dots$$

Then an expansion of ω into a simple continued fraction

$$\omega = b_0 + \frac{1}{b_1} + \dots + \frac{1}{b_n} + \dots$$

is obtained. If ω is irrational, this expansion is determined uniquely. Conversely, any infinite simple continued fraction converges to an irrational number. If ω is rational, the process is interrupted at a finite step ($\omega_m = b_m$), resulting in

$$\omega = b_0 + \frac{1}{b_1} + \dots + \frac{1}{b_m}.$$

An alternative representation of a rational number by a simple continued fraction is given by replacing b_m above by $(b_m - 1) + 1/1$.

Examples of infinite simple continued fractions are

$$\frac{e^{2/p} + 1}{e^{2/p} - 1} = p + \frac{1}{3p + \dots + \frac{1}{(2n+1)p + \dots}},$$

where p is a natural number (J. H. Lambert), and

$$e = 2 + \frac{1}{1 + \frac{1}{2 + \frac{1}{1 + \dots + \frac{1}{1 + \frac{1}{2n + \frac{1}{1 + \dots}}}}}}$$

(L. Euler).

B. Convergents

Let the n th convergent of a simple continued fraction be expressed in the form of an irreducible fraction

$$\frac{P_n}{Q_n} = b_0 + \frac{1}{b_1 + \dots + b_n}, \quad n \geq 0,$$

and for convenience put $P_{-2} = 0$, $P_{-1} = 1$, $Q_{-2} = 1$, $Q_{-1} = 0$. Then we have the recurrence relations

$$P_n = b_n P_{n-1} + P_{n-2}, \quad Q_n = b_n Q_{n-1} + Q_{n-2}, \quad n \geq 0,$$

whence follows

$$P_n Q_{n-1} - P_{n-1} Q_n = (-1)^{n+1}, \quad n \geq -1.$$

Any simple continued fraction represents a real number ω which satisfies

$$\omega = (\omega_{n+1} P_n + P_{n-1}) / (\omega_{n+1} Q_n + Q_{n-1})$$

in terms of the notation defined in this and the previous section.

In particular, let ω be an irrational number. Then each of the fractions

$$\frac{P_n^{(k)}}{Q_n^{(k)}} = \frac{P_{n-2} + k P_{n-1}}{Q_{n-2} + k Q_{n-1}}, \quad k = 1, 2, \dots, b_n - 1,$$

which are inserted between two convergents P_{n-2}/Q_{n-2} and $P_n/Q_n = (P_{n-2} + b_n P_{n-1}) / (Q_{n-2} + b_n Q_{n-1})$, is called an **intermediate convergent**, while the original convergent P_n/Q_n is called a **principal convergent**.

If a fraction P/Q approximating an irrational number ω satisfies $|\omega - P/Q| < |\omega - p/q|$ for any other fraction p/q with $q \leq Q$, then it is said to give the **best approximation**. The fraction giving the best approximation of ω is always a principal or intermediate convergent $P_n^{(k)}/Q_n^{(k)}$ of ω with $k > b_n/2$ or $k = b_n/2$, $Q_n > Q_{n-1} \omega_n$.

The convergents satisfy the relation $P_n/Q_n - P_{n-1}/Q_{n-1} = (-1)^{n-1} Q_n Q_{n-1}$; hence the se-

quence $\{P_{2n}/Q_{2n}\}$ (resp. $\{P_{2n+1}/Q_{2n+1}\}$) is monotonically increasing (decreasing). Approximation by convergents is shown in the relations

$$\left| \omega - \frac{P_n}{Q_n} \right| \leq \frac{1}{Q_{n+1} Q_n}, \quad \left| \omega - \frac{P_n}{Q_n} \right| < \left| \omega - \frac{P_{n-1}}{Q_{n-1}} \right|,$$

$$\omega = \lim_{n \rightarrow \infty} \frac{P_n}{Q_n} = b_0 + \sum_{n=0}^{\infty} \frac{(-1)^n}{Q_{n+1} Q_n}.$$

In particular, $|\omega - P_n/Q_n| < 1/Q_n^2$. On the other hand, if P, Q are relatively prime positive integers with $|\omega - P/Q| < 1/2Q^2$, then P/Q is a convergent to ω (A. M. Legendre). There are several results concerning the measure of approximation by convergents. Any ω satisfies $|\omega - P_n/Q_n| < 1/(\sqrt{5} Q_n^2)$ for infinitely many n , while there exists an ω which satisfies $|\omega - P_n/Q_n| < 1/(\lambda Q_n^2)$ for only a finite number of n provided that $\lambda > \sqrt{5}$ (e.g., $\omega = \sqrt{5}$, A. Hurwitz); at least one of two adjacent convergents satisfies the inequality $|\omega - P_n/Q_n| < 1/(2Q_n^2)$ (K. T. Vahlen); at least one of three consecutive convergents satisfies the inequality $|\omega - P_n/Q_n| < 1/(\sqrt{5} Q_n^2)$ (E. Borel); $|\omega - P/Q| < 1/\sqrt{8} Q^2$ has infinitely many rational solutions P/Q whenever ω is not equivalent to $(\sqrt{5} + 1)/2$ (Hurwitz). One calls an irrational number ω **badly approximable** if there is a constant $c = c(\omega) > 0$ such that $|\omega - P/Q| > c/Q^2$ for every rational P/Q . ω is badly approximable precisely if the partial quotients of the continued fraction expansion of ω are bounded. In particular, real quadratic irrationals have bounded partial quotients (\rightarrow Section C; 182 Geometry of Numbers F).

C. Quadratic Irrationals

If an infinite simple continued fraction

$[b_0, b_1, \dots]$ satisfies $b_{m+k+v} = b_{m+v}$ ($v = 0, 1, 2, \dots$), it is called a **periodic continued fraction** and is denoted by the symbol

$[b_0, b_1, \dots, b_m, \dots, b_{m+k-1}]$. According as $m = 0$ or $m > 1$, the periodic continued fraction is said to be **pure** or **mixed**, and the sequence $b_m, b_{m+1}, \dots, b_{m+k-1}$ is called a **period**. In order for the continued fraction of ω to be periodic, it is necessary and sufficient that ω be a quadratic irrational number, i.e., a root of $ax^2 + bx + c = 0$ with rational integral coefficients a, b, c and nonsquare discriminant $b^2 - 4ac$ (J. L. Lagrange). In order for ω to be represented by a purely periodic continued fraction, it is necessary and sufficient that ω be an **irreducible quadratic irrational number**, i.e., that ω satisfy $\omega > 1$ and $0 > \omega' > -1$, where ω' is the conjugate root of ω (E. Galois). In order for ω to be equal to the square root of a nonsquare rational number, it is necessary and sufficient

that its continued fraction be of the form $[b_0, b_1, \dots, b_{k-1}, 2b_0]$ (Legendre).

D. Application to Pell's Equation

Let $ax - by = 1$ ($(a, b) = 1$) be a \dagger Diophantine equation of the first degree, and $a/b = [b_0, b_1, \dots, b_m] = P_m/Q_m$. Since $P_m Q_{m-1} - P_{m-1} Q_m = (-1)^{m-1}$, a solution of the equation is given by $x_0 = (-1)^{m-1} Q_m$, $y_0 = (-1)^m P_m$. The general solution is then represented in the form $x_0 + bt$, $y_0 + at$ ($t \in \mathbf{Z}$). This method of obtaining a solution is essentially the same as the method which uses the \dagger Euclidean algorithm.

Pell's equation $x^2 - Dy^2 = 1$ (D is a non-square integer > 1) was solved by Lagrange in terms of continued fractions. If the length of the period of D is k , all positive solutions of Pell's equation are given by $x = P_{2vk-1}$, $y = Q_{2vk-1}$ if k is odd, and by $x = P_{vk-1}$, $y = Q_{vk-1}$ if k is even ($v = 1, 2, \dots$), where P_n/Q_n denotes the n th convergent of the continued fraction expansion of \sqrt{D} . Incidentally, $x = P_{(2v-1)k-1}$, $y = Q_{(2v-1)k-1}$ ($v = 1, 2, \dots$) are the positive solutions of $x^2 - Dy^2 = -1$ provided that k is odd. There are no solutions of $x^2 - Dy^2 = \pm 1$ other than x_v, y_v ($v = 1, 2, \dots$) given by $(x_1 + \sqrt{D} y_1)^v = x_v + \sqrt{D} y_v$, where x_1, y_1 is the least positive solution. For instance, the least positive solution of $x^2 - 211y^2 = 1$ is $x = 278,354,373,650$, $y = 19,162,705,353$.

Lagrange made further use of continued fractions in order to obtain approximate values of roots of algebraic equations. The method is especially useful for precise computation of neighboring roots.

The theory of continued fractions may be investigated geometrically making use of lattices ([2, 3]; \rightarrow 182 Geometry of Numbers) (F. Klein, G. Humbert). For instance, a measure of approximation of P_n/Q_n to ω in Diophantine approximation is represented by the closeness of a lattice point (P_n, Q_n) to the straight line $y = \omega x$ on the plane.

E. Continued Fractions with Variable Terms

There are few results on continued fractions with variable terms. It is noteworthy that from the expansion of $\tan z$ into a continued fraction

$$\tan z = \frac{z}{1 + \frac{-z^2}{3 + \frac{-z^2}{5 + \frac{-z^2}{7 + \dots}}}}$$

(Lambert), the irrationality of π and of $\tan z$ for rational z ($\neq 0$) can be deduced (A. Pringsheim).

Among continued fractions with variable

terms, those of the form

$$[a_0, a_n z]_1^\infty = \frac{a_0}{1} + \frac{a_1 z}{1} + \dots + \frac{a_n z}{1} + \dots$$

are called **normal continued fractions**. Let the convergent of such a continued fraction be $P_n(z)/Q_n(z)$, and for convenience put $P_{-1}(z) = 0$, $Q_{-1}(z) = 1$. Then we have the recurrence formulas

$$P_n(z) = P_{n-1}(z) + a_n z P_{n-2}(z),$$

$$Q_n(z) = Q_{n-1}(z) + a_n z Q_{n-2}(z), \quad n \geq 1.$$

There are the further relations

$$P_n(z) Q_{n-1}(z) - P_{n-1}(z) Q_n(z) = (-1)^n z^n \prod_{v=0}^n a_v,$$

$$[a_0, a_n z]_1^\infty = \sum_{n=0}^{\infty} \frac{(-1)^n z^n}{Q_{n-1}(z) Q_n(z)} \prod_{v=0}^n a_v,$$

where the latter is formal. Let the \dagger power series expansion of the n th convergent of $[a_0, a_n z]_1^\infty$ be

$$\frac{P_n(z)}{Q_n(z)} = \sum_{v=0}^{\infty} b_{nv} z^v, \quad n \geq 1.$$

Then $b_{mv} = b_{nv}$ ($0 \leq v \leq m \leq n$). If $[a_0, a_n z]_1^\infty$ has a power series expansion about the origin, then

$$[a_0, a_n z]_1^\infty = \sum_{n=0}^{\infty} b_{nn} z^n.$$

If the supremum \bar{g} of $\{|a_n|\}_1^\infty$ is finite, then $[a_0, a_n z]_1^\infty$ converges uniformly for $|z| \leq (1/4)\bar{g}$, and hence it represents an \dagger analytic function which is holomorphic in $|z| < (1/4)\bar{g}$.

84 (X.2) Continuous Functions

A. General Remarks

The notion of continuity is defined for a mapping or a function $f: X \rightarrow Y$ from a topological space X to a topological space Y (\rightarrow 425 Topological Spaces G). In the present article, however, we are concerned mainly with the case where both X and Y are \dagger metric spaces with the distances ρ_X and ρ_Y , respectively. The most usual case is $X = \mathbf{R}^n$ (Euclidean space), $Y = \mathbf{R}$ (real numbers).

A function $f: X \rightarrow Y$ is said to be **continuous** at a point $x_0 \in X$ if for every positive number ε , we can select a suitable positive number δ (depending on ε and also on x_0) such that $\rho_X(x, x_0) < \delta$ implies $\rho_Y(f(x), f(x_0)) < \varepsilon$. This is equivalent to the condition that $x \rightarrow x_0$ implies $f(x) \rightarrow f(x_0)$ (\rightarrow 87 Convergence). We call f **continuous** (on X) if it is continuous at every point x_0 of X . If for every positive number ε , we can select a suitable positive number δ independent of x and y such that $\rho_X(x, y) < \delta$ implies $\rho_Y(f(x), f(y)) < \varepsilon$ for all $x, y \in X$, we call f **uniformly continuous** on X .

The \dagger supremum $\omega(\delta)$ of $\rho_Y(f(x), f(y))$ for $x, y \in X$ satisfying $\rho_X(x, y) < \delta$ is called the **modulus of continuity** of the function f in X . Uniform continuity means that $\omega(\delta) \rightarrow 0$ for $\delta \rightarrow 0$.

If $\omega(\delta) \leq M\delta^\alpha$ for suitable constants $M, \alpha > 0$, that is, if the inequality $\rho_Y(f(x), f(y)) \leq M(\rho_X(x, y))^\alpha$ holds for $x, y \in X$, then f is said to satisfy the **Hölder condition of order α** , also known as the **Lipschitz condition of order α** . If $\alpha = 1$, this condition is called simply the **Lipschitz condition**. A function satisfying one of these conditions is uniformly continuous. The family of functions satisfying the Lipschitz condition of order α is sometimes denoted by **Lip α** .

In general, the composite function $g \circ f: X \rightarrow Z$ is continuous if both functions $f: X \rightarrow Y$ and $g: Y \rightarrow Z$ are continuous. If the ranges of f, g are both the real field \mathbf{R} (or the complex field \mathbf{C} , or more generally a \dagger topological field), then $f \pm g, fg$ are continuous if f and g are continuous; and f/g is continuous provided that $g(x) \neq 0$. If \mathbf{R} is the range of both f and g , then $\min(f, g)$ and $\max(f, g)$ are continuous when f and g are continuous. If X is \dagger connected (for example, an interval I in \mathbf{R}) and if f is continuous, the image $f(X)$ is also connected.

B. Continuity from One Side

In this section, we always assume that the domain X is an interval I in \mathbf{R} and f is a func-

tion from I to a metric space Y . A point x_0 of X is called a **discontinuity (point) of the first kind** of f if both limits $\lim_{x \uparrow x_0} f(x)$ and $\lim_{x \downarrow x_0} f(x)$ exist in Y and are different. Then we say also that f has a **jump** (or **gap**) at x_0 . If these two limits exist and have the same value, then f is continuous at x_0 .

We say that f has a **discontinuity of at most the first kind** at x_0 if f is continuous at x_0 or if x_0 is a discontinuity of the first kind for f . (Sometimes the phrase “discontinuity of the first kind” is used to mean “discontinuity of at most the first kind.”) A **discontinuity point** of f (i.e., a point at which f is not continuous) that is not of the first kind is called a **discontinuity point of the second kind**. When $\lim_{x \downarrow x_0} f(x) = f(x_0)$, we call f **right continuous** (or **continuous from the right**) at x_0 . In this case, $\lim_{x \uparrow x_0} f(x)$ need not exist. Replacing $x \downarrow x_0$ by $x \uparrow x_0$, we can similarly define the concept of being **left continuous** (or **continuous from the left**). If a function f has a finite number of discontinuity points of the first kind in the interval $[a, b]$ and is continuous at all other points, we call f a **piecewise continuous function** in $[a, b]$.

C. Semicontinuous Functions

In this section, we assume that the domain of the functions is a subset E of a metric space X , and that the range is the set of real numbers extended to include $\pm\infty$. Let x be a point in the closure of E . We denote by $M(x, \delta)$ and $m(x, \delta)$, respectively, the supremum and the infimum of the values of a given function f in the δ -neighborhood of x . We put

$$M(x) = \lim_{\delta \rightarrow 0} M(x, \delta), \quad m(x) = \lim_{\delta \rightarrow 0} m(x, \delta),$$

and call them the **upper limit function** and **lower limit function**, respectively. We have $-\infty \leq m(x) \leq M(x) \leq +\infty$. If $M(x_0) = f(x_0)$ at $x_0 \in E$, then f is called **upper semicontinuous** at x_0 . If $m(x_0) = f(x_0)$ at $x_0 \in E$ (i.e., if $-f$ is upper semicontinuous at x_0), then f is called **lower semicontinuous** at x_0 . The function with one of these two properties is said to be **semicontinuous** at x_0 .

Either of the following two conditions is necessary and sufficient for the function f to be upper semicontinuous at $x_0 \in E$: (1) $f(x_0) = +\infty$, or for every constant λ such that $f(x_0) < \lambda$, there exists a δ -neighborhood such that $M(x_0, \delta) < \lambda$. (2) For every sequence x_n of E converging to x_0 we have $\limsup_{n \rightarrow \infty} f(x_n) = f(x_0)$.

A function f is called **upper (lower) semicontinuous in E** if it is upper (lower) semicontinuous at every point $x \in E$. A necessary and sufficient condition for the upper semicontinu-

ity of the function $f(x)$ in E is that $\{x|f(x)<\alpha\}$ be a \dagger relatively open set in E for every real number α . We can define semicontinuity for functions on a topological space by using this latter property.

A real-valued function $f(x)$ is continuous at $x_0 \in E$ if and only if it is upper and lower semicontinuous at x_0 and $f(x_0)$ is finite. A function $f(x)$ is continuous on E if and only if it takes finite real values on E and both $\{x|f(x)<\alpha\}$ and $\{x|f(x)>\alpha\}$ are relatively open in E for any real number α . When E is \dagger compact, an upper (lower) semicontinuous function on E attains its (supremum) infimum at a point in E . In particular, a continuous function on a compact set E is bounded and assumes its maximum and minimum on E (**Weierstrass's theorem**). Furthermore, if E is connected (e.g., the interval I in \mathbf{R}), it follows from the connectedness of the image $f(E)$ that if $\alpha, \beta \in f(E)$ and γ lies between α and β , then $\gamma \in f(E)$ (**intermediate-value theorem**).

A real-valued function $f(x)$ on a set E of \mathbf{R} satisfies the Lipschitz condition if it is \dagger differentiable and the derivative is bounded. Such a function is also \dagger absolutely continuous, continuous, and of \dagger bounded variation. (For the polynomial approximation of real continuous functions \rightarrow 336 Polynomial Approximation.)

The limit function $f(x)$ of a monotone decreasing sequence of upper semicontinuous functions $f_n(x)$ is also upper semicontinuous. The limit function $f(x)$ of a uniformly converging sequence of continuous functions is continuous. (Regarding the \dagger equicontinuous family of functions \rightarrow 435 Uniform Convergence.)

D. Baire Functions

The limit function of a pointwise converging sequence of continuous functions defined on a metric space X is not necessarily continuous. R. Baire (*Ann. Mat. Pura Appl.*, (1899)) introduced the notion of Baire functions as follows: He named continuous functions the **functions of class 0**. Then he called a function that is a pointwise limit of a sequence of continuous functions a **function of at most class 1**. A function is said to be of class 1 if it is of at most class 1 and is not of class 0. He similarly defined the notion of **class n** for arbitrary natural number n .

Further, a function is said to be of at most class ω if it is a pointwise limit of a sequence of functions of class n , for a sequence of natural numbers n . A function is said to be of **class ω** if it is of at most class ω and is not of class n for any finite number n . In general, using \dagger transfinite induction, we can define the notion

of functions of **class ξ** for an arbitrary \dagger ordinal number ξ [4].

All these functions are called **Baire functions**. Actually, there is no function of class ξ for an uncountable ordinal number ξ . If X is a \dagger perfect set in Euclidean space, then there is actually a function defined on X of class ξ for an arbitrary countable ordinal number ξ . Hereafter, we shall be concerned with this case only.

If X has the cardinality of the \dagger continuum, then the set of all Baire functions on X has the cardinality of the continuum. On the other hand, the cardinality of all functions on X is actually greater than that of the continuum. Hence there exist functions that are not Baire functions on X . A function is a Baire function if and only if it is \dagger Borel measurable (H. Lebesgue). Therefore a necessary and sufficient condition for a function f to be a Baire function is that the set $\{x|f(x)>\alpha, x \in X\}$ be a Borel set for any real number α (\rightarrow 270 Measure Theory J). The limit of a countable sequence of Baire functions is also a Baire function. If $f(x)$ and $g(x)$ are of at most class α on X , then the following functions are also of at most class α : $|f(x)|$, $f(x) \pm g(x)$, $f(x) \cdot g(x)$, and $f(x)/g(x)$ (provided that $g(x) \neq 0$ on X).

The condition that a function f is of at most class 1 on X is equivalent to either of the following two conditions: (1) For any closed subset F of X , the restriction f^* of f to F has a continuity point in F . (2) For every real number α , the set $\{x|f(x)<\alpha, x \in X\}$ is an $\dagger F_\sigma$ set (Baire). In a \dagger complete metric space, a necessary and sufficient condition for a function f to be of at most class 1 is that the set of continuity points be dense in X .

For example, the **Dirichlet function**, which takes the value 1 at rational points and 0 at irrational points, is expressed as

$$\lim_{v \rightarrow \infty} \left(\lim_{k \rightarrow \infty} (\cos v! \pi x)^{2k} \right),$$

which is of class 2. A function $f(x, y)$ of two real variables that is continuous in each variable x and y separately is a function of at most class 1.

85 (VI.19) Continuous Geometry

A. General Remarks

The structure of a \dagger projective geometry is determined by the \dagger lattice (lattice-ordered set) of subspaces of the projective space. For this reason, this lattice itself is sometimes called a projective geometry. The concept of continuous geometry was introduced by J. von Neumann as an abstraction of lattice-theoretic properties from a special class of \dagger lattices (lattice-ordered sets) which he encountered in his research on \dagger operator rings in Hilbert spaces [1]. Continuous geometry contains projective geometry as a special case when the dimension is discrete; but more usually the lattices are of continuous dimension.

A **continuous geometry** is a \dagger complete and \dagger complemented \dagger modular lattice L (\rightarrow 243 Lattices F) that satisfies the following property and its dual (both called **properties of continuity**): For any element a of L and any subset W of L which is \dagger well ordered with respect to the ordering in L , we have $a \cap \sup w = \sup(a \cap w)$ ($w \in W$). The \dagger center Z of the lattice L is called the **center** of the continuous geometry L , which is said to be **irreducible** when Z has no elements other than the \dagger least element 0 and the \dagger greatest element I ; otherwise L is said to be **reducible**. A reducible continuous geometry is isomorphic to a sublattice of a \dagger direct product of irreducible continuous geometries.

On any continuous geometry L , there can be defined a function $d(x)$ whose values belong to a complete lattice-ordered linear space M and which satisfies the following four conditions: (1) $d(x) \geq 0$; (2) $d(x) = d(y)$ implies the existence of a common complement of x and y ; (3) $d(x \cup y) + d(x \cap y) = d(x) + d(y)$; (4) $\sup d(w) = d(\sup w)$ ($w \in W$) for any subset W of L which is well ordered with respect to the ordering in L . Such a function $d(x)$ is called a **dimension function** on L . Irreducibility of L is equivalent to the property that a real-valued dimension function can be introduced; in this case, if $d(w)$ takes only a finite number of values, then L is a finite-dimensional projective geometry; on the other hand, if $d(w)$ takes every number in the closed interval $[0, 1]$, then L is called a continuous geometry in the strict sense. An example of the latter can be constructed as a limit of a sequence of projective geometries of

increasing dimensions; another example is the lattice of projection operators of the \dagger von Neumann algebra of type II_1 . If a group G of \dagger automorphisms of L is given, there can be introduced a generalized dimension function which is invariant under G satisfying slightly weaker conditions (T. Iwamura [3]).

B. Representation of Continuous Geometry

A ring R is called a **regular ring** if it has a unity element and if, for any element a of R , there exists an element x in R such that $axa = a$. A continuous geometry L is isomorphic to the lattice (with \sup as its ordering) of \dagger principal left ideals of a regular ring R provided that $d(I) = n \cdot d(x)$ ($n \geq 4$) for some natural number n and some element x of L . The decomposition of R into a \dagger direct sum of ideals corresponds to the decomposition of L into a direct product of lattices. The condition that L is irreducible and finite-dimensional is equivalent to the condition that R is a matrix ring over a \dagger skew field; when these conditions hold and L is considered as a projective geometry, then the coordinates are given by this skew field. In continuous geometries, join and meet are often denoted by the symbols for sum and product, respectively, and sometimes a direct product of continuous geometries is called their direct sum. Sometimes, the requirement that a continuous geometry be complete is weakened to the requirement that it be \dagger conditionally σ -complete.

86 (XIX.11) Control Theory

A. General Remarks

The classical theory of automatic control mostly deals with linear feedback control

systems with single input and single output. Mathematical structures of such systems must be, in principle, described in terms of ordinary linear differential equations with constant coefficients. Hence control engineers use block diagrams to describe systems, and operational calculus based on Laplace transforms to obtain response characteristics (\rightarrow 240 Laplace Transform). Thus the input/output relation of a system is described in terms of transfer functions. The main objectives of control theory are to ensure system stability, to maximize closed-loop response characteristics by choosing the best feedback, and to obtain a desirable transient response to an impulse or step input. One of the remarkable contributions to classical control theory is Nyquist's criterion for stability testing of linear feedback systems [1]. The test consists of plotting the Nyquist diagram of a transfer function in the frequency domain (complex plane), and differs essentially from the Routh-Hurwitz stability test for linear differential equations with constant coefficient. Classical control theory was almost complete by the end of World War II.

Revolutionary technological innovations in electronics and computers and the invention of new control instruments and systems developed after World War II have opened the way to modern control theory. Around 1960, three remarkable contributions were made concurrently; they are dynamic programming (proposed by R. E. Bellman [2]), Pontryagin's maximum principle (L. S. Pontryagin et al. [3]), and linear system theory (R. E. Kalman [4]). The first two give rise to mathematical tools to solve optimal control problems and to design optimal controllers or regulators. In contrast to the classical theory of control, optimal control problems are formulated in terms of the system of linear or nonlinear multivariable differential equations with multi-input forcing terms called control variables. This leads to the **state-space approach**, which has become ubiquitous in modern control theory. Linear system theory derives from the concepts of controllability and observability. The former was introduced by Pontryagin et al. [3] and later modified by Kalman [5], and the latter was introduced by Kalman [5]. Controllability and observability are concerned with the interrelation between internal states of a system and its inputs and outputs. Hence linear system theory, profoundly related to the state-space approach, remains a principal theme of modern control theory. More advanced control theories, such as adaptive control or learning control, are mostly described and formulated in the framework of linear system theory.

Modern control theory has stimulated

the development of cybernetics, the science of control and communication, and control theory is important in the information sciences. In fact, current control theory has many features that might be considered to belong as well to other areas, such as mathematical programming (\rightarrow 264 Mathematical Programming), operations research (\rightarrow 307 Operations Research), game theory (\rightarrow 173 Game Theory), prediction and filtering theory, digital signal processing, circuit theory, and computer or microprocessor technology.

Current control theory embodied in modern instrumentation and computer technology has a vast range of applications. We do not consider these applications here; we confine ourselves to some important theories that continue to be major topics in control theory.

B. Linear Dynamical System

Let the state of a physical process to be controlled be represented by a real n -dimensional column vector $x(t) = (x_1(t), \dots, x_n(t))^T \in \mathbb{R}^n$, where T denotes the transpose of a vector or matrix. If the state is determined by a differential system with input $u(t) = (u_1(t), \dots, u_r(t))^T \in \mathbb{R}^r$ and output $y(t) = (y_1(t), \dots, y_m(t))^T \in \mathbb{R}^m$,

$$\begin{aligned} \frac{d}{dt}x(t) &= A(t)x(t) + B(t)u(t), \\ y(t) &= C(t)x(t), \end{aligned} \quad (1)$$

then the process is called a **linear dynamical system** or simply a linear system. The dimensions of the coefficient matrices are given by

$$A(t) \in \mathbb{R}^{n \times n}, \quad B(t) \in \mathbb{R}^{n \times r}, \quad C(t) \in \mathbb{R}^{m \times n}.$$

If $A(t)$, $B(t)$, and $C(t)$ are constant matrices, the system described by

$$\begin{aligned} \dot{x} &= \frac{d}{dt}x = Ax + Bu, \\ y &= Cx \end{aligned} \quad (2)$$

is called a **linear time-invariant system**. Correspondingly, the system described by equation (1) is called a **linear time-varying system**.

Given an initial state $x(t_0)$ and input function $u(t)$ for $t \geq t_0$, the state of system (1) is represented by

$$x(t) = \Phi(t, t_0)x(t_0) + \int_{t_0}^t \Phi(t, \tau)B(\tau)u(\tau)d\tau,$$

where $\Phi(t, \tau)$ is a fundamental solution to the matrix differential equation

$$\frac{\partial}{\partial t}\Phi(t, \tau) = A(t)\Phi(t, \tau),$$

$$\Phi(\tau, \tau) = I \quad (n \times n \text{ identity matrix}).$$

Hence the output of the system is described by

$$y(t) = C(t)\Phi(t, t_0)x(t_0) + \int_{t_0}^t C(t)\Phi(t, \tau)B(\tau)u(\tau)d\tau.$$

It is seen from this equation that the input-output relation of the system is governed by

$$W(t, \tau) = C(t)\Phi(t, \tau)B(\tau) \in \mathbf{R}^{m \times r},$$

which is called a **weighting matrix**. As a special case, the weighting matrix for the time-invariant system (2) becomes

$$W(t, \tau) = W(t - \tau) = Ce^{A(t-\tau)}B,$$

where e^{At} is a matrix exponential function defined by

$$e^{At} = I + tA + \frac{t^2}{2!}A^2 + \frac{t^3}{3!}A^3 + \dots$$

The Laplace transform of the weighting matrix is

$$G(s) = \int_0^\infty e^{-st}W(t)dt = C(sI - A)^{-1}B,$$

which is called a **transfer function matrix** of the system (2). First we note that the weighting matrix $W(t, \tau)$ for the system (1) is invariant under any linear transformation $\tilde{x}(t) = P(t)x(t)$ of the state, and also that the transfer function matrix $G(s)$ for the system (2) is invariant under $\tilde{x} = Px$. For example, the transformation $\tilde{x} = Px$ yields

$$\dot{\tilde{x}} = PAP^{-1}\tilde{x} + PBu,$$

$$y = CP^{-1}\tilde{x}. \quad (3)$$

In fact, the transfer function matrix for the system (3) becomes equivalent to that for the system (2), that is,

$$\tilde{G}(s) = CP^{-1}(sI - PAP^{-1})^{-1}PB = C(sI - A)^{-1}B = G(s).$$

As a converse to this, there arises the problem of whether any linear time-invariant systems with the same transfer function matrix are similar to each other. To solve this problem, it is necessary to introduce the concept of controllability and observability for the system (1) or (2).

C. Controllability and Observability

The concept of controllability and observability plays a fundamental role in linear system theory. Roughly, controllability implies the possibility of steering the state from the input.

Definition of controllability: The linear system (1) is said to be controllable at time t_0 if for any state $x(t_0) \in \mathbf{R}^n$ and $x^1 \in \mathbf{R}^n$ there exists a control input $u(t)$, $t \in [t_0, t_1]$, that transfers the

state $x(t_0)$ to the state x^1 at a finite time $t_1 > t_0$. Otherwise, the system (1) is said to be uncontrollable at time t_0 .

The controllability theorem states: The system (1) is controllable at time t_0 if and only if there exists a finite $t_1 (> t_0)$ such that the matrix

$$D(t_0, t_1) = \int_{t_0}^{t_1} \Phi(t_0, t)B(t)B^T(t)\Phi^T(t_0, t)dt \quad (4)$$

is nonsingular. Similarly, the linear time-invariant system (2) is controllable if and only if the $n \times (nr)$ matrix

$$D = [B, AB, \dots, A^{n-1}B] \quad (5)$$

has rank n . The matrix D is called the controllability matrix of the system (2).

The concept of observability is dual to that of controllability. It implies the possibility of estimating the state from the output.

Definition of observability: The linear system (1) is said to be observable at t_0 if for any state $x(t_0) \in \mathbf{R}^n$ there exists a finite $t_1 (> t_0)$ such that the knowledge of the input $u(t)$ and the output $y(t)$ over the time interval $[t_0, t_1]$ suffices to determine the state $x(t_0)$. Otherwise, the system (1) is said to be unobservable at t_0 .

The observability theorem states: The system (1) is observable at time t_0 if and only if there exists a finite $t_1 (> t_0)$ such that the matrix

$$M(t_0, t_1) = \int_{t_0}^{t_1} \Phi^T(t, t_0)C^T(t)C(t)\Phi(t, t_0)dt \quad (6)$$

is nonsingular. Similarly, the linear time-invariant system (2) is observable if and only if the $n \times (nm)$ matrix

$$M = [C^T, A^T C^T, \dots, (A^T)^{n-1} C^T] \quad (7)$$

has rank n . The matrix M is called the observability matrix of the system (2).

We deal only with linear time-invariant systems for simplicity, although some of the main results to be stated here can be extended to linear time-varying systems. If the controllability matrix D has rank $n_c (< n)$, there exists a linear transformation $\bar{x} = Px$ with nonsingular matrix P which transforms the system (2) into

$$\begin{bmatrix} \dot{\bar{x}}_c \\ \dot{\bar{x}}_{c'} \end{bmatrix} = \begin{bmatrix} A_c & A_{12} \\ 0 & A_{c'} \end{bmatrix} \begin{bmatrix} \bar{x}_c \\ \bar{x}_{c'} \end{bmatrix} + \begin{bmatrix} B_c \\ 0 \end{bmatrix} u, \quad (8)$$

$$y = [C_c \quad C_{c'}] \begin{bmatrix} \bar{x}_c \\ \bar{x}_{c'} \end{bmatrix}$$

so that the n_c -dimensional subsystem

$$\begin{aligned} \dot{\bar{x}}_c &= A_c \bar{x}_c + B_c u, \\ y &= C_c \bar{x}_c \end{aligned} \quad (9)$$

is controllable. Clearly this subsystem has the same transfer function matrix as the system (2).

If the observability matrix M has rank $n_o (< n)$, there exists a linear transformation $\bar{x} = Qx$ that transforms the system (2) into

$$\begin{bmatrix} \dot{x}_o \\ \dot{x}_{o'} \end{bmatrix} = \begin{bmatrix} A_o & 0 \\ A_{21} & A_{o'} \end{bmatrix} \begin{bmatrix} x_o \\ x_{o'} \end{bmatrix} + \begin{bmatrix} B_o \\ B_{o'} \end{bmatrix} u, \quad (10)$$

$$y = [C_o \quad 0] \begin{bmatrix} x_o \\ x_{o'} \end{bmatrix},$$

so that the n_o -dimensional subsystem

$$\begin{aligned} \dot{x}_o &= A_o x_o + B_o u, \\ y &= C_o x_o, \end{aligned} \quad (11)$$

is observable. This subsystem also has the same transfer function matrix as the system (2). Combination of these two properties yields the **canonical decomposition theorem** (found by Kalman [6]), which states: There is a nonsingular transformation $\bar{x} = Px$ by which the system (2) can be transformed into the canonical form

$$\begin{bmatrix} \dot{x}_{co} \\ \dot{x}_{co'} \\ \dot{x}_{c'o} \\ \dot{x}_{c'o'} \end{bmatrix} = \begin{bmatrix} A_{co} & 0 & A_{13} & 0 \\ A_{21} & A_{22} & A_{23} & A_{24} \\ 0 & 0 & A_{33} & 0 \\ 0 & 0 & A_{43} & A_{44} \end{bmatrix} \begin{bmatrix} x_{co} \\ x_{co'} \\ x_{c'o} \\ x_{c'o'} \end{bmatrix} + \begin{bmatrix} B_{co} \\ B_2 \\ 0 \\ 0 \end{bmatrix} u, \quad (12)$$

$$y = [C_{co} \quad 0 \quad C_3 \quad 0] \begin{bmatrix} x_{co} \\ x_{co'} \\ x_{c'o} \\ x_{c'o'} \end{bmatrix},$$

where the subvector x_{co} of \bar{x} is controllable and observable, $x_{co'}$ is controllable but not observable, $x_{c'o}$ is not controllable but observable, and $x_{c'o'}$ is neither controllable nor observable. Furthermore, the transfer function matrix of the system (2) is equal to that of the system (12), which is described by

$$G(s) = C_{co}(sI - A_{co})^{-1}B_{co},$$

that is, the transfer function matrix of the system (2) depends solely on the controllable and observable part of the state.

A linear system (2) is said to be **reducible** if and only if there exists a linear time-invariant system of smaller dimension that has the same transfer function matrix. Otherwise, the system is said to be **irreducible**. The canonical decomposition theorem implies that a linear time-invariant system is irreducible if and only if it is controllable and observable.

D. Realization Theory

Realization theory is concerned with determining (1) a linear time-invariant dynamical sys-

tem that has a prescribed **rational function matrix** or (2) a linear time-varying system that has a prescribed weighting matrix. Here we consider only the former, although there are many interesting results for the latter as well.

The rational function matrix $\tilde{G}(s)$ is said to be strictly proper if and only if $\tilde{G}(\infty) = 0$. A linear time-invariant system with a prescribed $\tilde{G}(s)$ as a transfer function matrix is called a **realization** of $\tilde{G}(s)$. A realization of $\tilde{G}(s)$ with the least possible dimension is said to be minimal. A minimal realization should be irreducible by definition. The fundamental theorem on minimal realization, which answers the question raised at the end of Section B, states: For a given strictly proper rational matrix $\tilde{G}(s)$, any two minimal realizations of $\tilde{G}(s)$ are mutually similar in the sense that there exists a linear transformation $\bar{x} = Px$ that transforms one of the systems into the other.

A **minimal realization** of a scalar transfer function

$$\tilde{g}(s) = \frac{b_1 s^{n-1} + \dots + b_{n-1} s + b_n}{s^n + a_1 s^{n-1} + \dots + a_{n-1} s + a_n} \quad (13)$$

is given by

$$\dot{x} = \begin{bmatrix} 0 & 1 & 0 & \dots & 0 \\ 0 & 0 & 1 & \dots & 0 \\ & & & \dots & \\ 0 & 0 & 0 & \dots & 1 \\ -a_n & -a_{n-1} & -a_{n-2} & \dots & -a_1 \end{bmatrix} x + \begin{bmatrix} 0 \\ 0 \\ \vdots \\ 0 \\ 1 \end{bmatrix} u, \quad (14)$$

$$y = [b_n \quad b_{n-1} \quad b_{n-2} \quad \dots \quad b_1]x.$$

It is easy to see that this system is controllable. Hence system (14) is called a controllable canonical realization. Kalman [4] showed that this realization is observable and therefore minimal if and only if there is no common factor between the denominator and the numerator of $\tilde{g}(s)$. An observable canonical realization of $\tilde{g}(s)$ can be similarly written down as a dual of the system (14).

For a given strictly proper matrix $\tilde{G}(s)$, the degree of the least common denominator of all entries of $\tilde{G}(s)$ is called the degree of $\tilde{G}(s)$, provided that there is no common factor between the denominator and the numerator of each entry. It was shown by Kalman [7], together with a realization procedure, that the dimension of minimal realization of $\tilde{G}(s)$ is equal to the degree of $\tilde{G}(s)$. Other important realization procedures for rational function matrices were proposed by B. L. Ho and Kalman [8], W. A. Wolovich and P. L. Falb [9, 10], J. Rissanen and T. Kailath [11], and

B. Dickinson et al. [12]. Procedures for time-varying system realization for prescribed weighting matrices were presented by Kalman [4], D. C. Youla [15], and L. M. Silverman [16]. Realization problems for a given impulse response matrix were first discussed by C. A. Desoer and P. P. Varaiya [17], and a fast algorithm for discrete-time system realization was proposed by C. T. Mullis and R. A. Roberts [18].

E. State Estimation

When a linear system is observable, it is possible to construct a device, called a **state estimator**, that approximates the state vector. For the given system (2), define a linear dynamical system

$$\dot{z} = Dz + Ey + Gu,$$

$$\hat{x} = L_1 z + L_2 y \quad (15)$$

with inputs $y \in \mathbf{R}^m$ and $u \in \mathbf{R}^r$, state $z \in \mathbf{R}^q$, and output $\hat{x} \in \mathbf{R}^n$. If the system (2) is observable, $\text{rank}(C) = m$, and $q \geq n - m$, there exist matrices D, E, G, L_1, L_2 , and M that satisfy

$$MA - DM = EC,$$

$$L_1 M + L_2 C = I_n \quad (n \times n \text{ identity matrix}),$$

$$G = MB.$$

Then it follows that

$$\dot{\hat{x}}(t) - x(t) = L_1 e^{Dt} [z(0) - Mx(0)].$$

Furthermore, it is possible to choose a matrix D which is asymptotically stable, that is, every eigenvalue of D has negative real part. Thus $\hat{x}(t) \rightarrow x(t)$ as $t \rightarrow \infty$, and system (15) yields a state estimator. This result was first shown by D. G. Luenberger [19, 20], and thus the system (15) is called a **Luenberger observer**.

The **Kalman filter** proposed by Kalman [21] for discrete-time processes and by Kalman and R. S. Bucy [22] for continuous-time processes is an optimal state estimator for a stochastic system. Let

$$\dot{x}(t) = A(t)x(t) + B(t)u(t),$$

$$y(t) = C(t)x(t) + v(t), \quad (16)$$

in which $u(t)$ is a white Gaussian noise (\dagger Brownian motion) (\rightarrow 45 Brownian Motion) such that

$$Eu(t) \equiv 0, \quad Eu(t)u^T(s) = U(t)\delta(t-s),$$

and $v(t)$ is also a white Gaussian noise such that

$$Ev(t) \equiv 0, \quad Ev(t)v^T(s) = V(t)\delta(t-s),$$

where E and T denote the \dagger expectation and the transpose, respectively. In addition, it is as-

sumed that

$$Ex(t_0) = 0, \quad Ex(t_0)x^T(t_0) = X_0,$$

and that $x(t_0)$, $u(t)$, and $v(s)$ are uncorrelated. Under these conditions, the process $x(t)$ becomes a wide-sense Gauss-Markov process (J. L. Doob [23]). The **Kalman-Bucy filter** is a linear dynamical system described by

$$\dot{\hat{x}}(t) = [A(t) - L(t)C(t)]\hat{x}(t) + L(t)y(t),$$

where

$$L(t) = P(t)C^T(t)V^{-1}(t)$$

and $P(t)$ is a solution to the **matrix Riccati differential equation**

$$\begin{aligned} \dot{P}(t) = & A(t)P(t) + P(t)A^T(t) + B(t)U(t)B^T(t) \\ & - P(t)C^T(t)V^{-1}(t)C(t)P(t), \end{aligned}$$

$$P(t_0) = X_0.$$

The **Wiener filter** proposed in 1949 [24] is a special case of the Kalman filter in which the signal process is stationary and of single input and single output. Extensions to nonlinear filtering were investigated first by H. J. Kushner [25] and subsequently by W. M. Wonham [26], R. S. Liptzer and A. N. Shiryayev [27], and M. Fuzisaki et al. [28].

F. Optimal Control

Consider a nonlinear dynamical system described by a system of differential equations

$$\dot{x} = f(x, u), \quad (17)$$

where $x \in \mathbf{R}^n$ and $u \in \mathbf{R}^r$. For a given set U in \mathbf{R}^r , a piecewise continuous function $u(t)$ defined over $[t_0, t_1]$ is said to be an admissible control function if $u(t) \in U$ for every $t \in [t_0, t_1]$. When a functional

$$J = \int_{t_0}^{t_1} f_0(x(t), u(t)) dt$$

is given as a performance index of control and two points x^0 and x^1 are given in \mathbf{R}^n , the optimal control problem consists of finding an admissible function $u(t)$ that minimizes J and simultaneously transforms the state from $x(t_0) = x^0$ to $x(t_1) = x^1$. To solve this, a necessary condition for optimality was developed by L. S. Pontryagin and his colleagues [3] and termed the **maximum principle**. It states: In order for an admissible control $u(t)$ and a corresponding solution trajectory of equation (17) to be optimal, it is necessary that there exist a nonzero vector $\psi(t) = (\psi_1(t), \dots, \psi_n(t))^T$ such that (i) $\psi(t)$ satisfies

$$\dot{\psi}(t) = - \frac{\partial H(\psi(t), x(t), u(t))}{\partial x(t)},$$

where

$$H(\psi, x, u) = -f_0(x, u) + \psi^T f(x, u),$$

(ii) the function $H(\psi(t), x(t), u)$ of the variable $u \in U$ attains its maximum at the point $u = u(t)$ almost everywhere in $[t_0, t_1]$, and (iii) at the terminal time t_1 it holds that

$$H(\psi(t_1), x(t_1), u(t_1)) = 0.$$

When $f(x, u)$ is linear in x and u , $f_0(x, u) \equiv 1$, and t_1 is free, we have the **time-optimal control** problem investigated by Bellman et al. [29] and J. P. LaSalle [30]. When $f_0(x, u)$ is instead a quadratic function of x and u , we have the **optimal regulator problem** solved by Kalman [31]. The relation between the maximum principle and the calculus of variations (\rightarrow 46 Calculus of Variations) has been pointed out by L. D. Berkovitz [32]. Generalizations of the maximum principle and other results on optimal control problems are found in [33–35].

G. Miscellany

There are many other areas of control theory. For details, we refer the reader to [36] for adaptive control, [37] for stability theory, and [38] for system identification.

87 (II.19) Convergence

A. Introduction

The notion of convergence was first introduced in the real number system to deal with sequences of numbers, functions, series, or definite integrals (\rightarrow 379 Series; 216 Integral Calculus). The notion was then extended to the case of generalized sequences where the index moves over a directed set, and the terms are in a topological space.

B. Convergence of Sequences of Numbers

A sequence $\{a_n\}$ of numbers is said to be **convergent** to a number a or to **converge** to a , written $\lim_{n \rightarrow \infty} a_n = a$ or $a_n \rightarrow a$ as $n \rightarrow \infty$, if for any positive number ε we can choose a (suffi-

ciently large) natural number n_0 such that for every n larger than n_0 the inequality $|a_n - a| < \varepsilon$ holds. Then a is called the **limit** (or **limit point**) of the sequence $\{a_n\}$. If $\{a_n\}$ has a limit, it is unique. A sequence which is not convergent is said to be **divergent** or to **diverge**.

A set A of real numbers is said to be **bounded from above** if there is a real number b such that $a \leq b$ for all $a \in A$, **bounded from below** if there is a real number c such that $a \geq c$ for all $a \in A$, and **bounded** if it is bounded from above and below. A sequence $\{a_n\}$ of real numbers is said to be **monotonically increasing** (**monotonically decreasing**), written $a_n \uparrow$ ($a_n \downarrow$), if $a_1 \leq a_2 \leq \dots \leq a_n \leq a_{n+1} \leq \dots$ ($a_1 \geq a_2 \geq \dots \geq a_n \geq a_{n+1} \geq \dots$). A monotonically increasing or decreasing sequence is called a **monotone sequence**.

C. Criteria for the Convergence of Sequences of Numbers

Every bounded monotone sequence of real numbers is convergent; its limit is $\sup\{a_n\}$ ($\inf\{a_n\}$) (\rightarrow 355 Real Numbers B) if it is monotonically increasing (decreasing). For any bounded sequence $\{a_n\}$ of real numbers, setting $\alpha_n = \inf\{a_n, a_{n+1}, \dots\}$ and $\beta_n = \sup\{a_n, a_{n+1}, \dots\}$, we have $\alpha_n \uparrow$, $\beta_n \downarrow$, and $\alpha_n \leq a_n \leq \beta_n$. Hence $\lim_{n \rightarrow \infty} \alpha_n = \alpha$ ($= \sup\{\alpha_n\}$) and $\lim_{n \rightarrow \infty} \beta_n = \beta$ ($= \inf\{\beta_n\}$) exist. α is called the **inferior limit** (or **limit inferior**) of $\{a_n\}$, written $\liminf_{n \rightarrow \infty} a_n$ or $\underline{\lim}_{n \rightarrow \infty} a_n$, while β is called the **superior limit** (or **limit superior**), written $\limsup_{n \rightarrow \infty} a_n$ or $\overline{\lim}_{n \rightarrow \infty} a_n$. If $\limsup_{n \rightarrow \infty} a_n = \liminf_{n \rightarrow \infty} a_n = \alpha$, then $\lim_{n \rightarrow \infty} a_n$ exists and equals α . The limit of a convergent subsequence of a sequence $\{a_n\}$ of numbers is called an **accumulation point** of the sequence. Here we should distinguish an accumulation point of a sequence $\{a_n\}$ from an accumulation point of $\{a_n\}$ viewed as a set (\rightarrow 425 Topological Spaces O); for example, if $a_n = 1$ for every n , then the former is 1 and the latter does not exist. For any bounded sequence of real numbers, its superior (inferior) limit is the maximum (minimum) of its accumulation points. Moreover, if β is the superior limit of a sequence $\{a_n\}$, then for any positive number ε , there exist only a finite number of n 's for which a_n is greater than $\beta + \varepsilon$, while there may exist an infinite number of n 's for which a_n is less than $\beta - \varepsilon$. The inferior limit of the sequence has a similar property.

Suppose that we are given a sequence $\{a_n\}$ of real numbers and that there exist two sequences $\{u_n\}$ and $\{v_n\}$ such that $u_n \leq a_n \leq v_n$, $\lim(u_n - v_n) = 0$, $\{u_n\}$ is monotonically increasing, and $\{v_n\}$ is monotonically decreasing. Then $\lim a_n$ exists and is equal to $\lim u_n =$

$\lim v_n$ (**principle of nested intervals**). In particular, if $\limsup a_n = \liminf a_n$, then $\lim a_n$ exists. The converse also holds.

If $\{a_n\}$ is convergent, then $|a_n - a_m| \rightarrow 0$ as $n, m \rightarrow \infty$, and vice versa; that is, $\{a_n\}$ is convergent if and only if for any positive number ε there exists a positive integer n_0 such that $|a_n - a_m| < \varepsilon$ for all $n, m \geq n_0$ (**Cauchy's criterion**).

D. Infinity

For a set A of real numbers, the expression $\sup A = +\infty$ means that A is not bounded from above; $\inf A = -\infty$ means that A is not bounded from below. For a sequence $\{a_n\}$ of real numbers, $\lim a_n = +\infty$ means that for any real number b there exists a positive integer n_0 such that $a_n > b$ for all $n \geq n_0$; the notation $\lim a_n = -\infty$ has a similar meaning. The symbols $+\infty$ and $-\infty$ are called **positive** (or **plus**) **infinity** and **negative** (or **minus**) **infinity**, respectively. We say that the limit of $\{a_n\}$ is $+\infty$ ($-\infty$) if $\lim a_n = +\infty$ ($-\infty$). In these cases, we customarily say that $\{a_n\}$ **diverges** (or is **divergent**) to $+\infty$ ($-\infty$), or that a_n becomes positively (negatively) infinite as $n \rightarrow \infty$. We also define $\limsup a_n = +\infty$ ($\liminf a_n = -\infty$) to mean $\sup\{a_n\} = +\infty$ ($\inf\{a_n\} = -\infty$). A sequence $\{a_n\}$ is said to **oscillate** if $\limsup a_n > \liminf a_n$.

We now have the following propositions concerning sequences of numbers: If $\lim a_n = a$ and $\lim b_n = b$, then $\lim(\alpha a_n + \beta b_n) = \alpha a + \beta b$, $\lim(a_n b_n) = ab$, and $\lim(a_n/b_n) = a/b$ (provided that $b_n \neq 0, b \neq 0$). For sequences of real numbers, these formulas also hold when a or b is infinity. In those cases we set $\alpha \cdot (\pm\infty) = \pm\infty$ ($\alpha > 0$), $\alpha \cdot (\pm\infty) = \mp\infty$ ($\alpha < 0$), $\alpha \pm \infty = \pm\infty$, $\alpha/(\pm\infty) = 0$ for a real number α . The cases $0 \cdot (\pm\infty)$, $+\infty + (-\infty)$, $\pm\infty/(\pm\infty)$ are excluded.

E. Convergence of Sequences of Points in a Topological Space

A sequence $\{a_n\}$ of points in a topological space (\rightarrow 425 Topological Spaces) is said to **converge** to a point a if for any neighborhood U of a there exists a positive integer n_0 such that $a_n \in U$ for all $n \geq n_0$. The point a is called a **limit** (or **limit point**) of $\{a_n\}$ and we write $\lim_{n \rightarrow \infty} a_n = a$ or $a_n \rightarrow a$ as $n \rightarrow \infty$. A sequence is said to **diverge** if it does not converge to any point.

In particular, the set \mathbf{R} of all real numbers is a topological space in which the set of intervals $(a - \varepsilon, a + \varepsilon)$ for some $\varepsilon > 0$ is a \dagger base for the neighborhood system of a point a , so that the notion of limit in \mathbf{R} explained previously is

a special case of the same notion in a topological space. By adding the symbols $+\infty$ and $-\infty$ to \mathbf{R} , we obtain the topological space $\bar{\mathbf{R}}$, in which any set containing $\{x | x > \alpha, x \in \bar{\mathbf{R}}\}$ ($\{x | x < \alpha, x \in \bar{\mathbf{R}}\}$) for some $\alpha \in \mathbf{R}$ is a neighborhood of $+\infty$ ($-\infty$), where the ordering is defined as $-\infty < \alpha < +\infty$ ($\alpha \in \mathbf{R}$). Then $\lim a_n = +\infty$ ($-\infty$) is interpreted as convergence in the topological space $\bar{\mathbf{R}}$. The elements of $\bar{\mathbf{R}}$ are called **extended real numbers**.

In the case where the topological space is a \dagger metric space (\rightarrow 273 Metric Spaces) with metric ρ , $a_n \rightarrow a$ is equivalent to $\rho(a_n, a) \rightarrow 0$.

For convergence of sequences of points in a topological space, the following properties (S) hold: (S) (1). If $a_n = a$ for all n , then $\lim a_n = a$; (2) if $a_n \rightarrow a$, then $a_{n_k} \rightarrow a$ for any subsequence $\{a_{n_k}\}$; (3) if there is a point a such that any subsequence $\{a_{n_k}\}$ of $\{a_n\}$ has a suitable subsequence converging to a , then $a_n \rightarrow a$. In a \dagger Hausdorff space (e.g., a metric space), the additional property (S*) holds: If a sequence $\{a_n\}$ has a limit, this limit is unique, and can be denoted $\lim a_n$.

F. Limits of Functions

Let a real-valued function $f(x)$ of a real variable x be defined for $x \neq a$ belonging to a neighborhood of the point a . We say that the **limit** of $f(x)$ is b as x tends to a , and write $\lim_{x \rightarrow a} f(x) = b$ or $f(x) \rightarrow b$ as $x \rightarrow a$, if for any positive number ε there exists a positive number δ such that $0 \neq |x - a| < \delta$ implies $|f(x) - b| < \varepsilon$. Replacing $0 \neq |x - a| < \delta$ by $a < x < a + \delta$ ($a - \delta < x < a$), we define $f(x) \rightarrow b$ as $x \rightarrow a + 0$ ($x \rightarrow a - 0$) and say that b is the **limit on the right** (**left**) of $f(x)$ as x tends to a . We define $f(x) \rightarrow +\infty$ or $f(x) \rightarrow -\infty$ as $x \rightarrow a$ analogously to the case of sequences. The expression $f(x) \rightarrow b$ as $x \rightarrow +\infty$ means that for any positive number ε there is a real number k such that $|f(x) - b| < \varepsilon$ for any $x > k$. There are similar definitions for $x \rightarrow -\infty$ and $b = \pm\infty$. When $f(x) \rightarrow \pm\infty$ as $x \rightarrow a$, we often say that f **diverges** definitely at a .

In general, for a mapping f from a subset D of a topological space X into a topological space Y , with a point a in the closure of D and a point b in Y , $\lim_{x \rightarrow a} f(x) = b$ or $f(x) \rightarrow b$ as $x \rightarrow a$ means that any neighborhood V of b contains $f(U \cap D - \{a\})$ for some neighborhood U of a . If Y is a Hausdorff space, b is unique (if it exists) for given f and a . This point b is called the **limit** (or **limit value**) of $f(x)$ as $x \rightarrow a$.

It is easy to see that this definition of $\lim_{x \rightarrow a} f(x) = b$ is a generalization of the cases where the topological spaces are $\bar{\mathbf{R}}$ or \mathbf{R} . Let \mathbf{N} be the set of all natural numbers, and let $\bar{\mathbf{N}} =$

$\mathbf{N} \cup \{+\infty\}$ be supplied with the \dagger relative topology as a subspace of $\bar{\mathbf{R}}$. A sequence $\{a_n\}$ of real numbers or points can be identified with a mapping f from \mathbf{N} into \mathbf{R} ($\mathbf{N} \rightarrow \mathbf{R}$) defined by $f(n) = a_n$. It converges to a if and only if $\lim_{n \rightarrow \infty} f(n) = a$.

Suppose, in particular, that f is a mapping from a metric space (X, ρ) into a metric space (Y, σ) . Then, $f(x) \rightarrow b$ as $x \rightarrow a$ means that for any $\varepsilon > 0$ there exists a $\delta > 0$ such that $\sigma(f(x), b) < \varepsilon$ for all $x \in D$ such that $0 < \rho(x, a) < \delta$. Thus $f(x) \rightarrow b$ as $x \rightarrow a$ if and only if $f(x_n) \rightarrow b$ for any $\{x_n\}$ in D with $x_n \rightarrow a$. If we set $\rho(z_1, z_2) = |z_1 - z_2|$ for complex numbers z_1, z_2 , the function ρ supplies the set of all complex numbers \mathbf{C} with a metric and \mathbf{C} becomes isometric to the plane \mathbf{R}^2 (\rightarrow 74 Complex Numbers). Thus the cases $X = \mathbf{C}$ or $Y = \mathbf{C}$ are particular cases of the above generalization. Furthermore, we introduce the \dagger Riemann sphere $\bar{\mathbf{C}} = \mathbf{C} \cup \{\infty\}$ by adding the \dagger point at infinity ∞ to \mathbf{C} . We can define a topology on $\bar{\mathbf{C}}$ such that any set containing $\{\infty\} \cup \{z \mid |z| > r\}$ for some positive number r is a neighborhood of ∞ . Thus we can define the notions $f(z) \rightarrow b$ as $z \rightarrow \infty$, $f(x) \rightarrow \infty$ as $x \rightarrow a$, etc., for a complex-valued function f by considering f as a mapping from the topological space $\bar{\mathbf{C}}$ into itself. Then $f(x) \rightarrow \infty$ is equivalent to $1/f(x) \rightarrow 0$.

G. Orders of Infinities and Infinitesimals

Let f be a complex-valued function defined on a topological space X and a a point of X . Then f is called an **infinity** (at a) or an **infinitesimal** (at a) if $f(x) \rightarrow \infty$ as $x \rightarrow a$ or $f(x) \rightarrow 0$ as $x \rightarrow a$, respectively. Suppose that f and g are infinities and f/g is an infinitesimal. Then f is said to be of **lower order** than g , and g is said to be of **higher order** than f . If both f/g and g/f are bounded, then f is said to be of **the same order** as g . This last relation, written $f \sim g$, is an equivalence relation. An infinity f is said to be of **the n th order** with g if $f \sim g^n$. For two infinitesimals f and g , f is called of **higher order** than g and g of **lower order** than f if f/g is an infinitesimal. For infinitesimals, the terms of **the same order** and of **the n th order** are defined similarly as above. In particular, when $X = \mathbf{C}$ and $a = \infty$, we usually omit the phrase "at ∞ ." Also, for such a function f , we customarily say that the **order of an infinity (infinitesimal)** is n if $f \sim z^n$ (z^{-n}).

To describe the order of an infinity or an infinitesimal simply, the following notions, due to E. Landau [10], are in common use. Let f and g be two functions. If $|f(x)/g(x)|$ is bounded as $x \rightarrow a$, then f is called **at most of the order of g** as $x \rightarrow a$, and we write $f(x) =$

$O(g(x))$ as $x \rightarrow a$. Second, if $f(x)/g(x)$ is an infinitesimal at a , then f is said to be of lower order than g as $x \rightarrow a$, and we write $f(x) = o(g(x))$ as $x \rightarrow a$. The symbols O, o , indicating the word "order," are called **Landau's symbols**. The notation $f(x) = h(x) + O(g(x))$ means $f(x) - h(x) = O(g(x))$. When we use the symbols O, o we should indicate clearly the phrase "as $x \rightarrow a$," which is sometimes omitted when no confusion is to be feared (e.g., for the case of a complex variable with $a = \infty$). These symbols are employed for sequences as well, to describe their behavior as $n \rightarrow \infty$.

H. Convergence of Nets (Moore-Smith Convergence) [7, 8]

Let \mathfrak{A} be a (preordered) \dagger directed set. A family of points in a set X with index set \mathfrak{A} (namely, a mapping from \mathfrak{A} to X) is called a **net** in X . A net is denoted by $\{x_\alpha\}_{\alpha \in \mathfrak{A}}$ ($\{x_\alpha\}_\mathfrak{A}$ or $\{x_\alpha\}$). A net $\{y_\beta\}_\mathfrak{B}$ in X is called a **subnet** of $\{x_\alpha\}_\mathfrak{A}$ if there exists a mapping $\varphi: \mathfrak{B} \rightarrow \mathfrak{A}$ such that (1) $y_\beta = x_{\varphi(\beta)}$ and (2) for any $\alpha_0 \in \mathfrak{A}$ there exists a $\beta_0 \in \mathfrak{B}$ such that $\beta \geq \beta_0$ implies $\varphi(\beta) \geq \alpha_0$. In particular, if \mathfrak{B} is a cofinal directed subset of \mathfrak{A} , $\{x_\beta\}_\mathfrak{B}$ is called a cofinal subnet of $\{x_\alpha\}_\mathfrak{A}$. A net is called a **universal net** if either $\{\alpha \mid x_\alpha \in Y\}$ or $\{\alpha \mid x_\alpha \in X - Y\}$ is residual in \mathfrak{A} for any subset Y of X . For any net there is a universal subnet.

For a net $\{x_\alpha\}_\mathfrak{A}$ in a topological space X , $\{x_\alpha\}$ is said to **converge** to a point x in X if for any neighborhood U of x there is an α_0 such that $\{x_\alpha \mid \alpha \geq \alpha_0\} \subset U$. Then a is called a **limit** of the net $\{x_\alpha\}$. We then write $x_\alpha \rightarrow x$ ($\alpha \in \mathfrak{A}$) (or simply $x_\alpha \rightarrow x$). The convergence of sequences of points is the special case where $\mathfrak{A} = \mathbf{N}$. The notion of convergence using nets was introduced by E. H. Moore and H. E. Smith.

Concerning this convergence, we have the following propositions (**D**): (**D**) (1) If $x_\alpha = x$ for all α , then $x_\alpha \rightarrow x$. (2) If $x_\alpha \rightarrow x$ and $\{y_\beta\}$ is a subnet of $\{x_\alpha\}$, then $y_\beta \rightarrow x$. (3) If for a net $\{x_\alpha\}$ there is a point x such that any subnet $\{y_\beta\}$ of $\{x_\alpha\}$ has a suitable subnet converging to x , then $x_\alpha \rightarrow x$. (4) Suppose that $x_\alpha \rightarrow x$ ($\alpha \in \mathfrak{A}$) and $y_{\alpha\beta} \rightarrow x_\alpha$ ($\beta \in \mathfrak{B}_\alpha$) for each α . Then let $\mathfrak{C} = \mathfrak{A} \times \prod \mathfrak{B}_\alpha$ be the direct product of directed sets with projections $p: \mathfrak{C} \rightarrow \mathfrak{A}$ and $p_\alpha: \mathfrak{C} \rightarrow \mathfrak{B}_\alpha$, and for $\gamma \in \mathfrak{C}$ define $z_\gamma = y_{\alpha\beta}$, where $\alpha = p(\gamma)$ and $\beta = p_\alpha(\gamma)$. Then $z_\gamma \rightarrow x$ ($\gamma \in \mathfrak{C}$). Furthermore, the space X is a \dagger Hausdorff space if and only if we have the condition (**D***): Any net in X has at most one limit.

A limit of $\{x_\alpha\}$ is denoted by $\lim x_\alpha$ or $\lim_{\alpha \in \mathfrak{A}} x_\alpha$. Then $x_\alpha \rightarrow x$ if and only if x is contained in the closure of any subnet $\{y_\beta \mid \beta \in \mathfrak{B}\}$ of $\{x_\alpha\}$. (We may consider this to be a definition of $x_\alpha \rightarrow x$.)

I. Convergence of Filters [9]

Let X be a set. A set Φ of subsets of X is called a **filter** if the following conditions are satisfied:

(i) $\emptyset \notin \Phi$ (\emptyset is the empty set); (ii) $A \subset B \subset X$ and $A \in \Phi$ imply $B \in \Phi$; (iii) $A, B \in \Phi$ imply $A \cap B \in \Phi$. Let \mathfrak{B} be a set of subsets of X and Φ be the collection of subsets of X such that each element A of Φ contains a subset belonging to \mathfrak{B} . If Φ is a filter, then \mathfrak{B} is called a **filter base** which **generates** Φ . \mathfrak{B} is a filter base if and only if (i) $\emptyset \notin \mathfrak{B}$; (ii) $A, B \in \mathfrak{B}$ implies that there is a $C \in \mathfrak{B}$ with $A \cap B \supset C$. A filter Φ is called an **ultrafilter** (or **maximal filter**) if there exists no filter which contains Φ properly. For any filter there exists an ultrafilter containing it. If $\{\Phi_\lambda\}_\Lambda$ is a family of filters, then the intersection $\bigcap \Phi_\lambda$ is a filter. If \mathfrak{F} is a filter base in the index set Λ , then $\bigcup_{M \in \mathfrak{F}} (\bigcap_{\lambda \in M} \Phi_\lambda)$ is also a filter.

We denote by $\mathcal{U}(x)$ the 'neighborhood system' of a point x in a topological space X . A filter Φ in X is said to **converge** to a point a , written $\Phi \rightarrow a$, if $\mathcal{U}(x) \subset \Phi$. A filter base \mathfrak{B} is said to **converge** to a if the filter generated by \mathfrak{B} converges to a .

The convergence of filters just defined has the following fundamental properties (L): (1) for a point a in X the filter $\Phi_a = \{A \mid a \in A \subset X\}$ converges to a ; (2) for two filters Φ and Ψ , $\Phi \rightarrow a$ and $\Phi \subset \Psi$ imply $\Psi \rightarrow a$; (3) if $\Phi_\lambda \rightarrow a$ for all members in a family $\{\Phi_\lambda\}$ of filters, then $\bigcap \Phi_\lambda = \Phi \rightarrow a$; (4) suppose that filters $\Phi_y \rightarrow y$ are assigned for all points y in a subset Y of X , and that we are given a filter Ψ in X which converges to a , generated by a filter base \mathfrak{B} in Y ; then $\bigcup_{B \in \mathfrak{B}} (\bigcap_{y \in B} \Phi_y) \rightarrow a$. Furthermore, the space X is Hausdorff if and only if we have the condition (L*): Each filter in X has at most one limit.

J. Relations among Various Definitions of Convergence

Convergence of sequences of points is a special case of that of nets. Properties (1), (2), and (3) of (D) imply (1), (2), and (3) of (S), respectively, and (D*) implies (S*). Consider a net $\{x_\alpha\}_{\alpha \in \mathfrak{A}}$ in X . Then the set $\{x_\alpha \mid \alpha \in \mathfrak{A}, \alpha \geq \alpha_0\} \mid \alpha_0 \in \mathfrak{A}\}$ of subsets of X is a filter base in X which generates a filter Φ , and $\Phi \rightarrow x$ if and only if $x_\alpha \rightarrow x$. In this situation, (L) implies (D), and (L*) implies (D*). Suppose that we are given a function $f: X \rightarrow Y$ with the domain D and a point $a \in X$. Let $\mathcal{U}(a)$ be the neighborhood system of a and assume that, for any $U \in \mathcal{U}(a)$, $U \cap D - \{a\} \neq \emptyset$. Then the set $\{f(U \cap D - \{a\}) \mid U \in \mathcal{U}(a)\}$ is a filter base. Let Φ be the filter generated by it. Then $f(x) \rightarrow b$ as $x \rightarrow a$ if and only if $\Phi \rightarrow b$. Consequently, the various types of convergence described previously can

be expressed by means of convergence of filters.

K. Convergence and Topology

In a topological space X , the concept of convergence of nets and that of filters can be defined. Conversely, convergence of nets in X defines a topology of X . In fact, let us assume that we are given a set X and a definition of convergence of filters which satisfies the properties (L). Then convergence of nets that satisfies (D) can be introduced as above. If \bar{A} is defined as the set of limits of all nets contained in a subset A of X , then \bar{A} satisfies the axiom of closures (\rightarrow 425 Topological Spaces), and a topology can be defined on X . Then we have the following propositions: (i) $a \in \bar{A}$ if and only if there is a net $\{x_\alpha\}$ with $x_\alpha \in A$ converging to a ; (ii) U is a neighborhood of a if and only if $x_\alpha \rightarrow a$ implies that there exists an α_0 such that $x_\alpha \in U$ for all $\alpha \geq \alpha_0$. Thus, if X is a topological space, it carries a "new" topology defined by way of convergence of nets. But this "new" topology coincides with the original one. Similarly, starting from convergence of filters (or nets), we can obtain a "new" definition of convergence of filters (or nets), which coincides with the initial one. In conclusion, defining a topology on a space X is the same thing as defining convergence of filters in X or of nets in X .

We shall describe here a few notions on topological spaces in terms of convergence. The fact that a topological space X is compact is equivalent to the fact that every universal net in X converges, and to the fact that every ultrafilter in X converges. Also equivalent is the fact that every net has a convergent subnet. A mapping f from a topological space X into a topological space Y is continuous at a if and only if one of the following conditions is satisfied: (1) for any net $\{x_\alpha\}$ in X converging to $a \in X$, we have $f(x_\alpha) \rightarrow f(a)$ in Y ; (2) for any filter Φ in X converging to $a \in X$, we have $f(\Phi) = \{f(M) \mid M \in \Phi\} \rightarrow f(a)$ in Y ; (3) $f(x) \rightarrow f(a)$ in Y as $x \rightarrow a$ in X (in the sense of the limit of a function at a).

M. Fréchet [6] gave a definition of a topology on a space using the notion of convergence as a foundation. A set is called an **L-space** (or **Fréchet L-space**) if convergence of sequences of points in it is defined so as to satisfy conditions (1) and (2) of (S) and (S*) (1906). Such convergence is called **star convergence** if it also satisfies (3) of (S), and in that case the space is called an **L*-space**. For any subset A of an L -space X , define \bar{A} as the set of all points a such that $x_n \rightarrow a$ for some sequence $\{x_n\}$ contained in A . Then the axioms

$\bar{A} \supset A$, $\overline{A \cup B} = \bar{A} \cup \bar{B}$, and $\overline{\emptyset} = \emptyset$ are satisfied, so that X is a \dagger generalized topological space (the axiom $\bar{A} = \bar{\bar{A}}$ is not necessarily satisfied). For a Hausdorff space X with the \dagger first countability axiom and convergence of sequences defined by means of its topology, the closure operation defined above gives the same topology as the initial one.

L. (o)-Convergence

A sequence $\{a_n\}$ of elements of an ordered set S is said to be (o)-**convergent** to an element a of S if there exist two sequences $\{u_n\}$ and $\{v_n\}$ such that $u_n \leq a_n \leq v_n$, $u_n \leq u_{n+1}$, and $v_n \geq v_{n+1}$, and $a = \sup u_n = \inf v_n$. When we write this $a_n \rightarrow a$, properties (1) and (2) of (S) and (S*) concerning the convergence of sequences hold. Next, a sequence $\{a_n\}$ is said to be (o)-**star convergent** to a if any subsequence of $\{a_n\}$ has a suitable subsequence which converges to a . Then (o)-star convergence satisfies the properties (S) and (S*).

For any set X the set $\mathfrak{P}(X)$ of all subsets of X is an ordered set under the inclusion relation. The fact that a sequence $\{A_n\}$ of subsets is (o)-convergent to a subset A is equivalent to:

$$A = \bigcap_{m=1}^{\infty} \bigcup_{n=m}^{\infty} A_n = \bigcup_{m=1}^{\infty} \bigcap_{n=m}^{\infty} A_n.$$

The set A is also equal to $\lim A_n$, which is the \dagger limit of a sequence $\{A_n\}$ of subsets.

88 (X.4) Convex Analysis

A. Convex Functions

A real-valued function $f(x)$ defined on a \dagger convex set D in a linear space over \mathbf{R} is called a **convex function** if for every $x, y \in D$ and $0 \leq \lambda \leq 1$ we have

$$f(\lambda x + (1 - \lambda)y) \leq \lambda f(x) + (1 - \lambda)f(y). \quad (1)$$

The function $f(x)$ is called a **strictly convex function** if the sign \leq in (1) is replaced by $<$ for $x \neq y$ except when λ is either 0 or 1. If $-\psi(x)$ is convex (strictly convex), the function $\psi(x)$ is called a **concave function** (**strictly concave function**). The notion of convex function was introduced by J. L. W. V. Jensen [1] for the case where the domain D is an interval on the real line \mathbf{R} .

Sometimes the condition for a convex function is weakened in such a way that (1) is assumed only for $\lambda = 1/2$. However, if D is a \dagger topological linear space and f is continuous, then the weakened condition implies the original one. Hereafter, we mainly consider the case where D is an interval on the real line. In this case, a convex function $f(x)$ (in the weaker sense) is continuous in the interior of the interval if $f(x)$ is \dagger measurable or bounded from above on a set of positive measure (the latter was proved by A. Ostrowski [2]). In particular, suppose that $f(x)$ is defined in the interval I and is bounded from below. Then either $f(x)$ is continuous or its graph is dense in the set $\{(x, y) | x \in I, y \geq g(x)\}$, where $g(x)$ is a suitable convex continuous function (Hukuhara [3]). We note here that the original definition of a convex function $f(x)$ implies the continuity of $f(x)$ in the interior of the interval. In such a case, $f(x)$ always has \dagger right and \dagger left derivatives and satisfies $f'_-(x) \leq f'_+(x) \leq f'_-(y) \leq f'_+(y)$ for $x < y$. Hence it is differentiable except for at most countably many points.

A function $f(x)$ is a continuous convex function in $a \leq x \leq b$ if and only if it is expressible in the form

$$f(x) = f(a) + \int_a^x \varphi(t) dt,$$

where $\varphi(t)$ is a monotone increasing function. If $f(x)$ is twice differentiable, then $f''(x) \geq 0$ ($a < x < b$) is a necessary and sufficient condition for $f(x)$ to be convex in (a, b) .

B. Convex Functions and Inequalities

If $f(x)$ is convex (in the original sense), we have, for $a_v > 0$,

$$f\left(\frac{\sum a_v x_v}{\sum a_v}\right) \leq \frac{\sum a_v f(x_v)}{\sum a_v}. \quad (2)$$

Similarly, we have, for $\varphi > 0$,

$$f\left(\frac{\int \varphi \psi dx}{\int \varphi dx}\right) \leq \frac{\int \varphi f(\psi) dx}{\int \varphi dx}. \quad (3)$$

The functions x^a ($a > 1$ or $a < 0$), $-x^a$ ($0 < a < 1$), $-\log x$, $x \log x$ are strictly convex for $x > 0$, and the functions x^{2n} ($n \geq 1$), $\exp x$, $\log(1 + e^x)$, $\sqrt{a^2 + x^2}$ ($a \neq 0$) are strictly convex in $-\infty < x < +\infty$. Applying the inequalities (2) or (3) to these functions, we obtain various inequalities, including the inequalities on means (\rightarrow 211 Inequalities).

A continuous convex function $f(x)$ over a topological linear space satisfying the relation $f(\alpha x) = \alpha f(x)$ for an arbitrary positive number α is called a **subadditive functional** and is often utilized in functional analysis.

C. M. Riesz's Convexity Theorem

Let $x = (\xi_1, \dots, \xi_n)$ be an n -tuple of complex numbers, and let $v \geq 0$. We put $N_v(x) = (\sum_{j=1}^n |\xi_j|^{1/v})^v$ for $v > 0$ and $N_0(x) = \sup |\xi_j|$. Let (α_{ij}) be an $m \times n$ complex matrix, $x = (\xi_1, \dots, \xi_n)$, $z = (\zeta_1, \dots, \zeta_m)$, $v \geq 0$, and $\mu \geq 0$. We put

$$M(v, \mu) = \sup_{N_v(x) \leq 1, N_\mu(z) \leq 1} \left| \sum_{i=1}^m \sum_{j=1}^n \alpha_{ij} \xi_i \zeta_j \right|.$$

Then $\log M(v, \mu)$ is a convex function of (v, μ) in the following sense: Let $0 < v_i \leq 1$, $0 < \mu_i \leq 1$, and $v_i + \mu_i \geq 1$ ($i = 1, 2$). Then $\log M((1-t)v_1 + tv_2, (1-t)\mu_1 + t\mu_2)$ is a convex function with respect to t for $0 \leq t \leq 1$ [4, 5]. These results are called **M. Riesz's convexity theorem**. Famous inequalities such as the \dagger Hölder inequality or the \dagger Minkowski inequality follow from this theorem. For example, let T be an \dagger additive operator from the \dagger function space $L_p(\Omega)$ into $L_p(\Omega)$ for all $1 \leq p \leq \infty$. If T is a continuous operator for $p = 1$ and $p = \infty$, and the norm of T is $\leq C$ for $p = 1$ and $p = \infty$, then T is continuous for all p ($1 < p < \infty$), and its norm is always $\leq C$.

D. Subdifferentials of Convex Functions

Currently, **convex analysis** is playing an important role in the study of nonlinear evolution equations. This analysis treats convex functions on infinite-dimensional spaces [9].

In convex analysis, it is sometimes convenient to consider a proper convex function φ on a Hilbert space X . A mapping φ from X into $(-\infty, +\infty]$ is called a **proper convex function** if φ is not identically equal to $+\infty$ and if

$$\varphi(\lambda x + (1-\lambda)y) \leq \lambda \varphi(x) + (1-\lambda)\varphi(y)$$

for every $x, y \in X$ and $0 \leq \lambda \leq 1$. The convex set

$$D(\varphi) = \{x \in X \mid \varphi(x) < \infty\} \subset X$$

is called the **effective domain** of φ . The **subdifferential** $\partial\varphi$ of φ is defined to be a multivalued function which assigns to each x in $D(\varphi)$ all elements $y \in X$ satisfying $\varphi(\xi) \geq \varphi(x) + \langle y, \xi - x \rangle$ for any $\xi \in X$. Then $\partial\varphi$ is monotone in X in the following sense: If $y_1 \in \partial\varphi(x_1)$ and $y_2 \in \partial\varphi(x_2)$, then

$$\langle y_1 - y_2, x_1 - x_2 \rangle \geq 0.$$

Under some conditions on φ , $\partial\varphi$ becomes a single-valued function, as is seen in the following example: Let A be a nonnegative self-adjoint operator in a Hilbert space X . For the \dagger fractional power \sqrt{A} of A , define φ by

$$\varphi(x) = \begin{cases} \frac{1}{2} \|\sqrt{A}x\|^2, & x \in D(\sqrt{A}), \\ +\infty, & \text{otherwise.} \end{cases}$$

Then $D(\varphi) = D(\sqrt{A})$ and $\partial\varphi = A$.

E. Convex Functions and Nonlinear Semigroups

Let φ be a lower semicontinuous proper convex function on a Hilbert space X . Since $A = -\partial\varphi$ is a maximal \dagger dissipative operator in X , it generates a nonlinear semigroup $\{T_t \mid t \geq 0\}$ on the closed convex set $\overline{D(A)}$:

$$T_t x = \lim_{\tau \downarrow 0} (I - \tau A)^{-[t/\tau]} x$$

(\rightarrow 286 Nonlinear Functional Analysis, 378 Semigroups of Operators and Evolution Equations). It can be shown that for any $a \in \overline{D(A)}$, $T_t a \in D(A)$ whenever $t > 0$. Thus the \dagger abstract Cauchy problem

$$\frac{du}{dt} + \partial\varphi(u) \ni 0 \quad (t > 0),$$

$$u(+0) = a,$$

is considered to be "parabolic." Furthermore,

we have

$$\left\| \frac{d}{dt} T_t a \right\| \leq \frac{1}{t} \|a - T_t a\| \quad (t > 0)$$

for all $a \in \overline{D(A)}$ (H. Brézis [10]).

89 (VI.11) Convex Sets

A. General Remarks

A nonempty subset X of the n -dimensional Euclidean space \mathbf{R}^n is called a **convex set** if for any elements x, y in X and any number a such that $0 \leq a \leq 1$, the element $ax + (1-a)y$ of \mathbf{R}^n is also contained in X . The \dagger interior and the \dagger closure of a convex set are also convex. A point x of a convex set X is called an **extreme point** of X if x cannot be expressed as $(x_1 + x_2)/2$ in terms of a pair of distinct points x_1, x_2 in X . A bounded closed convex set is called a **convex body** if it has \dagger interior points.

Given an arbitrary nonempty subset X of \mathbf{R}^n , the minimum convex set containing X exists, called the **convex hull** of X and denoted by $[X]$. Each point x of $[X]$ can be expressed as $x = \sum_{i=1}^{n+1} a_i x_i$, where x_i belongs to X and the a_i are nonnegative numbers such that $\sum_{i=1}^{n+1} a_i = 1$. When X is a finite set, $[X]$ is called a **convex polyhedron**. If \dot{X} denotes the set of extreme points (also called **vertices**) of a convex polyhedron X , then $X = [\dot{X}]$.

For elements x, y of \mathbf{R}^n , denote the inner product by (x, y) . Given a nonzero element v of \mathbf{R}^n and a fixed number a , the \dagger hyperplane $H = \{x | (v, x) = a\}$ divides the space \mathbf{R}^n into two \dagger half-spaces $\{x | (v, x) \leq a\}$ and $\{x | (v, x) \geq a\}$, each of which is a closed convex set. If a convex set X is contained in one of the half-spaces S determined by the hyperplane H and the boundaries of X and H intersect, then we say that H is a **supporting hyperplane** of X and S is a **supporting half-space** of X . A closed convex set X is the intersection of its supporting half-spaces. A boundary point of a convex set X is contained in a supporting hyperplane of X . Given mutually disjoint convex sets X and Y , the **separation theorems** (1) and (2) hold.

(1) If X has inner points, then there exist a nonzero element v of \mathbf{R}^n and a number a such that X is contained in the set $\{x | (x, v) \geq a\}$ and Y is contained in the set $\{x | (x, v) \leq a\}$.

(2) If X and Y are closed and X is bounded, then we can replace the signs \leq and \geq in (1) by $<$ and $>$, respectively (when the separation of convex sets X and Y is described by strict inequalities, we say that X and Y are **strongly separated**).

As an immediate consequence of the separation theorems, we obtain the following proposition: Suppose that A is an $m \times n$ matrix with real entries. For an element z in a Euclidean space, we write $z \geq 0$ (> 0) if each component of z is ≥ 0 (> 0). Now if $\dagger Ay > 0$ never holds for an m -dimensional vector $y > 0$, then there exists a nonzero n -dimensional vector $x \geq 0$ such that $Ax \leq 0$ (\rightarrow 173 Game Theory).

The definitions given previously for subsets of \mathbf{R}^n can be naturally extended to the case of \dagger real topological linear spaces (\rightarrow Section G). Also, in the theory of analytic functions of several complex variables, various notions of convexity of the subsets of \mathbf{C}^n are considered (\rightarrow 21 Analytic Functions of Several Complex Variables).

B. Helly's Theorem

Suppose that we are given an index set Λ of cardinality greater than $n + 1$, and bounded closed convex sets C_λ ($\lambda \in \Lambda$) in \mathbf{R}^n . If any $n + 1$

sets of the C_λ have nonempty intersection, then the intersection of all the C_λ is nonempty (**Helly's theorem**).

This theorem has a wide range of applications. For example, we have propositions (1)–(4).

(1) If a convex set X of \mathbf{R}^n is covered by a finite number of half-spaces, then X can be covered by no more than $n+1$ half-spaces among them. (2) Let X and Y be finite subsets of \mathbf{R}^n . X and Y are strongly separated by a hyperplane if for an arbitrarily chosen subset S of $X \cup Y$ consisting of at most $n+2$ points, the sets $S \cap X$ and $S \cap Y$ are strongly separated by a hyperplane. (3) If the \dagger diameter of a subset X of \mathbf{R}^n is not greater than 2, then X is contained in a \dagger ball of radius $(2n/(n+1))^{1/2}$. (4) Let X be a convex body in \mathbf{R}^n . There exists a point x in X such that $\|x-u\|/\|v-u\| \leq n/(n+1)$, where u, v are points of intersection of an arbitrary straight line passing through x with the boundary of X , and $\|x\|$ denotes the length $(x, x)^{1/2}$ of x .

Helly's theorem can also be applied to problems of approximation of functions.

C. Ovals

The boundaries of convex bodies in \mathbf{R}^2 and \mathbf{R}^3 are called **ovals** and **ovaloids**, respectively. An oval E is a \dagger Jordan curve $C(t)$ which admits at every point $P_0 = C(t_0)$ left and right "tangents" $l_{p_0}^+$ and $l_{p_0}^-$, where $l_{p_0}^\pm$ is a straight line expressed as the set of points $P(\lambda)$, $\lambda \in \mathbf{R}$ such that $P(\lambda) - P_0 = \lambda a^\pm$, with $a^\pm = \lim_{t \rightarrow \pm 0} (C(t) - P_0)/|C(t) - P_0|$. There may exist exceptional points P on E for which left and right tangents do not coincide, but the set of such points is at most countable. Each tangent $l_{p_0}^\pm$ shares a point or a segment with E . A line satisfying this condition is called a **supporting line** of the oval. It is also a supporting hyperplane in \mathbf{R}^2 of the convex body $[E]$ in the sense of Section A. If we fix an interior point O of a convex body X and take an arbitrary point P different from O , then the boundary E of X admits one and only one supporting line $l(P)$ which is perpendicular to the line OP and meets the half-line OP . Take a rectangular coordinate system with the origin O , and let (x, y) denote the coordinates of P . Then the points (ξ, η) on $l(P)$ satisfy the equation $\xi x + \eta y = H(x, y)$, where $H(x, y)$ is a function determined for all (x, y) in \mathbf{R}^2 and satisfying the following conditions: (i) $H(0, 0) = 0$; (ii) $H(tx, ty) = tH(x, y)$, for $t \geq 0$; (iii) $H(x_1 + x_2, y_1 + y_2) \leq H(x_1, y_1) + H(x_2, y_2)$. The function $H(x, y)$ is called the **supporting line function** of E . The magnitude and shape of E are determined by H , and any function satisfying con-

ditions (i)–(iii) is a supporting line function of an oval. An oval E has a finite length $L = L(E)$, and the convex body $[E]$ has a finite area $F = F(E)$. If OP' denotes the half-line with direction opposite to that of OP and l' denotes the supporting line $l(P')$, the distance between the parallel lines l and l' is called the **breadth** of E in the direction PP' . Let $D = D(E)$ and $\Delta = \Delta(E)$ be the maximum and minimum of the breadth of E , respectively. D is the \dagger diameter of E (or $[E]$), and Δ is called the **thickness** of E (or $[E]$). In particular, if $D = \Delta$, then the oval E is called a **curve of constant breadth**. In the following inequalities, equality holds only when E is one of the figures mentioned in parentheses: (1) $L^2 \geq 4\pi F$ (circles, J. Steiner (1838)) (\rightarrow 228 Isoperimetric Problems); (2) $\pi D^2 \geq 4F$ (circles, L. Bieberbach (1915)); (3) $L \leq \pi D$ (curves of constant breadth, W. Blaschke (1916)); (4) $F \geq \Delta^2/\sqrt{3}$ (regular triangles, J. Pál (1921)). See T. Kubota, *Tôhoku Sci. Bull.*, I, 12, 13; *Tôhoku Math. J.*, 24, 49.

D. Linear Combinations of Ovals

Let H_1 and H_2 be supporting line functions of ovals E_1 and E_2 , and let t_1 and t_2 be positive numbers. Since the function $t_1 H_1 + t_2 H_2$ satisfies conditions (i)–(iii), given before, it is a supporting line function of an oval $E(t_1, t_2)$. In this case, we can also write $E(t_1, t_2) = t_1 E_1 + t_2 E_2$ and call it a **linear combination** of E_1 and E_2 . In particular, the oval $(E_1 + E_2)/2$ is called the **mean oval** of E_1 and E_2 . In general, there exists a quantity M , called the **mixed area** of E_1 and E_2 , such that $F(E(t_1, t_2)) = F(E_1)t_1^2 + 2Mt_1t_2 + F(E_2)t_2^2$. M does not depend on the choice of t_1 and t_2 , and $M^2 \geq F(E_1)F(E_2)$. Here, the equality holds if and only if E_1 and E_2 are homothetic and situated in a position of homothety. Furthermore, if $0 \leq t \leq 1$, then the square root of $F(E(t, 1-t))$ is a \dagger convex function of t (H. Minkowski).

E. Specific Ovals

Suppose that we are given an equilateral triangle ABC . Draw three circles C_1, C_2 , and C_3 with centers A, B , and C and radii equal to the length of the sides of ABC . The minor arcs AB, BC , and CA of the circles form an oval which is called a **Reuleaux triangle**. This oval is of constant breadth. Furthermore, given a fixed breadth D , the area $F(E)$ of an oval E of constant breadth D attains its minimum when E is a Reuleaux triangle. A Reuleaux triangle obtained from a triangle ABC revolves freely within the square of side AB and touches each side. In general, an oval which revolves touch-

ing the sides of a convex polygon from the inside is called an **inrevolvable** oval. Any such oval revolves inside some regular polygon (M. Fujiwara, S. Kakeya).

Various properties of an oval already described can be generalized to the case of a boundary of a convex body in \mathbf{R}^n . For the volumes of subsets A, B in \mathbf{R}^n and $A + B = \{x + y | x \in A, y \in B\}$ in \mathbf{R}^n , the Brunn-Minkowski inequality

$$[\text{vol}(A + B)]^{1/n} \geq [\text{vol}(A)]^{1/n} + [\text{vol}(B)]^{1/n}$$

holds.

F. Convex Cones

A nonempty subset X of \mathbf{R}^n is called a convex cone if for any elements x, y of X and a non-negative number a , ax and $x + y$ are contained in X . A convex cone is a convex set. Given any nonempty subset X of \mathbf{R}^n , the minimum convex cone $K(X)$ containing X exists. Given two convex cones X and Y , a convex cone $X + Y$, called the **sum** of X and Y , is defined as the set of elements $x + y$, where x, y are elements of X, Y . The intersection of convex cones X and Y is also a convex cone. Given a convex cone X , the subset of \mathbf{R}^n consisting of the elements y such that $(x, y) \leq 0$ for any element x in X is a convex cone which is called the **dual convex cone** (or **conjugate convex cone**) of X , denoted by X^* . If X is a finite set, $K(X)$ is called a **convex polyhedral cone**. For example, if v is a nonzero vector, then the half-line $(v) = \{x | x = av, a \geq 0\}$ or the half-space $(v)^* = \{x | (v, x) \leq 0\}$ is a convex polyhedral cone. A convex polyhedral cone is closed. A convex cone X is a convex polyhedral cone if and only if X is the sum of a finite number of half-lines. Given convex cones X and Y , we have propositions (1)–(3): (1) If $X_1 \subset X_2$, then $X_2^* \subset X_1^*$; (2) $(X_1 + X_2)^* = X_1^* \cap X_2^*$; (3) $X_1^* + X_2^* \subset (X_1 \cap X_2)^*$. If X_1 and X_2 are convex polyhedral cones, then $X_1^* + X_2^* = (X_1 \cap X_2)^*$. Generally, $X \subset (X^*)^* = X^{**}$ for a convex cone X . If X is a closed convex cone, then $X = X^{**}$. Namely, the **duality principle** holds for closed convex cones. A linear subspace of \mathbf{R}^n is a convex polyhedral cone. Also, if A is an $m \times n$ real matrix, the subsets $\{x | Ax = 0, x \geq 0\}$ and $\{x | Ax \geq 0\}$ are convex polyhedral cones. Since the duality principle holds for convex polyhedral cones, we obtain the \dagger Minkowski-Farkas theorem (i.e., if A is an $m \times n$ real matrix and v is an element of \mathbf{R}^m , then the equation $Ay = v$ has a solution $y \geq 0$ in \mathbf{R}^n if and only if $(v, x) \geq 0$ for all $x \in \mathbf{R}^m$ such that $Ax \geq 0$). (For linear inequalities \rightarrow 255 Linear Programming.)

G. Convex Sets in Function Spaces

The definitions of convex sets and convex cones in \mathbf{R}^n can be naturally extended to the case of any real linear space. Some of their properties can be generalized and applied to the case of function spaces.

(1) Let E be a \dagger locally convex real topological linear space satisfying Hausdorff's \dagger separation axiom. Let A and B be convex sets in E , and assume that B has interior points and $A \cap B$ is empty. Then A and B are separated by a hyperplane. Namely, there exists a nonzero \dagger continuous linear functional f on E such that $\sup f(A) \leq \inf f(B)$.

(2) Let E be as in (1), and let C be a convex set in E . If a boundary point x of C admits a nonzero continuous linear functional f such that $f(x) = \sup f(C)$, we call such a point x a **supporting point** of C , and f a **supporting functional** of C . If C has interior points, then any boundary point x of C is a supporting point of C .

(3) Let C be a closed convex set of a \dagger Banach space E . The set of supporting points of C is dense in its boundary.

A convex set C contained in the dual space E^* of a real topological linear space E is called a **regularly convex set** if for any f_0 in E^* not contained in C , there exists a point x_0 in E such that $\sup\{f(x_0) | f \in C\} < f_0(x_0)$.

Let E be a real topological linear space satisfying Hausdorff's separation axiom, and let C be a closed convex cone having 0 as its extreme point. Furthermore, assume that $C \cap (-C) = \{0\}$. If we set $x \leq y$ when $y - x \in C$, a partial ordering \leq is defined in E . For example, if E is \mathbf{R}^n , then the **positive orthant** $C = \{x = (x_i) | x_i \geq 0, i = 1, \dots, n\}$ satisfies these requirements, and the partial ordering $x \leq y$ defined by means of C is equivalent to the relation $x_i \leq y_i$ for all i .

Some of the properties of matrices of positive entries or \dagger integral operators whose \dagger kernel functions are positive-valued can be generalized to properties of mappings $f: E \rightarrow E$ such that $f(C) \subset C$ (\rightarrow 255 Linear Programming; for the \dagger Krein-Milman theorem \rightarrow 424 Topological Linear Spaces).

90 (VI.13) Coordinates

A. General Remarks

Suppose that we are given a Euclidean plane E^2 and two lines $X'X$ and $Y'Y$ in E^2 perpendicular to each other. Let O be the point of intersection of $X'X$ and $Y'Y$. We identify each of the straight lines $X'X$ and $Y'Y$ with the set of real numbers \mathbf{R} ; the point O on each line is identified with zero. Let P be an arbitrary point in E^2 . We draw lines PQ , PR parallel to $Y'Y$, $X'X$, where Q , R are on $X'X$, $Y'Y$, respectively. Let x and y be the real numbers corresponding to Q and R . Thus we obtain a mapping sending the point P to the ordered pair (x, y) of real numbers. This mapping gives a one-to-one correspondence between the points P of E^2 and the ordered pairs (x, y) of real numbers in \mathbf{R}^2 . The numbers x and y are called the **coordinates** of P .

In general, given a set of mathematical objects, if we have a mechanism that assigns quantities to each element of the set, then such a mechanism is called a **coordinate system** on the set, and the quantities corresponding to each element are called its **coordinates**. In the previous example, the mechanism is called a rectangular coordinate system. Coordinate systems are also useful in expressing quantitative concepts by geometric ones which are intuitively easier to grasp, e.g., diagrams of train schedules and \dagger nomograms. \dagger Map projection, \dagger graphical calculation, \dagger descriptive geometry, etc., may be viewed as applications of the concept of coordinate systems.

In many cases, when we introduce a coordinate system in a space, it is determined uniquely by fixing a basic figure in the space.

In the case of a rectangular coordinate system on a plane E^2 , the basic figure consists of $X'X$ and $Y'Y$, which are called coordinate axes (the point O is called the origin). Sometimes it is convenient to consider real-valued functions f and g on \mathbf{R} and a coordinate system on the plane E^2 determined by the function that sends an arbitrary point P to $(f(x), g(y))$, where (x, y) are the coordinates of P in the rectangular coordinate system. Logarithmic papers, \dagger probability papers, and \dagger stochastic papers (binomial probability papers), etc., are constructed in this way to fit their respective purposes.

In various branches of mathematics there are many varieties of coordinate systems. In this article we deal with frames and coordinates, curvilinear coordinates, and local coordinates.

B. Frames and Coordinates

Suppose that we are given a space M and a \dagger transformation group G acting on M . It is desirable to introduce a coordinate system that best represents the geometric structure of M . Let G_* be a set of figures in M such that G acts \dagger simply transitively on G_* . Each element of G_* is called a **frame**. Utilizing each frame as basic figure, we introduce a coordinate system that is " G -invariant" in the following sense: Let $R \in G_*$, $X \in M$, and $C_R(X)$ be the coordinates of X with R as basic figure. Then the coordinate system is G -invariant if $C_R(X) = C_{gR}(gX)$ for any element g in G . If we have such a coordinate system for each $R \in G_*$, then the expressions of geometric properties of M in terms of the coordinates are independent of the choice of frames.

(1) Projective Coordinates. Let M be an n -dimensional \dagger projective space \mathbf{P}^n over a field K , and let G be the \dagger projective transformation group of \mathbf{P}^n . As a frame we can take the system of $n+1$ points (A_0, A_1, \dots, A_n) in general position. The \dagger homogeneous coordinates of an arbitrary point $X \in \mathbf{P}^n$ are given by the $(n+1)$ -tuple (x_0, x_1, \dots, x_n) satisfying the equation $X = \sum_{j=0}^n x_j A_j$, $x_j \in K$. They are called \dagger projective coordinates. In fact, if $(x_0, x_1, \dots, x_n) \neq (0, 0, \dots, 0)$, then (x_0, x_1, \dots, x_n) and $(\lambda x_0, \lambda x_1, \dots, \lambda x_n)$ ($\lambda \neq 0$) represent the same point in \mathbf{P}^n . A \dagger hyperplane π of \mathbf{P}^n is expressed as the set of points whose coordinates (x_0, x_1, \dots, x_n) satisfy a linear homogeneous equation $\sum_{j=0}^n x_j u_j = 0$, $u_j \in K$. Therefore, the hyperplane π is represented by the homogeneous coordinates (u_0, u_1, \dots, u_n) , called \dagger hyperplane coordinates of π .

(2) Affine Coordinates. Let M be an n -dimensional \dagger affine space E^n , and let G be the \dagger group of affine transformations of E^n . As a frame we can take the system $(O; \mathbf{e}_1, \mathbf{e}_2, \dots, \mathbf{e}_n)$, where O , called the origin, is a point in E^n , and the set of vectors $\{\mathbf{e}_i\}$ is a basis of the \dagger standard vector space of E^n . Then \dagger inhomogeneous coordinates of an arbitrary point $X \in E^n$ are given by the n -tuple (x_1, x_2, \dots, x_n) , where $X = O + \sum_{i=1}^n x_i \mathbf{e}_i$. They are also called \dagger affine coordinates of X in E^n . Sometimes we replace G above by the group of \dagger equivalent affinities and consider the frames $(O; \mathbf{e}_1, \mathbf{e}_2, \dots, \mathbf{e}_n)$ such that the volume of $[\mathbf{e}_1, \dots, \mathbf{e}_n] = 1$.

Furthermore, if E^n has the structure of a \dagger Euclidean space, we sometimes replace G by the \dagger group of motions and consider a system of **rectangular coordinates** determined by an \dagger orthogonal frame, that is, a frame $(O; \mathbf{e}_1, \mathbf{e}_2, \dots, \mathbf{e}_n)$ such that the inner product $(\mathbf{e}_i, \mathbf{e}_j) = \delta_{ij}$, where δ is the \dagger Kronecker delta. By contrast, the general affine coordinate system of a Euclidean space is called a system of **oblique coordinates**. In this case the inner products $(\mathbf{e}_i, \mathbf{e}_j) = g_{ij}$ are invariants of Euclidean geometry, and the distance ρ between two points (x_i) and (y_i) is given by $\rho = (\sum_{i,j=1}^n g_{ij}(y_i - x_i)(y_j - x_j))^{1/2}$. We sometimes consider an oblique coordinate system satisfying $(\mathbf{e}_i, \mathbf{e}_j) = 1$ ($i = 1, \dots, n$). In such cases the angle θ_{ij} between two basis vectors \mathbf{e}_i and \mathbf{e}_j is determined by $g_{ij} = \cos \theta_{ij}$.

(3) Barycentric Coordinates. In an n -dimensional affine space E^n , we take $n+1$ linearly independent points A_0, A_1, \dots, A_n and denote the position vectors from a point O to these points by $\mathbf{a}_0, \mathbf{a}_1, \dots, \mathbf{a}_n$, respectively. Then for any point $X \in E^n$ there exists a unique set of numbers $(\lambda_0, \lambda_1, \dots, \lambda_n)$ such that $X = O + \sum_{j=0}^n \lambda_j \mathbf{a}_j$, $\sum_{j=0}^n \lambda_j = 1$. We call these numbers **barycentric coordinates** of X in E^n . They are independent of the choice of the point O .

(4) Plücker Coordinates. Let $V(n, m)$ be the set of all m -dimensional subspaces in an n -dimensional projective space \mathbf{P}^n . Then $V(n, m)$ has the structure of a \dagger Grassmann manifold. In order to introduce a coordinate system on $V(n, m)$, we fix a projective coordinate system on \mathbf{P}^n . An m -dimensional subspace $\pi \in V(n, m)$ in \mathbf{P}^n is spanned by $m+1$ independent points $B_0, B_1, \dots, B_m \in \mathbf{P}^n$. We denote projective coordinates of these points by $(b_{0j}), (b_{1j}), \dots, (b_{mj})$ and construct the determinants

$$p_{j_0 j_1 \dots j_m} = \begin{vmatrix} b_{0j_0} & b_{0j_1} & \dots & b_{0j_m} \\ \dots & \dots & \dots & \dots \\ b_{mj_0} & b_{mj_1} & \dots & b_{mj_m} \end{vmatrix}, \quad 0 \leq j_0, \dots, j_m \leq n.$$

Then the subspace π can be represented by homogeneous coordinates $(\dots, p_{j_0 j_1 \dots j_m}, \dots)$.

These coordinates are independent of the choice of $m+1$ points that span π and are called **Plücker coordinates** (or **Grassmann coordinates**) of π in $V(n, m)$. In these coordinates, the $p_{j_0 j_1 \dots j_m}$ are alternating and satisfy the **Plücker relations**

$$\sum_{k=0}^{m+1} (-1)^k p_{i_1 i_2 \dots i_{m+1} k} p_{j_0 \dots \hat{j}_k \dots j_{m+1}} = 0,$$

where \hat{j}_k means that j_k is removed. In particular, when $n=3$ and $m=1$, we have only one Plücker relation $Q: p_{01}p_{23} - p_{02}p_{13} + p_{03}p_{12} = 0$, which is a homogeneous equation of the second degree. In other words, the set $V(3, 1)$ of all lines in a 3-dimensional projective space \mathbf{P}^3 is realized as a quadric surface Q in a 5-dimensional projective space \mathbf{P}^5 that has $(p_{01}, p_{02}, p_{03}, p_{12}, p_{13}, p_{23})$ as projective coordinates. Moreover, when \mathbf{P}^3 is a complex projective space, we put

$$p_{01} = \xi_0 + i\xi_3, \quad p_{02} = \xi_1 + i\xi_4, \quad p_{03} = \xi_2 + i\xi_5, \\ p_{23} = \xi_0 - i\xi_3, \quad p_{13} = -\xi_1 + i\xi_4, \quad p_{12} = \xi_2 - i\xi_5$$

and obtain a relation

$$\xi_0^2 + \xi_1^2 + \xi_2^2 + \xi_3^2 + \xi_4^2 + \xi_5^2 = 0$$

corresponding to the Plücker relation. Thus every line in \mathbf{P}^3 can be represented by homogeneous coordinates $(\xi_0, \xi_1, \dots, \xi_5)$, which we call **Klein's line coordinates**.

(5) $(n+2)$ -Hyperspherical Coordinates. Let $(x_0, x_1, \dots, x_n, x_\infty)$ be projective coordinates in an $(n+1)$ -dimensional real projective space \mathbf{P}^{n+1} . An n -dimensional \dagger conformal space S^n is realized as a quadric hypersurface S^n in \mathbf{P}^{n+1} : $\sum_{i,j=1}^n g_{ij}x_i x_j - 2x_0 x_\infty = 0$, where (g_{ij}) is a positive definite symmetric matrix. A general point in \mathbf{P}^{n+1} represents a \dagger hypersphere of S^n . That is, a hypersphere represented by a point $X \in \mathbf{P}^{n+1}$ is realized as the intersection of S^n with the \dagger polar hyperplane of X with respect to S^n ; according as X lies outside of S^n , on S^n , or inside of S^n , it represents a real hypersphere, a point hypersphere, or an imaginary hypersphere. Therefore any hypersphere of S^n in \mathbf{P}^{n+1} is expressed by homogeneous coordinates $(x_0, x_1, \dots, x_n, x_\infty)$, called **$(n+2)$ -hyperspherical coordinates**. When $n=2$, they are called **tetracyclic coordinates**, and when $n=3$, **pentaspherical coordinates**. Therefore, if we restrict $(n+2)$ -hyperspherical coordinates for points on S^n , then they satisfy the quadratic relation stated before. In the frame $(A_0, A_1, \dots, A_n, A_\infty)$ of \mathbf{P}^{n+1} which defines the $(n+2)$ -hyperspherical coordinates, A_0 and A_∞ are points on S^n , and the other A_i are real hyperspheres passing through the points A_0 and A_∞ . It is possible to choose a frame $(A_0, A_1, \dots, A_n, A_\infty)$ such that the equation for S^n becomes $\sum_{i=1}^n x_i^2 - 2x_0 x_\infty = 0$ (i.e.,

$g_{ij} = \delta_{ij}$). Among hypersurfaces in S^n , one that is expressed by a homogeneous equation of the second degree with respect to $(n+2)$ -hyperspherical coordinates is called a **cyclide**. It is an algebraic surface of the fourth order and is an enveloping surface of the family of hyperspheres that are tangent to n fixed hyperspheres.

(6) Moving Coordinates. When we study the differential geometry of an m -dimensional surface W in a space M on which a transformation group G acts, it is often preferable to take a frame or frames at each point of W and consider a t connection among them. These frames are called **moving frames**, and the set of coordinate systems with respect to moving frames is called a **moving coordinate system** (\rightarrow 111 Differential Geometry of Curves and Surfaces).

C. Curvilinear Coordinates

Let (x_1, x_2, \dots, x_n) be a rectangular coordinate system on an n -dimensional Euclidean space E^n . If $x_i = x_i(u_1, u_2, \dots, u_n)$, $i = 1, \dots, n$, are functions of n variables (u_1, u_2, \dots, u_n) of class C^r ($r \geq 1$) and the t functional determinant $D(x_1, \dots, x_n)/D(u_1, \dots, u_n)$ is not equal to zero in some open domain, then (u_1, u_2, \dots, u_n) are considered local coordinates in E^n . We call them **curvilinear coordinates** of E^n . A hypersurface $u_i = \text{constant}$ (obtained by fixing the value of one of the variables u_i) is called a **coordinate hypersurface**, and a curve $u_j = \text{constant}$ ($j \neq i$) is called a **coordinate curve**. The line element ds of a Euclidean space E^n is given by

$$ds^2 = \sum_{k=1}^n dx_k^2 = \sum_{i,j=1}^n g_{ij} du_i du_j,$$

$$g_{ij} = \sum_{k=1}^n \frac{\partial x_k}{\partial u_i} \frac{\partial x_k}{\partial u_j}.$$

Thus E^n is equipped with a t Riemannian metric. However, as E^n is t flat, its t curvature tensor satisfies $R_{jkl}^i = 0$. If the metric is diagonal, namely, if $ds^2 = \sum_{i=1}^n g_i du_i^2$, the coordinates are called **orthogonal curvilinear coordinates**. Moreover, if $g_1 = \dots = g_n$, the coordinates are called **isothermal coordinates**. The metric is diagonal if and only if coordinate curves are mutually perpendicular at the points of intersection. Actually, curvilinear coordinate systems that are often used practically are diagonal. The concept of curvilinear coordinates has been generalized to the case of t differentiable manifolds and is utilized to determine their local coordinates.

On any 2-dimensional Riemannian manifold there always exist isothermal coordinates in a neighborhood of any point [7].

(1) Curvilinear Coordinates on Planes or Spaces (\rightarrow Appendix A, Table 3.V). Let (x, y) be rectangular coordinates of a point in a Euclidean plane E^2 . We have the following coordinate systems on E^2 :

Polar coordinates (r, θ) , where

$$x = r \cos \theta, \quad y = r \sin \theta.$$

Elliptic coordinates (λ, μ) , where

$$x^2 = (\lambda + a^2)(\mu + a^2)/(a^2 - b^2),$$

$$y^2 = (\lambda + b^2)(\mu + b^2)/(b^2 - a^2),$$

$$a > b > 0, \quad \lambda > -b^2 > \mu > -a^2.$$

Parabolic coordinates (α, β) , where

$$x = -(\alpha + \beta), \quad y = \sqrt{-4\alpha\beta}, \quad \alpha > 0 > \beta.$$

Equilateral (or rectangular) hyperbolic coordinates (u, v) , where

$$x = uv, \quad y = (u^2 - v^2)/2.$$

Bipolar coordinates (ξ, η) , where

$$x = a \sin \xi / (\cosh \xi + \cos \eta),$$

$$y = a \sin \eta / (\cosh \xi + \cos \eta),$$

$$-\infty < \xi < \infty, \quad 0 \leq \eta \leq 2\pi.$$

Next we consider the case of a 3-dimensional Euclidean space E^3 and let (x, y, z) be rectangular coordinates on E^3 . The following systems of coordinates on E^3 are sometimes useful.

Cylindrical coordinates (r, θ, z) , where

$$x = r \cos \theta, \quad y = r \sin \theta, \quad z = z.$$

Spherical coordinates (r, θ, φ) , where

$$x = r \sin \theta \cos \varphi, \quad y = r \sin \theta \sin \varphi, \quad z = r \cos \theta.$$

Ellipsoidal coordinates (λ, μ, ν) , where

$$x^2 = (\lambda + a^2)(\mu + a^2)(\nu + a^2)/(a^2 - b^2)(a^2 - c^2),$$

$$y^2 = (\lambda + b^2)(\mu + b^2)(\nu + b^2)/(b^2 - c^2)(b^2 - a^2),$$

$$z^2 = (\lambda + c^2)(\mu + c^2)(\nu + c^2)/(c^2 - a^2)(c^2 - b^2),$$

$$a > b > c > 0, \quad \lambda > -c^2 > \mu > -b^2 > \nu > -a^2.$$

These coordinate systems are all systems of orthogonal curvilinear coordinates. Suppose that we are given two rectangular coordinate systems (ξ, η, ζ) and (x, y, z) sharing the same origin. The correlation of the two is given by **Euler's angles** (θ, φ, ψ) , where θ , φ , and ψ are the angles between the z -axis and ζ -axis, zx -plane and $z\zeta$ -plane, and $\zeta\zeta$ -plane and ζz -plane, respectively. The Euler angles θ , φ , and ψ are subject to the inequalities $0 \leq \theta \leq \pi$ and $0 \leq \varphi, \psi < 2\pi$. They are often utilized in the dynamics of rigid bodies.

(2) Multipolar Coordinates. Let P_1, P_2, \dots, P_m be m points in general position in an n -dimensional Euclidean space E^n , $m \leq n$. If we

denote by $\rho_i (\geq 0)$ the distance between a point X of E^n and P_i , then $(\rho_1, \rho_2, \dots, \rho_m)$ can be regarded as coordinates of a point X contained in a suitable domain of E^n . They are called **multipolar coordinates**. In particular, if $m=2$ they are called **bipolar coordinates**, and if $m=3$, **tripolar coordinates**. When $m>n$, these coordinates satisfy $m-n$ relations. Next let $\alpha_1, \alpha_2, \dots, \alpha_m$ be m hyperplanes in general position in E^n , $m \leq n$. For an arbitrary point X of E^n , we denote by ξ_i the directed distance of X from each hyperplane α_i . The m -tuple $(\xi_1, \xi_2, \dots, \xi_m)$ provides coordinates of X that are called **multiplanar coordinates** in E^n . When $m>n$, these coordinates satisfy $m-n$ relations. In particular, when $n=2$ and $m=3$, they are called **trilinear coordinates**. In this case, if we denote by S the area of the triangle defined by three lines $\alpha_1, \alpha_2, \alpha_3$, and by a_1, a_2, a_3 the lengths of the three sides of the triangle, then the trilinear coordinates (ξ_1, ξ_2, ξ_3) satisfy a linear relation $a_1 \xi_1 + a_2 \xi_2 + a_3 \xi_3 = 2S$.

(3) Tangential Polar Coordinates. In a Euclidean plane E^2 , we take a directed line l_0 passing through a point O . For an arbitrary directed line g , let p be the directed distance between O and g , and let θ be the angle between l_0 and g . Then (p, θ) are called **tangential polar coordinates** (Fig. 1). They are useful for representing tangent lines to curves in E^2 . Let C be an \dagger oval in E^2 . A line is called a \dagger supporting line of C if its intersection with C consists of a point or a line segment. In this case we take the origin O inside C and consider the coordinates (p, θ) of the supporting lines of C . Then the equation of C can be represented as $p = p(\theta)$, where $p(\theta)$ is a periodic function of period 2π . The coordinates (p, θ) are especially useful when the function $p(\theta)$ can be expanded in a \dagger Fourier series. In the case of Euclidean space E^3 , the notion of tangential polar coordinate system can also be defined by using tangent planes.

Fig. 1
Tangential polar coordinates.

(4) Normal Coordinates. Let M be an n -dimensional \dagger Riemannian manifold, and let $T_A(M)$ be the tangent space to M at a point A . For each tangent vector $\mathbf{v} \in T_A(M)$, we draw a

\dagger geodesic through A with the initial direction \mathbf{v} and take a point P on the geodesic such that the distance from A to P is equal to the length of \mathbf{v} . Then the correspondence that sends \mathbf{v} to P is a \dagger diffeomorphism of a neighborhood of the zero vector 0 of $T_A(M)$ with a neighborhood of A in M . Therefore the components (v^1, v^2, \dots, v^n) of \mathbf{v} with respect to a basis of $T_A(M)$ give the coordinates of the points P contained in a suitable neighborhood of A . We call them **normal coordinates** about the point A of M . In these coordinates, each geodesic passing through A is given by equations $v^i = \alpha^i r$ ($i=1, 2, \dots, n$), where the (α^i) are components of the unit vector in the direction of \mathbf{v} and r is the parameter that represents the arc length from A to the point (v^1, \dots, v^n) . In particular, when $n=2$, we fix a tangent vector \mathbf{v}_0 at A and denote the angle between \mathbf{v} and \mathbf{v}_0 by θ . Then (r, θ) are coordinates of P called **geodesic polar coordinates**. The notion of normal coordinates can also be defined for \dagger Lie groups or differentiable manifolds with \dagger affine connections.

D: Local Coordinates

Suppose that we have a space M that has a covering by a family of open neighborhoods with coordinate systems. If, for each pair of neighborhoods with nonempty intersection, the coordinate transformation in the intersection satisfies certain specified conditions, then a mathematical structure on M can be defined.

Let E be a \dagger topological space. Suppose that Φ is a family of open sets in E such that the union of any number of open sets in Φ and the intersection of any finite number of open sets in Φ also belong to Φ . A set Γ of \dagger homeomorphisms is called a **pseudogroup of transformations** on E if Γ satisfies the following three conditions: (i) Any homeomorphism $f \in \Gamma$ is defined on an open set $U \in \Phi$, and $f(U) \in \Phi$. (ii) When an open set $U \in \Phi$ is expressed as the union of a family $\{U_i\}$ of open sets $U_i \in \Phi$, a homeomorphism f defined on U belongs to Γ if and only if its restriction to each U_i belongs to Γ . (iii) For any open set $U \in \Phi$, the identity mapping on U belongs to Γ , and if $f, g \in \Gamma$, then the inverse f^{-1} and the composition $g \circ f$, if it exists, belong to Γ .

Let E and M be topological spaces. A homeomorphism $\varphi: U \rightarrow V$ of an open set U in E to an open set V in M is called a **local coordinate system** of M with respect to E . For two local coordinate systems $\varphi_1: U_1 \rightarrow V_1$ and $\varphi_2: U_2 \rightarrow V_2$, the homeomorphism

$$\varphi_2^{-1} \circ \varphi_1: \varphi_1^{-1}(V_1 \cap V_2) \rightarrow \varphi_2^{-1}(V_1 \cap V_2)$$

is called a **transformation of local coordinates**.

Let Γ be a pseudogroup of transformations

on E . A set Σ of local coordinate systems of M with respect to E is said to define a Γ -structure on M if Σ satisfies the following two conditions: (1) the totality of the images of local coordinate systems belonging to Σ covers M ; (2) if two local coordinate systems ϕ_1 and ϕ_2 of Σ have a transformation of local coordinates, it belongs to Γ . Now suppose that two sets Σ and Σ' of local coordinate systems define Γ -structures on M . If the union of Σ and Σ' defines a Γ -structure, then we say that the first two Γ -structures are equivalent. Let Γ be a pseudogroup of t diffeomorphisms, each defined from an open subset of the n -dimensional space \mathbf{R}^n onto another open set. If a Γ -structure is defined on a space M , then M is an n -dimensional t differentiable manifold.

On the other hand, let Γ be a pseudogroup of complex analytic homeomorphisms in an n -dimensional complex number space \mathbf{C}^n . If a Γ -structure is defined on a space M , then M is an n -dimensional t complex analytic manifold. Locally homogeneous spaces, t foliated manifolds, the t fiber bundles are all equipped with local coordinate systems with suitable Γ -structures.

91 (IX.3) Covering Spaces

A. General Remarks

A continuous mapping $p: \tilde{Y} \rightarrow Y$ of an t arcwise connected topological space \tilde{Y} onto a con-

nected topological space Y is called a **covering mapping (covering map)** if the following condition (C) is satisfied: (C) Each point of Y has an open neighborhood V such that every t connected component of $p^{-1}(V)$ is mapped homeomorphically onto V by p . Here we note that Y is in fact arcwise connected.

If there is a covering mapping $p: \tilde{Y} \rightarrow Y$, we call \tilde{Y} a **covering space** of Y and (\tilde{Y}, p, Y) a **covering**. In particular, for a t differentiable manifold Y , if \tilde{Y} is also a differentiable manifold and p is differentiable, then \tilde{Y} is called a **covering (differentiable) manifold** of Y . (In the theory of t Riemann surfaces, a t covering surface may have some t branch points violating condition (C). Upon removing such points, we obtain a covering space as defined above.)

For each t path $w: I \rightarrow Y$ ($I = [0, 1]$) of Y , a path $\tilde{w}: I \rightarrow \tilde{Y}$ with $p \circ \tilde{w} = w$ is uniquely determined by the point $\tilde{w}(1) \in p^{-1}(w(1))$, and a bijection $w_{\#}: p^{-1}(w(1)) \rightarrow p^{-1}(w(0))$ is determined by $w_{\#}(\tilde{w}(1)) = \tilde{w}(0)$. Thus there exists a one-to-one correspondence between $p^{-1}(y)$ and $p^{-1}(y')$ for every pair of points y, y' of Y , and $(\tilde{Y}, p, Y, p^{-1}(y_0))$ is a t locally trivial fiber space with discrete fiber $p^{-1}(y_0)$. When the cardinal number of $p^{-1}(y)$ is a finite number n , we call (\tilde{Y}, p, Y) an n -fold covering. In this case, for a t loop $w(I, \dot{I}) \rightarrow (Y, y_0)$ with base point y_0 , $w_{\#}: p^{-1}(y_0) \rightarrow p^{-1}(y_0)$ is a permutation of the n elements in $p^{-1}(y_0)$, and we obtain a homomorphism of the t fundamental group $\pi_1(Y) = \pi_1(Y, y_0)$ of Y into the t symmetric group \mathfrak{S}_n , given by the correspondence $w \rightarrow w_{\#}$. The permutation group \mathfrak{M} , which is the image of this homomorphism, is called the **monodromy group** of the n -fold covering.

Two coverings (\tilde{Y}_i, p_i, Y) ($i = 1, 2$) are said to be **equivalent** if there is a homeomorphism $\phi: \tilde{Y}_1 \rightarrow \tilde{Y}_2$ with $p_2 \circ \phi = p_1$; such a ϕ is called an **equivalence**. In particular, a self-equivalence $\phi: \tilde{Y} \rightarrow \tilde{Y}$ of a covering (\tilde{Y}, p, Y) is called a **covering transformation**. The set π of all covering transformations forms a group by the composition of mappings, which is called the **covering transformation group** of \tilde{Y} . We call (\tilde{Y}, p, Y) a **regular covering** if for each $y \in Y$ and $\tilde{y}_1, \tilde{y}_2 \in p^{-1}(y)$, there exists a unique covering transformation that maps \tilde{y}_1 to \tilde{y}_2 . In this case, the t orbit space \tilde{Y}/π is homeomorphic to Y , (\tilde{Y}, p, Y, π) is a t principal bundle, and the monodromy group \mathfrak{M} is isomorphic to π .

For a covering (\tilde{Y}, p, Y) , we call \tilde{Y} a **covering group** of Y if \tilde{Y} and Y are topological groups and p is a homomorphism. Then (\tilde{Y}, p, Y) is a regular covering, and its covering transformation group is isomorphic to $p^{-1}(e)$ (e is the identity element of Y), which is a discrete subgroup lying in the center of \tilde{Y} (\rightarrow 423 Topological Groups O).

B. Universal Covering Spaces

For a covering (\tilde{Y}, p, Y) , we have the following relations of the \dagger homotopy groups: $p_*: \pi_i(\tilde{Y}) \rightarrow \pi_i(Y)$ is isomorphic (monomorphic) for $i \geq 2$ ($i = 1$), and $\pi_1(Y)/p_*(\pi_1(\tilde{Y}))$ is in one-to-one correspondence with $p^{-1}(y_0)$ ($y_0 \in Y$). If \tilde{Y} is \dagger simply connected, \tilde{Y} is called a **universal covering space** of Y ; if in addition \tilde{Y} is a covering group, \tilde{Y} is called a **universal covering group** of Y .

For a \dagger locally arcwise connected space Y , a covering (\tilde{Y}, p, Y) is regular if and only if $p_*(\pi_1(\tilde{Y}))$ is a normal subgroup of $\pi_1(Y)$, and a universal covering space of Y is a covering space of any covering space of Y . Moreover, if Y is a topological group, any covering space \tilde{Y} of Y can be given a unique topological group structure with which \tilde{Y} is a covering group of Y .

Let Y be an arcwise connected, locally arcwise connected, and \dagger locally simply connected space. Then the following classification theorem of coverings holds: The set of equivalence classes of coverings of Y is in one-to-one correspondence with the set of conjugate classes of subgroups of the fundamental group $\pi_1(Y)$; in particular, the equivalence class of a covering (\tilde{Y}, p, Y) corresponds to the conjugate class of the subgroup $p_*(\pi_1(\tilde{Y}))$. Also, there is a unique universal covering space \tilde{Y} of Y up to homeomorphism. If in addition Y is a topological group, then \tilde{Y} is a unique universal covering group of Y up to isomorphism of topological groups. Such a space \tilde{Y} is obtained as follows: Consider the \dagger path space $\Omega(Y; y_0, Y)$ of all paths in Y starting from a fixed point $y_0 \in Y$, and define two paths $w_0, w_1: (I, 0) \rightarrow (Y, y_0)$ such that $w_0(1) = w_1(1)$ to be equivalent if and only if there is a \dagger homotopy $w_t: (I, 0) \rightarrow (Y, y_0)$ with $w_t(1) = w_0(1)$ ($0 \leq t \leq 1$). Then we obtain the \dagger identification space \tilde{Y} of $\Omega(Y; y_0, Y)$ by this equivalence relation and the mapping $p: \tilde{Y} \rightarrow Y$ by $p\{w\} = w(1)$; this \tilde{Y} is the universal covering space of Y .

Let (\tilde{Y}, p, Y) be a regular covering with the covering transformation group π . Then there is a \dagger locally trivial fiber space (Y', q, B, \tilde{Y}) such that the total space Y' has the same \dagger (co) homology groups as Y , and the base space B is an \dagger Eilenberg-MacLane space $K(\pi, 1)$. The (co) homology \dagger spectral sequence of this fiber space is called that of the given regular covering (\tilde{Y}, p, Y) , E_∞ is a bigraded module \dagger associated with a certain filtration of the \dagger singular (co) homology module $H(Y)$, and E_2 is the (co) homology module $H(\pi; H(\tilde{Y}))$ of the group π , where π operates on the coefficient module $H(\tilde{Y})$ via the induced homomorphisms of covering transformations (\rightarrow 148 Fiber Spaces).

For any group π , there is a regular covering (E_π, p, B_π) with the covering transformation group π such that E_π is \dagger contractible; B_π is an Eilenberg-MacLane space $K(\pi, 1)$. We can take S^1 (1-sphere) as $B_{\mathbb{Z}}$ of the infinite cyclic group \mathbb{Z} , and the following infinite lens space as $B_{\mathbb{Z}_k}$ of the finite cyclic group \mathbb{Z}_k (\rightarrow 70 Complexes).

C. Lens Spaces

Let k be a positive integer and l_1, \dots, l_n be integers prime to k . Let $S^{2n+1} = \{(z_0, \dots, z_n) \in \mathbb{C}^{n+1} \mid |z_0|^2 + \dots + |z_n|^2 = 1\}$ be the unit sphere in the $(n+1)$ -dimensional complex linear space \mathbb{C}^{n+1} , and define the rotation γ by $\gamma(z_0, z_1, \dots, z_n) = (z_0 \exp 2\pi i/k, z_1 \exp 2\pi i l_1/k, \dots, z_n \exp 2\pi i l_n/k)$. Then the \dagger orbit space $S^{2n+1}/\mathbb{Z}_k = L(k; l_1, \dots, l_n)$, where $\mathbb{Z}_k = \mathbb{Z}/k\mathbb{Z}$ is interpreted as the cyclic group generated by γ , is called a **lens space**. It is an orientable $(2n+1)$ -dimensional \dagger differentiable manifold. Also, the **infinite lens space** $L^\infty(k) = L(k; 1, \dots, 1, \dots)$ is defined by taking $n = \infty$; the infinite sphere S^∞ is a k -fold covering space of $L^\infty(k)$, and $L^\infty(k) = B_{\mathbb{Z}_k} = K(\mathbb{Z}_k, 1)$. Its \dagger cohomology ring is given as follows.

(1) For integral coefficients, $H^{2i+1}(L^\infty(k)) = 0$, $H^{2i}(L^\infty(k)) = \mathbb{Z}_k$ ($i > 0$), and the \dagger cup product of generators of degree $2i$ and $2j$ is a generator of degree $2(i+j)$.

(2) Let $k = p^k$ (p is a prime). If $p \neq 2$, or $p = 2$ and k' is even, $H^*(L^\infty(k); \mathbb{Z}_p) = \wedge(e_1) \otimes \mathbb{Z}_p[e_2]$. If $p = 2$ and k' is odd, $H^*(L^\infty(k); \mathbb{Z}_2) = \mathbb{Z}_2[e_1]$ (e_i is an element of degree i). Here \wedge indicates the \dagger exterior algebra over \mathbb{Z}_p , and $\mathbb{Z}_p[\]$ the \dagger polynomial ring over \mathbb{Z}_p .

Two lens spaces $L(k; l_1, \dots, l_n)$ and $L(k'; l'_1, \dots, l'_n)$ are of the same homotopy type if and only if $k = k'$ and there is an integer m prime to k with

$$l_1 \dots l_n \equiv \pm m^{n+1} l'_1 \dots l'_n \pmod{k}$$

[8]. Furthermore, the condition $k = k'$, $l \equiv \pm l' \pmod{k}$ holds if and only if $L(k; l)$ and $L(k'; l')$ are homeomorphic. (Sufficiency is shown in [1]; necessity follows from the fact that the \dagger Hauptvermutung is valid for combinatorial 3-manifolds and that the condition holds if the polyhedra $L(k; l)$ and $L(k'; l')$ have isomorphic subdivisions [6].) Also \rightarrow [7, 11] and 65 Combinatorial Manifolds.

92 (IV.15) Crystallographic Groups

A. Space Groups and Point Groups

Let G be a discrete subgroup of the group of motions \mathfrak{G} in the real n -dimensional Euclidean space V . If G contains n linearly independent translations, then G is called an n -dimensional **crystallographic space group**, a **space group**, or a **crystallographic group**. The following assertions are known to be equivalent to each other: (i) A discrete subgroup G of \mathfrak{G} is a space group; (ii) \mathfrak{G}/G is compact; (iii) V/G is compact; (iv) There is a compact subset P of V such that $V = GP = \bigcup_{g \in G} gP$ [1]. The subgroup T consisting of all translations in G is called the **lattice group** of G . T is a normal subgroup of G and is generated by n linearly independent translations, say, t_1, t_2, \dots, t_n . Take a point x of V . Then the T -orbit of the point x is called a **lattice** of G (or T). t_1, \dots, t_n can be identified with a basis of V . Let K be the quotient group G/T and $k = gT$ an element of K . Then k gives rise to a linear transformation \bar{k} on T via the formula $\bar{k}(t) = gtg^{-1}$ (the product in G), $t \in T$, and K can be regarded as a subgroup of the orthogonal group of V via the above identification of T with a lattice in V . That is, the set of orthogonal transformations stabilizing x , $\{\bar{g} | (\bar{g}(y) = x + g(y) - g(x), y \in V), g \in G\}$ forms a group isomorphic to K . The quotient group K is a finite group and is called the **point group** of G . A group isomorphic to a point group of an n -dimensional space group is sometimes called

an n -dimensional **crystallographic group**. An algebraic characterization of space groups among abstract groups is given by “A group G is isomorphic to an n -dimensional space group $\Leftrightarrow G$ has a normal free Abelian subgroup of rank n , which is maximal Abelian and has finite index” [1].

By representing the action of K on T in terms of a basis of T , K can be regarded as a subgroup of $GL(n, \mathbb{Z})$. Hence we obtain the following **crystallographic restriction**: If K contains an element of order m , then $n \geq \varphi(m)$. Here φ is the Euler function. For example, if $n = 2, 3$, then $m = 1, 2, 3, 4$ or 6 ; and if $n = 4, 5$, then $m = 1, 2, 3, 4, 5, 6, 8, 10$, or 12 . The number of nonconjugate finite subgroups of $GL(n, \mathbb{Z})$ is finite (Jordan-Zassenhaus theorem; $\rightarrow [2, 3, 21]$).

Two space groups G_1 and G_2 are called **equivalent** if they are conjugate via an affine transformation f of V , i.e., $G_2 = fG_1f^{-1}$. Let T_i and K_i be the lattice group and the point group of G_i ($i = 1, 2$), respectively. Then $T_2 = hT_1$ and $K_2 = hK_1h^{-1}$ for the linear transformation h induced by f . Moreover, there is an orthogonal transformation k such that $K_2 = kK_1k^{-1}$; this k can naturally be considered as an element of $GL(n, \mathbb{Z})$. G_1 and G_2 are equivalent $\Leftrightarrow G_1$ and G_2 are isomorphic (as abstract groups) [1]. In applications it is often required that in the definition of equivalence f be an orientation-preserving affine transformation. Under this definition, there can be a pair G_1, G_2 such that G_1 and G_2 are mutually isomorphic but not equivalent, since they are conjugate only by means of an orientation-reversing affine transformation. In this case, they are called **enantiomorphous** to each other, or the pair is called an **enantiomorphic pair** (Table 1 below). For a given dimension n , there is only a finite number of equivalence classes of space groups [1]. We also conclude from this that point groups have finitely many equivalence classes up to conjugacy in the orthogonal group $O(V)$ or in $GL(n, \mathbb{Z})$.

B. Crystal Classes, Bravais Types

Let T be an n -dimensional lattice in n -dimensional Euclidean space V , and K a finite subgroup of the orthogonal group $O(V)$. Denote by a pair (T, K) a faithful linear representation of K on T , i.e., a monomorphism of groups $K \rightarrow \text{Aut}(T)$. A space group G determines a pair $(T, G/T)$. Conversely, for any pair (T, K) the following holds: “Any group extension of K over the kernel T is isomorphic to a space group” (\rightarrow the algebraic characterizations in Sections A and C). Thus to each pair (T, K) there corresponds a set of space groups.

Two pairs (T_1, K_1) and (T_2, K_2) are called **arithmetically equivalent** (this is denoted by $(T_1, K_1) \approx (T_2, K_2)$) if there exists an invertible linear transformation $g \in GL(V)$ such that $T_2 = gT_1$, $K_2 = gK_1g^{-1}$. These pairs are called **geometrically equivalent** or simply **equivalent** (this is denoted by $(T_1, K_1) \sim (T_2, K_2)$) if there exists a $g \in GL(V)$ such that $K_2 = gK_1g^{-1}$. The relation $\approx (\sim)$ is an equivalence relation, and equivalence classes are called **arithmetic (geometric) crystal classes**. The set of geometric crystal classes is in one-to-one correspondence with the set of equivalence classes of point groups up to conjugacy, and is sometimes called the set of **crystal classes**. The geometric crystal class of (T, K) is usually denoted by K .

Now let T be a lattice. Then the group of all orthogonal transformations that leave T invariant is called the **Bravais group** of T and is denoted by $B(T)$, i.e., $B(T) = \{g \in O(V) | gT = T\}$. The group $B(T)$ is finite and determines a pair $(T, B(T))$. Two lattices T_1 and T_2 are called **arithmetically equivalent** (this is denoted by $T_1 \approx T_2$) if $(T_1, B(T_1))$ and $(T_2, B(T_2))$ are arithmetically equivalent. An equivalence class is called a **Bravais type**, and an arithmetic crystal class determined by $(T, B(T))$ is called a **Bravais class**. For each Bravais type, a representative is said to be its **Bravais lattice** (Fig. 3 below).

Define an \dagger order relation on the set of lattices belonging to an arithmetic crystal class as follows. When $(T_1, K_1) \approx (T_2, K_2)$, define $T_2 \leq T_1$ if there exists a $g \in GL(V)$ such that $T_2 = gT_1$, $K_2 = gK_1g^{-1}$, and $B(T_2) \subseteq gB(T_1)g^{-1}$. Note that $T_1 \approx T_2 \Leftrightarrow T_1 \leq T_2$ and $T_2 \leq T_1$. In each arithmetic crystal class, there is a pair (T, K) with a \dagger minimal T with respect to this order relation. In this case the Bravais type of T is referred to as the **Bravais type** of the class of (T, K) . This lattice T is, intuitively, of the most general type appearing in the class. Now define a relation $T_1 \sim_f T_2$ if there are pairs (T_i, K_i) , $i = 1, 2$, such that $(T_1, K_1) \sim (T_2, K_2)$ and T_i is minimal in the class of (T_i, K_i) . The equivalence class of the equivalence relation generated by the relation \sim_f is called a **crystal family**.

Summarizing, we have defined the following. Let $\mathcal{S}, \mathcal{A}, \mathcal{G}, \mathcal{B}, \mathcal{CF}$ be the set of equivalence classes of space groups, arithmetic crystal classes, geometric crystal classes, Bravais types, and crystal families, respectively. Then we have the relations shown in Fig. 1. (All arrows in Fig. 1 are surjective.) \mathcal{CF} is nothing but the \dagger coproduct of \mathcal{G} and \mathcal{B} over \mathcal{A} , $\mathcal{CF} \simeq \mathcal{G} \amalg_{\mathcal{A}} \mathcal{B}$.

Fig. 1

Fig. 2

Moreover, there are injective mappings $\mathcal{B} \hookrightarrow \mathcal{A}$ and $\mathcal{A} \hookrightarrow \mathcal{S}$ such that the composites $\mathcal{B} \hookrightarrow \mathcal{A} \rightarrow \mathcal{B}$ and $\mathcal{A} \hookrightarrow \mathcal{S} \rightarrow \mathcal{A}$ are identities. The first is the mapping sending a Bravais type T to the arithmetic crystal class defined by $(T, B(T))$. The second one sends a class of (T, K) to a \dagger semidirect product of T and K (\rightarrow 190 Groups N). A space group belonging to a class of the image of $\mathcal{A} \hookrightarrow \mathcal{S}$ is said to be **symmorphic** or **symmorphous**. A class which belongs to the image \mathcal{H} of the composite $\mathcal{B} \hookrightarrow \mathcal{A} \rightarrow \mathcal{G}$ is called a **holohedral** or **holosymmetric class**, or a **holohedry**. Define a mapping M of \mathcal{G} to the power set $\mathfrak{P}(\mathcal{B})$ by $M = (\mathcal{B} \leftarrow \mathcal{A}) \cdot (\mathcal{A} \rightarrow \mathcal{G})^{-1}$. For two elements C_1 and C_2 of \mathcal{G} , define $C_1 \sim_s C_2$ if $M(C_1) = M(C_2)$. Each equivalence class is called a **crystal system**, and the set of crystal systems is denoted by \mathcal{CS} . Two elements C and C' of \mathcal{G} belong to the same crystal family if and only if there exists a sequence of elements of \mathcal{G} , C_1, C_2, \dots, C_k such that $C_1 = C$ and $C_k = C'$ and $M(C_i) \cap M(C_{i+1}) \neq \emptyset$ for $i = 1, \dots, k-1$. Therefore there is a surjective mapping $\mathcal{CS} \rightarrow \mathcal{CF}$ (Fig. 2). When $n \leq 4$, the composite $\mathcal{H} \hookrightarrow \mathcal{G} \rightarrow \mathcal{CS}$ is bijective. It should be remarked that when $n \geq 3$, there is no mapping $\mathcal{B} \rightarrow \mathcal{CS}$ such that $\mathcal{A} \rightarrow \mathcal{G} \rightarrow \mathcal{CS}$ and $\mathcal{A} \rightarrow \mathcal{B} \rightarrow \mathcal{CS}$ coincide.

The numbers of elements of these sets are shown in Table 1.

Table 1

	$n =$	1	2	3	4
\mathcal{CF} , crystal families		1	4	6	23
\mathcal{CS} , ^a crystal systems		1	4	7	33
\mathcal{B} , Bravais types		1	5	14	64
\mathcal{G} , point groups (isomorphic classes) ^b		2 (2)	10 (9)	32 (18)	227 (118)
\mathcal{A} , arithmetic crystal classes		2	13	73	710
\mathcal{S} , space groups		2	17	219 ^c	4783 ^d

^a When $n \leq 4$, the number of elements of \mathcal{H} coincides with that of \mathcal{CS} .

^b The number in parentheses denotes the number of equivalence classes under algebraic isomorphism.

^{c,d} The number of equivalence classes under orientation-preserving transformations is 230 and 4895, respectively.

C. Construction of Space Groups

Take an element (T, K) of an arithmetic crystal class. Since K is finite and T is \dagger finitely generated, the \dagger cohomology groups $H^i(K, T)$ are finite groups (\rightarrow 200 Homological Algebra G). Let α be a \dagger second cocycle representing an element $[\alpha]$ of $H^2(K, T)$. Let $(T, K)_\alpha$ be the \dagger extension of K with kernel T corresponding to $[\alpha]$ (\rightarrow 190 Groups N). Then the set of elements of $(T, K)_\alpha$ is given by $\{\langle t, k \rangle |$

$t \in T, k \in K$, and the product is defined by $\langle t_1, k_1 \rangle \langle t_2, k_2 \rangle = \langle t_1 + k_1 t_2 + \alpha(k_1, k_2), k_1 k_2 \rangle$. Since $H^1(K, V) = 0, i \geq 1$, there is a \dagger first co-chain $\beta \in C^1(K, V)$ such that $\alpha(k_1, k_2) = \beta(k_1) + k_1 \beta(k_2) - \beta(k_1 k_2)$, and the \dagger first cocycle β on V/T defined by β induces an isomorphism $H^1(K, V/T) \cong H^2(K, T), [\beta] \mapsto [\alpha]$. Define an action of $\langle t, k \rangle$ on V by

$$\langle t, k \rangle(x) = kx + t + \beta(k), \quad x \in V.$$

Then $(T, K)_\alpha$ acts on V as a space group. Concerning their equivalence, this result holds:

"The equivalence classes of $(T, K)_\alpha, [\alpha] \in H^2(K, T)$ are in one-to-one correspondence with the orbits of $N(K)$, the normalizer of K in $\text{Aut}(T)$ acting on $H^2(K, T)$ " [4]. The action of $h \in N(K)$ is given by ${}^h\alpha(k) = h\alpha(h^{-1}kh), \alpha \in C^2(K, T)$.

For a pair (T, K) the **weight lattice** or the **weight group** T^* of (T, K) is defined by $\{v \in V \mid v - kv \in T, \forall k \in K\}$. Let R be an irreducible reduced \dagger root system, $Q(R)$ its lattice, and $W(R)$ its \dagger Weyl group. Then for a pair $(Q(R), W(R))$, $Q(R)^*$ is nothing but the usual weight lattice $P(R)$. (\rightarrow 248 Lie Algebras). Suppose that K of (T, K) does not contain the central inversion $-I_n: v \mapsto -v, v \in V$. Denote the group $K \cup (-I_n)K$ by $\pm K$. Then there is an isomorphism

$$H^1(\pm K, V/T) \cong [H^1(K, V/T)]_2 \times (T^*/T)/2(T^*/T).$$

Here $[\cdot]_2$ denotes the subgroup of elements of order not greater than 2 [5]. This isomorphism provides powerful means for the construction of space groups.

In constructing a pair (T, K) , it is useful to take a basis of T in a special form. Let $\{t_1, t_2, \dots, t_n\}$ be a basis of a lattice T , and set $a_{ij} = (t_i, t_j)$, where (\cdot) is the inner product in V . The $n \times n$ matrix $A = (a_{ij})$ is \dagger symmetric and \dagger positive definite, and the numbers a_{ij} are called the **lattice constants** of T . A basis $\{t_1, \dots, t_n\}$ is called a **reduced basis** if the \dagger quadratic form $(Ax, x) = \sum a_{ij}x_i x_j$ is reduced (\rightarrow 348 Quadratic Forms). A lattice admits at least one reduced basis, and in this case $\pm 2a_{ij} \leq a_{ii} \leq a_{jj}, i < j$ [6, Table 5.1; 7]. The totality of an n -dimensional reduced basis forms in a natural manner a semialgebraic set of dimension $(n+2)(n-1)/2$ in $\mathbf{R}^{(n+1)n/2}$. Its closure, say Q_n , is compact. On the other hand, the set $L_n = (\mathbf{R}_+ \times O(\mathbf{R}^n)) \backslash GL(n, \mathbf{R})/GL(n, \mathbf{Z})$ is identified with the set of equivalence classes of n -dimensional lattices under the relation of "same shape." There is a natural inclusion $L_1 \cup \dots \cup L_n \subset Q_n$, and L_n is dense in Q_n . Moreover, the inclusion gives a bijective homeomorphism when $n \leq 4$ [8].

A finite subgroup K of the orthogonal group $O(V)$ is said to be **fully transitive** if there

is a set $S = \{e_1, \dots, e_s\}$ that spans V on which K acts \dagger transitively and if K has no \dagger invariant subspace in V . In this case one can choose S as either of the following: (i) the **primitive hypercubic** type, $S = \{e_1, \dots, e_n\}, (e_i, e_j) = \delta_{ij}$ (\dagger Kronecker delta); (ii) the **primitive hyperbolic** type, $S = \{f_1, \dots, f_{n+1}\}, (f_i, f_i) = 1, i = 1, \dots, n+1, (f_i, f_j) = -1/n, i, j = 1, \dots, n+1, i \neq j$ (especially, $\sum_{i=1}^{n+1} f_i = 0$) [10].

D. Color Symmetry Groups, Twinning

A **color symmetry group**, or a **colored symmetry group**, associated with a space group G is a pair (G, G') such that G' is a subgroup of G with finite index. The index $r = [G : G']$ is called the **number of colors**. We call (G, G') a **white group** when $r = 1$, a **black and white group** or a **magnetic group** when $r = 2$, and a **polychromatic group** when $r \geq 3$. G' is also a space group with the lattice group $T' = G' \cap T$, where T is the lattice group of G . Two color symmetry groups (G_1, G'_1) and (G_2, G'_2) are called **equivalent** if there exists an \dagger affine transformation f such that $G_2 = fG_1f^{-1}$ and $G'_2 = fG'_1f^{-1}$. Then (G_1, G'_1) and (G_2, G'_2) are equivalent if and only if there is an isomorphism $\sigma: G_1 \rightarrow G_2$ such that $\sigma(G'_1) = G'_2$. A color symmetry group (G, G') is called **lattice equivalent** if $T' = T, K' \subset K$, and is called **class equivalent** if $T' \subset T, K' = K$. Take a pair (G, G') , and let G'' be the \dagger inverse image of K' under the canonical \dagger epimorphism $G \rightarrow K$. Then (G, G'') is lattice equivalent and (G'', G') is class equivalent. Fix the color number r . Then (i) the equivalence classes of lattice equivalent color symmetry groups are in one-to-one correspondence with the conjugacy classes of subgroups K_1 of index r , and (ii) the number of equivalence classes of class equivalent color symmetry groups is finite. When r is prime to the order of K , the classes are in one-to-one correspondence with K -invariant sublattices T_1 of index r in T . Therefore, when the number of colors is given, the set of equivalence classes of n -dimensional color symmetry groups is finite.

In case (i), a pair (K, K_1) is called a **color point group**, and in case (ii), (T, T_1) is called a **color lattice**. In particular, when $r = 2$, they are called a **black and white point group** and a **black and white lattice**, respectively. Their equivalence is defined in a similar way.

Take a color lattice (T, T_1) of color number r . Let m be the least natural number such that $mT \subset T_1$, then m is a divisor of r . Let $m = p_1^{n_1} \dots p_k^{n_k}, p_i \neq p_j (i \neq j)$ be the decomposition of m into its prime factors. Then there is a sequence of K -invariant sublattices of $T, T_i, i = 2, \dots, k-1$, such that (i) $T_1 \subset T_2 \dots \subset T_k \subset T_{k+1} = T$; (ii) $p_i^{n_i} T_{i+1} \subset T_i, i = 1, \dots, k$; (iii) the

submodules $T_i/p_i^{n_i}T_{i+1}$ of $i = 1, \dots, k$, $\mathbf{Z}^n \otimes \mathbf{Z}/p_i^{n_i}\mathbf{Z}$ are uniquely determined independently of the choice of such a sequence $\{T_i\}$. Thus the existence of color lattices is related to the \dagger modular representation of K (\rightarrow 362 Representations G). For example, if r is a prime number, then the representation of K on $T/rT \simeq \mathbf{Z}^n \otimes \mathbf{Z}/r\mathbf{Z}$ is the reduction modulo r of that of K on T .

A mathematical treatment of twinning is given as follows. Let V be an n -dimensional Euclidean space and T an n -dimensional lattice in V . The volume of T , $\text{vol}(T)$, is defined by $\text{vol}(T) = (|\det A|)^{1/2}$, where $A = (a_{ij})$ is the matrix of lattice constants. This definition is independent of the choice of a basis of T . If T' is a sublattice of index r in T , $\text{vol}(T') = r \cdot \text{vol}(T)$ follows. Let K be a finite subgroup of $O(V)$, T_1 and T_2 K -invariant lattices, and U a hyperplane in V . Then the quadruple (T_1, T_2, K, U) is called a **twinning structure** if it satisfies the following: (i) $\text{vol}(T_1) = \text{vol}(T_2)$; (ii) the lattice T_i is minimal in the arithmetic crystal class of (T_i, K) , $i = 1, 2$; and (iii) $T_1 \cap U = T_2 \cap U = T_0$, and T_0 is an $(n-1)$ -dimensional lattice in U . Two arithmetic crystal classes are said to be **twinable** if there exist representatives (T_1, K) , (T_2, K) , and a hyperplane U such that (T_1, T_2, K, U) is a twinning structure. Let (T_1, K) and (T_2, K) be two arithmetic crystal classes. If there exists a K -invariant hyper-surface U such that $T_0 = T_1 \cap U = T_2 \cap U$ is an $(n-1)$ -dimensional lattice in U , then two classes (T_1, K) and (T_2, K) are twinable.

E. Three- and Two-Dimensional Crystallography

Three-dimensional crystal classes are listed in Appendix B, Table 5.IV. To name these crystal classes, both Schoenflies' notation and the international notation are used.

Fix an \dagger orthogonal \dagger right-handed system (x, y, z) in V . For each crystal system, define three axes as follows. The first axis is the z -axis. The second is the line $x = y = z$ for the cubic system and the x -axis for the others. The third is the y -axis for orthorhombic, trigonal, and hexagonal systems, and the line $x = y, z = 0$ for the others. Then a crystal class is expressed by its generators with respect to these axes. The symbol k ($k = 1, 2, 3, 4, 6$) denotes the rotation by the angle $2\pi/k$ around the axis; \bar{k} is a composition of the rotation k and the central inversion ($v \mapsto -v, v \in V$), and k/m ($k = 2, 4, 6$) means the composition of k and the reflection about the hyperplane perpendicular to the above axis. The symbol m denotes $\bar{2}$. Usually, 1 is omitted. This is the **full international nota-**

tion and a set of generators can be read from it. The **short international notation** is also used.

Schoenflies' notation consists of the letters C_n, D_n, S_n, T, O , and the subscripts h, v, d . The letters denote the group and order: C_n is the \dagger cyclic group of order n ; D_n is the dihedral group of order $2n$; T is the \dagger tetrahedral group isomorphic to the fourth \dagger alternating group; O is the \dagger octahedral group isomorphic to the fourth \dagger symmetric group; and $S_2 = \bar{1}, S_4 = \bar{4}, S_6 = \bar{3}$. The subscripts h, v, d mean that the group is generated by reflections in the hyperplane which is horizontal, vertical, or perpendicular to a diagonal, respectively. The orientation is appropriately given. For example, in C_{nh} and D_{nh} there is an n th order rotation around the z -axis and the horizontal plane is the xy -plane.

The above notations are also applied to noncrystallographic finite subgroups of the 3-dimensional orthogonal group [13].

The symbol for Bravais type is specified by the name of its crystal system and one of the letters P, A, B, C, F, I . Six kinds of **simple Bravais lattices** are given as follows. A simple lattice is generated by $\{\mathbf{a}, \mathbf{b}, \mathbf{c}\}$ and satisfies the following condition. Denote the lengths of vectors by $a = \|\mathbf{a}\|, b = \|\mathbf{b}\|, c = \|\mathbf{c}\|$, and let $\alpha = \angle(\mathbf{b}, \mathbf{c}), \beta = \angle(\mathbf{c}, \mathbf{a}), \gamma = \angle(\mathbf{a}, \mathbf{b})$ be the angles between the indicated pairs of vectors. For **triclinic P**, $a \neq b \neq c \neq a, \alpha \neq \beta \neq \gamma \neq \alpha$; for **monoclinic P**, $a \neq b \neq c \neq a, \alpha = \gamma = 90^\circ \neq \beta$; for **orthorhombic P**, $a \neq b \neq c \neq a, \alpha = \beta = \gamma = 90^\circ$; for **tetragonal P**, $a = b \neq c, \alpha = \beta = \gamma = 90^\circ$; for **hexagonal P** or **trigonal P**, $a = b \neq c, \alpha = \beta = 90^\circ, \gamma = 120^\circ$; for **cubic P**, $a = b = c, \alpha = \beta = \gamma = 90^\circ$. Let T be one of the above lattices generated by $\{\mathbf{a}, \mathbf{b}, \mathbf{c}\}$. Then the lattices generated by $\{\mathbf{a}, \mathbf{b}, (\mathbf{b} + \mathbf{c})/2\}$, $\{(\mathbf{c} + \mathbf{a})/2, \mathbf{b}, \mathbf{c}\}$, $\{\mathbf{a}, (\mathbf{a} + \mathbf{b})/2, \mathbf{c}\}$, $\{(\mathbf{a} + \mathbf{b} + \mathbf{c})/2, \mathbf{b}, \mathbf{c}\}$, $\{(\mathbf{a} + \mathbf{b})/2, (\mathbf{b} + \mathbf{c})/2, (\mathbf{c} + \mathbf{a})/2\}$ are called **A, B, C, I, F lattices** determined by T . The original lattice T is called the **primitive lattice**. The **trigonal R** lattice is generated by $\{\mathbf{a}', \mathbf{b}', \mathbf{c}'\}$ satisfying $a' = b' = c', \alpha' = \beta' = \gamma' < 120^\circ, \neq 90^\circ$. Set $\mathbf{a} = \mathbf{a}' - \mathbf{b}', \mathbf{b} = \mathbf{b}' - \mathbf{c}', \mathbf{c} = \mathbf{a}' + \mathbf{b}' + \mathbf{c}'$. Then the hexagonal P lattice generated by $\{\mathbf{a}, \mathbf{b}, \mathbf{c}\}$ is defined to be the primitive lattice of the trigonal R lattice. The fourteen Bravais lattices are illustrated in Fig. 3.

An arithmetic crystal class (T, K) is denoted by the symbol of the Bravais lattice T and the symbol of K with respect to the action of K on T . Let the primitive lattice of T be generated by $\{\mathbf{a}, \mathbf{b}, \mathbf{c}\}$. Put the vector \mathbf{a} on the x -axis, and \mathbf{b} on the xy -plane. The action of K is then determined by the international notation for K , except when $K = \bar{4}2m, 32, 3m, \bar{3}m, \bar{6}m2$, and T is the primitive or I lattice. In these cases two kinds of actions interchanging the second and the third symbols are not equivalent. If such is the case, 1 is inserted into the third position for trigonal systems. Let (K) be

the symbol determined as above and (T) be the symbol of T . Then the action (T, K) is expressed by $((T), (K))$. For example, when $K = 32$, there are three arithmetic crystal classes $(P, 321)$, $(P, 312)$ $(R, 32)$.

Fig. 3
The conventional unit cell for each of the 14 Bravais lattices.

The notation of space groups determined by (T, K) is given by writing both the symbol (T), and the symbols of actions of elements on V which appear in the symbol (K) defined above. The symbol $(T)(K)$ denotes the 'semidirect product of T and K by the action (T, K) , and is the symmorphic space group determined by (T, K) . Other nonsymmorphic groups are designated by replacing symbols in (K) . If k is replaced by k_j ($j = 1, \dots, k-1$), then k_j is a k -fold screw glide with pitch j/k , that is, the composite of the rotation k and the translation $j\mathbf{f}/k$, where \mathbf{f} is the vector of minimum length of T along the axis of k . If m is replaced by a, b, c, n, d , then it is a **glide reflection**, that is, the composite of the reflection m and the translation in the reflecting hyperplane with the direction of $\mathbf{a}, \mathbf{b}, \mathbf{c}$, a face diagonal and a diamond, respectively. See [6] for the precise meaning of the notation discussed in this paragraph.

The notations for 2-dimensional point groups and space groups can be adopted from the ones for 3-dimensional ones by setting the reference plane as the xy -plane and the z -axis perpendicular to that plane. In this setting, the notation of a plane point group is given by the

corresponding point group in 3-space, and similarly for plane space groups. There is only one **glide operation**, denoted by g . The motion g is the composite of the line reflection about an axis and half the translation along the axis with the vector of minimum length of T . In [13], the precise group-theoretic description of space groups can be found. It should be noted that the notations for the two groups $p3m1$ and $p31m$ are frequently interchanged in the literature (including earlier editions of [13]).

F. History

The first mathematical study of the structure of crystals was done by the mineralogist J. F. C. Hessel (1830). He enumerated the finite subgroups of the 3-dimensional orthogonal group. Afterward, his result was rediscovered many times. A. Bravais (1850) showed that in 3-dimensional Euclidean space there are only 14 different lattices. All space groups consisting of orientation-preserving transformations were determined by C. Jordan (1868, 1869) and L. Sohnke (1879). Finally, almost all the space groups were determined independently by E. S. von Fedorov (1885, 1889) and A. Schoenflies (1887, 1889). Probably as a result of comparison of each other's lists, they established in 1891 the existence of the 230 space groups. Then A. Barlow (1894, 1896) derived these space groups by adding reflection operations to Sohnke's 65 groups.

In 1900 in his eighteenth problem D. Hilbert raised the question of whether the number of equivalence classes of space groups of a given dimension is finite. This was answered affirmatively by L. Bieberbach (1910 [1]). An algorithm for determining space groups was given by H. Zassenhaus (1948 [4]). Their results, including [2, 3], and work by C. Hermann (1949 [9], 1952 [10]) gave a solid foundation for n -dimensional crystallography.

Then followed a concrete treatment of 4-dimensional crystallography. A. C. Hurley (1951), using an earlier work of M. E. Goursat (1889) on finite subgroups of the 4-dimensional special orthogonal group, determined 221 of the 4-dimensional point groups. In the 1960s A. L. Mackay and G. S. Pawley (1963) and others gave 56 of the 4-dimensional Bravais types. After E. C. Dade (1965) determined 9 maximal finite subgroups of $GL(4, \mathbb{Z})$, R. Bülow (1967) and H. Brown, J. Neubüser, and H. Zassenhaus (1968) independently determined 710 arithmetic crystal classes. They reconfirmed the result with H. Wondratschek, and as a result, 64 Bravais types and 227 geometric crystal classes were established (1971 [15]). They ran Brown's computer

program for the determination of space groups based on [4] and obtained 4,783 space groups. Their work culminated in a book (1978 [16]). There have been several attempts to establish a unified treatment of n -dimensional crystallography [5, 8, 14, 17] and crystallography in complex Euclidean spaces.

Two-dimensional space groups were empirically known in ancient times, as demonstrated by artistic decorations. All the 17 2-dimensional space groups appear in the tile patterns of the Alhambra in Granada. A discrete subgroup of the plane motion group whose translation subgroup is only rank one is called a **frieze group**.

The notion of black and white groups was introduced by H. Heesch (1930), H. J. Woods (1935), and A. V. Shubnikov (1951). Only with the introduction of the use of neutron diffraction techniques did it become apparent that these groups could be used in the description of magnetically ordered structures [12]. Color symmetry groups were defined by B. L. van der Waerden and J. J. Bruckhardt (1961 [11]) for an arbitrary number of colors. A mathematical treatment of the twinning structure is found in papers by T. Ito (1938) and R. Sadanaga (1959).

93 (VI.20) Curves

A. Introduction

In the beginning of his *Elements*, Euclid gave definitions such as: A line is a length having no width; an end of a line is a point. However, he left notions such as width and length undefined. Thus his definitions were far from satisfactory. Actually, it was only during the latter half of the 19th century that efforts were made to obtain exact definitions of lines and curves. Euclid, among others, distinguished two kinds of curves: **straight lines** and **curves**. Nowadays, however, **lines** in the sense of Euclid are called curves, and a straight line is considered a curve. A first effort to give an exact definition

of a curve using analytic methods was made by C. Jordan in his *Cours d'analyse I* (1893).

B. Jordan Arcs and Jordan Curves

Following Jordan, we define a **continuous plane curve** C to be the image of a †continuous mapping sending the interval $[0, 1]$ into the Euclidean plane E^2 . Namely, C is the set of points (x, y) in E^2 such that

$$x = f(t), \quad y = g(t), \quad 0 \leq t \leq 1,$$

with continuous functions f, g defined on $[0, 1]$. A continuous curve is also called a **continuous arc**. We call $(f(0), g(0))$ and $(f(1), g(1))$ the **ends** of the arc. Given continuous functions f, g defined on $(0, 1)$, the set $\{(x, y) | x = f(t), y = g(t), 0 < t < 1\}$ is called an **open arc**. More generally, the image of a continuous mapping of $[0, 1], (0, 1), [0, 1)$, or $(0, 1]$ is called an **arc** (or **curve**). Suppose that C is an arc that is the image of an interval I and $P = (x, y)$ is a point on C to which there correspond two elements t_1, t_2 ($t_1 < t_2$) of I such that P is the image of both t_1, t_2 . In this case, the point P is called a **multiple point** on C . An arc having no multiple point is called a **simple arc** or **Jordan arc**.

An arc with one and only one multiple point $P = (f(0), g(0)) = (f(1), g(1))$ is called a **Jordan curve** or **simple closed curve** (\rightarrow Section K). A Jordan curve can be regarded as a topological image in a plane of a circle. Let C be a curve that is the image $\varphi(I)$ of an interval. Then C is said to be of **class C^k (analytic)** if the mapping φ is of †class C^k (†analytic). In general, if S is a topological space, then the image $\varphi(I)$ in S of an interval is called a **curve** in S . In particular, if S has the structure of a differentiable (analytic) manifold, we can define the notion of **curve of class C^k (analytic curve)** in S .

C. Ordinary Curves

A †connected subset of E^2 that is the union of a finite number of simple arcs meeting at a finite number of points is called an **ordinary curve**. An ordinary curve is called a **tree** if it does not contain a subset that is homeomorphic to a Jordan curve. Let p be a point on an ordinary curve C . The †boundary of a sufficiently small †neighborhood of p meets C at a finite number of points, and this number is independent of the choice of the small neighborhood. We call it the **order** of p in C . A point of order 1 is called an **endpoint** of C , a point of order 2 an **ordinary point**, and a point of order ≥ 3 a **branch point**. If we can represent an ordinary curve C as a continuous curve tracing each simple arc of C just once,

we say that C is **unicursal** (Fig. 1). A necessary and sufficient condition for C to be unicursal is that the number of points of odd orders in C be less than or equal to 2 (L. Euler).

Fig. 1

D. Further Consideration of Definitions

Although the set of ordinary curves as defined above contains most familiar curves, it does not contain a point set defined by $y = \sin 1/x$ in $0 < x \leq 1$ and $-1 \leq x < 0$, and by $-1 \leq y \leq 1$ at $x = 0$ (Fig. 2). This point set is called a **sinusoid**, and it is desirable to obtain a definition of curves wide enough to contain a sinusoid. On the other hand, the notion of continuous curves is, in a sense, too wide, because a curve such as a Peano curve (\rightarrow Section J), which covers a whole square, is among such curves. The notion of simple arcs is too narrow, because even a circle is not a simple arc. As a point set in E^2 , a continuous arc is characterized as a †locally connected †continuum and is sometimes called a **Peano continuum** (H. Hahn, S. Mazurkiewicz). On the other hand, A. Schoenflies, inspired by the statement of the Jordan curve theorem (\rightarrow Section K), considered a closed set that divides the plane into two parts, forming the common boundary of both domains, and called it a closed curve. According to this definition, however, a simple curve is not a closed curve. Thus as a general definition of curves it is not appropriate.

Fig. 2

To give a general notion of curves on a plane (containing sinusoids), we may define a curve as a continuum that is †nowhere dense in E^2 (i.e., a continuum that is a boundary of open sets on the plane) (G. Cantor). Furthermore, to deal with the curves on a topological space, P. S. Uryson and K. Menger defined a **general curve** to be a 1-dimensional continuum (Menger, 1921–1922 [1]). In E^2 , the latter notion coincides with the notion of curves defined by Cantor, while in E^3 a general curve

is a continuum that does not divide any domain (\rightarrow 79 Connectedness).

E. Universal Curve

Consider a 3-dimensional cube I^3 ($I = [0, 1]$). Draw two planes parallel to each face so that the two planes parallel to a face trisect the edges of the cube meeting the planes. Thus I^3 is divided into 3^3 cubes. Let M_1 be the closure of the subset of I^3 that is obtained from I^3 by deleting the cube I_1^3 ($I_1 = [1/3, 2/3]$) and the 6 cubes having common faces with I_1^3 . Then M_1 consists of 20 cubes (Fig. 3). We apply to each of the 20 cubes forming M_1 the same operation that we applied to I^3 and denote by M_2 the union of point sets thus obtained (consisting of 20^2 cubes, the length of whose edges equals $1/3^2$). Repeating this process, we obtain a point set M_n consisting of 20^n cubes, the length of whose edges equals $1/3^n$. Thus we obtain the sequence $M_1 \supset M_2 \supset M_3 \supset \dots$. The set $U = \bigcap_{n=1}^{\infty} M_n$ is a general curve in the sense of Uryson and Menger. Moreover, we can prove that an arbitrary general curve is homeomorphic to a subset of U . Hence we call U the **universal curve**.

Fig. 3

F. Length of a Curve

In this section, by a curve we mean a continuous curve in a Euclidean space E^n . Let C be a curve in E^n defined by $x_i = f_i(t)$ ($i = 1, 2, \dots, n$; $a \leq t \leq b$); the f_i are real-valued continuous functions defined in $[a, b]$. (We sometimes write this simply as $X = \bar{f}(t)$, where $X = (x_1, \dots, x_n)$.) We divide $[a, b]$ arbitrarily and denote the dividing points by $a = t_0 < t_1 < t_2 < \dots < t_r = b$. Let $X_k = \bar{f}(t_k)$, $k = 0, \dots, r$, and let $\overline{X_{k-1}X_k}$ be the length of the straight line segment joining X_{k-1} and X_k . If the length $l = \sum_{k=1}^r \overline{X_{k-1}X_k}$ of the broken line $(X_0X_1 \dots X_r)$ (Fig. 4) is bounded for any subdivision of $[a, b]$, C is called a **rectifiable curve**, and the upper limit of l with respect to the subdivisions is called the **length** of C . For C to be rectifiable, it is necessary and sufficient that the f_i ($i = 1, 2, \dots, n$) be of bounded variation (Jordan). Thus if C is a rectifiable curve, then each $f_i(t)$ ($i = 1, 2, \dots, n$) is almost everywhere differentiable (H. Lebesgue). In particular, if C

is of class C^1 , then C is rectifiable, and its length can be represented by

$$s = \int_a^b \left(\sum_{i=1}^n \left(\frac{df_i}{dt} \right)^2 \right)^{1/2} dt$$

(\rightarrow 246 Length and Area).

Fig. 4

G. Shapes of Curves

In this section by a curve we mean the image $\varphi(I)$ in a Euclidean space E^n of an interval I (bounded or unbounded), where φ is a continuous mapping. When a curve C of class C^k is given in a Euclidean space E^n , it often becomes necessary to examine the shape of C globally. The determination of the global shape of C from the equation of the curve is called the **curve tracing** of C . The problem has been thoroughly studied in the particular case in which $n = 2$ and the equation of C is given by $f(x, y) = 0$ in a rectangular coordinate system (by $F(r, \theta) = 0$ in a polar coordinate system), where f (or F) is an analytic function. The problems in the case of a rectangular coordinate system are as follows:

Let φ be a single-valued analytic function and I a (bounded or unbounded) interval on the x -axis. If a curve C_0 represented by $y = \varphi(x)$ ($x \in I$) is a subset of C , then C_0 is called a **branch** of C . According as I is bounded or unbounded, C_0 is said to be a **finite branch** or **infinite branch** of C . When a curve represented by $x = \psi(y)$ ($y \in J$) (ψ is a single-valued analytic function and J is an interval on the y -axis) is a subset of C , it is also called a branch of C . If it is necessary to distinguish these two branches, we call the former the **x -branch** and the latter the **y -branch**. C consists of an at most denumerable set of branches. If $P(x_0, y_0) \in C$ and $f_y = \partial f / \partial y \neq 0$ at P , then there exists an x -branch containing P ; if $f_x = \partial f / \partial x \neq 0$, there exists a y -branch of C . If $\partial f / \partial x = 0$, $\partial f / \partial y = 0$ at P , then P is called a **singular point** of C . Points on C that are not singular points are called **ordinary points** of C .

When P is an ordinary point of C , a branch C_0 of C containing P is determined, and the **tangent line** and **normal line** to C at P are the same as those to C_0 and are uniquely determined. The equations of these are $(x - x_0)f_x(x_0, y_0) + (y - y_0)f_y(x_0, y_0) = 0$ and $(x - x_0)f_y(x_0, y_0) - (y - y_0)f_x(x_0, y_0) = 0$, respec-

tively. If we choose a coordinate system with P as origin and the tangent line and normal line as ξ -axis and η -axis, respectively, then the equation of C with respect to this coordinate system is of the form $\eta = c_2\xi^2 + c_3\xi^3 + \dots$ in the neighborhood of P . If we denote by ρ the curvature of C at P , then $\rho = 2c_2 = -(f_{xx}f_y^2 - 2f_{xy}f_xf_y + f_{yy}f_x^2)/(f_x^2 + f_y^2)^{3/2}$. When $c_2 = \rho = 0$, P is a stationary point. A stationary point of a curve of class C^2 on C is also called a **point of inflection**. When P is not a point of inflection and (ξ, η) are points on C in a neighborhood V of P , the sign of η is definite if V is small enough (Fig. 5). However, if P is a point of inflection and $c_3 \neq 0$, then C is of the shape shown in Fig. 6. At a point of inflection, if $c_3 = \dots = c_{v-1} = 0$, $c_v \neq 0$, and v is even, C is of the shape shown in Fig. 5, and if v is odd, C is of the shape shown in Fig. 6.

Fig. 5

Fig. 6

In a neighborhood of a singular point, C takes various shapes. For example, consider a curve represented by $y^2 = x^2(x + a)$, and let P be the origin $(0, 0)$. If $a > 0$, then there are two branches of C passing through P , and they have different tangents at P (Fig. 7). As in this case, if there are a finite number of different branches passing through P with different tangents, P is called a **node** of C . If $a < 0$, then $P \in C$, but there is no other point of C in the neighborhood of P (Fig. 8). Such a point is called an **isolated point** of C . If $a = 0$, then there are two branches of C starting from P , and the tangents to these at P are the same (Fig. 9). Such a point is called a **cusp** of C . When C is

Fig. 7

Fig. 8

Fig. 9

an algebraic curve, we can examine the shape of a curve in a neighborhood of a singular point using the Puiseux series.

When C has an infinite branch C_0 (for example, when $C_0: y = \varphi(x)$ ($x \in I$) is an x -branch of C and $I = [a, \infty)$), if the tangent to C_0 at $P(x_0, y_0)$ ($x_0 \in I$) has a limiting line for $x_0 \rightarrow \infty$, then the limiting line l is called an **asymptote** of C_0 . In this case, the distance from a point $P(x_0, y_0)$ of C_0 to l converges to zero when $x_0 \rightarrow \infty$. An asymptote of an infinite branch of C is also called an asymptote of C .

H. Special Plane Curves

The following are the well-known curves (for ellipses, parabolas, and hyperbolas → 78 Conic Sections).

Among curves of the third order, those having an equation of the form

$$y^2 = f(x)/(x - a) \tag{1}$$

($f(x)$ is a rational expression of at most the third order in x) are symmetric with respect to the x -axis and have $x = a$ as an asymptote. In particular, if $a > 0$, $f(x) = -x^3$ in (1), then the curve is as shown in Fig. 10 and the origin is a cusp. Let a half-line starting from the origin meet the curve, the circle with diameter $[0, a]$, and the straight line $x = a$ at points X , Y , and A , respectively. Then we have $OX = YA$. This curve is called a **cisoid of Diocles**.

If $a = 0$, $f(x) = c^2(c - x)$ ($c > 0$) in (1), then the curve takes the shape shown in Fig. 11. Let A , C be the points whose coordinates are $(a, 0)$, $(c, 0)$ ($0 < a < c$), respectively, and let X , Y be the points in the first quadrant at which the straight line parallel to the y -axis and passing through A meets the curve and the circle with diameter OC , respectively (Fig. 11). Then we have $AX : AY = OC : OA$. This curve is called a **witch of Agnesi**.

Fig. 10

Fig. 11

If $a < 0$, $f(x) = -x^2(x/3 + a)$ in (1), then the curve takes the shape shown in Fig. 12a. If we rotate it by $\pi/4$ and put it in the position shown in Fig. 12b, then the equation of the curve takes the form $x^3 + y^3 = 3cxy$ ($c = -\sqrt{2}$

a). If we take as parameter $t = y/x$, then we get the parametric representation $x = 3ct/(1 + t^3)$, $y = 3ct^2/(1 + t^3)$. This curve is called a **folium cartesii** (or **folium of Descartes**). A curve that has a parametric representation of the form $x = \varphi(t)$, $y = \psi(t)$, where φ, ψ are rational functions, is called an (algebraic) **unicursal curve** (or **rational curve**). Such a curve is an algebraic curve of \dagger genus 0.

Fig. 12

Let $r = f_1(\theta), r = f_2(\theta), \dots, r = f_k(\theta)$ be equations of curves C_1, C_2, \dots, C_k with respect to a polar coordinate system with origin O . A curve C having equation $r = \lambda_1 f_1(\theta) + \dots + \lambda_k f_k(\theta)$ (the λ_i are constants, usually $+1$ or -1) in the same coordinate system is called a **cissoidal curve** with respect to O . (Fig. 13: $r = -f_1(\theta) + f_2(\theta)$). In Fig. 10, let C_1 be the circumference of the circle with the diameter $[0, a]$, let C_2 be the straight line $x = a$, and put $\lambda_1 = -1, \lambda_2 = 1$. Then we have a cissoid of Diocles. We can regard the folium cartesii as a cissoidal curve obtained from a straight line and an ellipse. When C_1 is a circle with center at O , we call C a **conchoidal curve** of C_2 with respect to O . In particular, when C_2 is a straight line and O is not on C_2 , the conchoidal curve is called a **conchoid of Nicomedes**.

Fig. 13

As shown in Fig. 14, when C_2 is perpendicular to the initial line of the polar coordinate system, the equation of the conchoid is $r = a \sec \theta \pm b$ (b is the radius of C_1), and the Cartesian equation of the curve is $(x - a)^2(x^2 + y^2) = b^2x^2$. According as $a > b, a = b$, or $a < b$, the curve has a node, cusp, or isolated point, respectively. When C_2 is a circle and O is on C_2 , the conchoidal curve of C_2 with respect to O is called a **limaçon** (or **limaçon of Pascal**) (Fig. 15). The equation of a limaçon C with respect to a polar coordinate system having

the diameter of a circle passing through O as its initial line is $r = a \cos \theta \pm b$, while the equation of C with respect to a Cartesian coordinate system is $(x^2 + y^2 - ax)^2 = b^2(x^2 + y^2)$. In this case, if $a > b$, O is a node of the curve; if $a = b$, O is a cusp. When $a = b$, the curve is called a **cardioid** (the curve shown by a dashed line in Fig. 15; see also Fig. 26 below).

Fig. 14

Fig. 15

The locus of a point X having a constant product of its distances from two fixed points A, B is called **Cassini's oval** (Fig. 16). The equation of this curve with respect to the Cartesian coordinate system whose origin O is the midpoint of the segment AB and whose x -axis is the straight line AB is $(x^2 + y^2)^2 - 2a^2(x^2 - y^2) = k^4 - a^4$ (where $AB = 2a, k^2 = AX \cdot BX$). In particular, if $a^2 = k^2$, then O is a nodal point of the curve. In this case, the curve (shown by the dashed line in Fig. 16) is called a **lemniscate** (or **Bernoulli's lemniscate**) (Jakob Bernoulli).

Fig. 16

The locus of the foot of the perpendicular drawn from a fixed point O to the tangent of a fixed curve C at each point of the curve is called the **pedal curve** of C with respect to O . The pedal curve of a rectangular hyperbola with respect to its center is a lemniscate (Fig. 17), and the pedal curve of a circle with respect to a point is a limaçon.

Fig. 17

When a curve C' rolls on a fixed curve C without slipping and is always tangent to C , the locus Γ of a point X kept fixed with respect to the curve C' is called a **roulette** whose **base** is C , **rolling curve** is C' , and **pole** is X . In particular, when C is a straight line, C' is a circle, and X is on C' , Γ is called a **cycloid** (Fig. 18). When X is not on C' , Γ is called a **trochoid** (Fig. 19). A trochoid is represented parametrically by the equations $x = a\theta - b \sin \theta$, $y = a - b \cos \theta$, where the parameter θ is the angle of rotation of C' . When $a = b$, the equation represents a cycloid. The **evolute** and **involute** of a cycloid are also cycloids (Fig. 20).

Fig. 18

Fig. 19

Fig. 20

Suppose that we are in a gravitational field with a given path represented as a cycloid, as is shown in Fig. 21. Assuming that there is no friction, the time necessary for a particle to slide down the path from a point X on the curve to the lowest point C of the curve is independent of the initial position X (C. Huygens). Because of this property, the cycloid is also called a **tautochrone**. Suppose that a particle starts from a point A in the space and slides down to a lower point B along a curve Γ (without friction) under the effect of a gravitational force. To minimize the elapsed time, we simply take Γ as a cycloid that lies in the vertical plane containing AB and has a horizontal line through A as the base (Fig. 22). Because of this property, the cycloid is called

also a **brachistochrone**, i.e., the **line of swiftest descent** (Johann Bernoulli and others).

Fig. 21

Fig. 22

When the base curve C and the rolling curve C' are both circles and X is on C' , we call Γ an **epicycloid** if C , C' are externally tangent (Fig. 23), and a **hypocycloid** if C , C' are internally tangent (Fig. 24). When X is not on C' , corresponding to these two cases, we have an **epitrochoid** and a **hypotrochoid**, respectively. Let a , b be radii of C , C' , respectively, c the distance from the center of C' to X , and θ the angle of rotation of C' . Then the parametric equations of these curves are $x = (a \pm b) \cos \theta \mp c \cos((a \pm b)/b)\theta$, $y = (a \pm b) \sin \theta - c \sin((a \pm b)/b)\theta$. (Take the upper signs when the curve is an epicycloid and the lower signs when the curve is a hypocycloid. When $b = c$ the equations are equations of epicycloids and hypocycloids.) When the ratio $a : b$ is a rational number p/q (p , q are mutually prime), then C' returns to its initial position after rotating q times around C ; in this case each Γ becomes

Fig. 23

Fig. 24

an algebraic curve. In particular, when $a = 4b = 4c$, the hypocycloid is called an **astroid** (Fig. 25). Its equation (with respect to a Cartesian coordinate system) is $x^{2/3} + y^{2/3} = a^{2/3}$. The envelope of line segments of length a whose endpoints are on the x -axis and y -axis, respectively, is an astroid (Fig. 25). When $a = b = c$ an epicycloid is a **cardioid** (Fig. 26).

Fig. 25

Fig. 26

When the base C is a straight line, the rolling curve C' is an ellipse or a hyperbola, and the pole is a focus of C' , then the roulette is called a **Delaunay curve** (Fig. 27).

Fig. 27

When C is a straight line, C' is a parabola, and X is the focus of C' , the roulette is called a **catenary** (Fig. 28). When we hold two ends of a string of homogeneous density in the gravitational field, the string takes the form of this curve. The equation of the catenary with respect to a Cartesian coordinate system is $y = a \cosh x/a = a(e^{x/a} + e^{-x/a})/2$. The involute starting at the point $A(0, a)$ of this curve is called a **tractrix** (Fig. 29). Let Q be the point of intersection of the tangent at P to the tractrix and the x -axis; then the length of PQ is constant and is equal to a . Consequently, when we drag a weight at A by a string of length OA along the x -axis, the curve described by the weight is the tractrix. The parametric equations of the tractrix are $x = a(\log \tan t/2 + \cos t)$, $y = a \sin t$.

Fig. 28

Fig. 29

Suppose that a point Q moves with constant velocity on the x -axis and another point P also moves with constant velocity always toward Q .

The locus of the point P is called a **curve of pursuit** (Fig. 30). When the velocity of Q is α times that of P , the equation of the curve of pursuit is $2(x-a) = y^{1-\alpha}/c(1-\alpha) - cy^{1+\alpha}/(1+\alpha)$ if $\alpha \neq 1$ and $2(x-a) = (1/c)\log y - cy^2/2$ if $\alpha = 1$. We can consider similar problems when Q moves on a general curve instead of on the x -axis.

Fig. 30

Many plane curves that are called **spirals** can be expressed by $r = f(\theta)$ (f monotonic) in polar coordinates (r, θ) . An **Archimedes spiral** is a curve having the equation $r = a\theta$ (Fig. 31). Archimedes found that the area bounded by two straight lines $\theta = \theta_1$, $\theta = \theta_2$ ($\theta_1 < \theta_2$) and the curve is $a^2(\theta_2^3 - \theta_1^3)/6$. A **logarithmic spiral** (equiangular spiral or Bernoulli spiral) is a curve having the equation $r = ke^{a\theta}$ (Fig. 32). The angle between the straight line $\theta = \text{constant}$ and the tangent to the curve is constant. Johann Bernoulli found that the involute and evolute of this curve are congruent to the original curve. A curve having the equation $r = a/\theta$ is called a **hyperbolic spiral** (or **reciprocal spiral**), and the one having the equation $r^2\theta = a$ is called a **lituus**. These two spirals are shown in Figs. 33 and 34, respectively. Let $\rho = \varphi(s)$ be the natural equation of a curve. Properties of the curves for which the functions $\varphi(s)$ are simple have been investigated. Specifically, a curve having the natural equation $\rho = ks$ (k is a constant) is a logarithmic spiral. A curve having the equation $\rho = a^2/s$ is called a **Cornu spiral** (or **clothoid**); → 167 Functions of Con-

Fig. 31

Fig. 32

Fig. 33

Fig. 34

fluent Type). Its parametric representation is

$$x = a\sqrt{\pi} \int_0^t \cos \frac{\pi t^2}{2} dt,$$

$$y = a\sqrt{\pi} \int_0^t \sin \frac{\pi t^2}{2} dt$$

(†Fresnel integral). M. A. Cornu used this curve in the representation of diffraction in physical optics.

There are also curves that appear as graphs of elementary functions. For example, a curve having the equation $y = \sin x$ is called the **sine curve**, and the graphs of equations $y = e^x$ and $y = \log x$ are called the **exponential curve** and the **logarithmic curve**, respectively, although they are congruent. In contrast to algebraic curves, these analytic curves that are not algebraic are called **transcendental curves**. (Regarding the differential geometric properties of plane and spaces curves → 111 Differential Geometry of Curves and Surfaces; for plane algebraic curves → 9 Algebraic Curves.)

I. Envelopes

Let $\tilde{f}(s, t)$ be a function of class C^1 of real variables s, t . If we fix $t = t_0$, then $r = \tilde{f}(s, t_0)$ is the equation of a curve C_{t_0} with a parameter s . If $s(t)$ is a function of t , then $\tilde{f}(s(t_0), t_0)$ represents a point P_{t_0} on C_{t_0} . Let E be the locus of P_{t_0} when t_0 moves. If $s(t)$ is a function of class C^1 , then E is a curve of class C^1 . If E and C_{t_0} are always tangent at each point P_{t_0} , we call E the **envelope** of the family of curves C_t . When $\tilde{f}(s, t)$ is given, to find E we need only determine the function $s(t)$. We note that $\partial \tilde{f} / \partial s = \lambda \partial \tilde{f} / \partial t$ is a condition that must be satisfied by the function $s(t)$. When $n = 2$ and the equation of C_{t_0} is given in the form $f(x, y, t_0) = 0$, the point of intersection of C_{t_0} and $f_t(x, y, t_0) = 0$ ($f_t = \partial f / \partial t$) is P_{t_0} . The equation $R(x, y) = 0$ obtained by eliminating t from $f(x, y, t) = 0$ and $f_t(x, y, t) = 0$ is called the **discriminant** of $f(x, y, t) = 0$. The set of points (x, y) satisfying the discriminant $R = 0$ is the union of E and the locus of the singular points of C_{t_0} .

J. Peano Curve

A †continuous curve in the Euclidean plane E^2 (i.e., the image $f(I)$ of a segment $I = [0, 1]$ under a continuous mapping $f: I \rightarrow E^2$) may cover a square. We call such a curve a **Peano curve** after G. Peano, who gave the first example. D. Hilbert simplified the example and constructed a Peano curve as follows (*Math. Ann.*, 36 (1890), 38 (1891)).

Divide a square and a segment into four

equal parts (Fig. 35) and let each square D_i correspond to the segment T_i ($i = 0, 1, 2, 3$). Then divide each D_i into four equal parts (Fig. 36) and let D_{ij} correspond to T_{ij} ($j = 0, 1, 2, 3$), and continue this process (Fig. 37). A sequence of squares $D_i \supset D_{ij} \supset D_{ijk} \supset \dots$ has the unique common point $p_{ijk\dots}$, and we let this point correspond to the unique common point $t_{ijk\dots}$ of the sequence of segments $T_i \supset T_{ij} \supset T_{ijk} \supset \dots$. The correspondence $t_{ijk\dots} \rightarrow p_{ijk\dots}$ is a continuous mapping of the segment $[0, 1]$ onto the square D , and this continuous curve has double points, triple points, and quadruple points. The set of multiple points has the cardinal number of the continuum and is a †dense set in the square. We can improve this method so that there are no multiple points other than double and triple points, but it is impossible to eliminate triple points altogether.

Fig. 35

Fig. 36

Fig. 37

We can also construct Peano curves as shown in Figs. 38, 39, and 40. That is, we “bisect” a triangle and a segment $[0, 1]$ successively and build a correspondence as follows: Let a point represented by a binary number $t = 0.ijk\dots$ ($i, j, k, \dots = 0, 1$) correspond to the unique common point of the sequence

$\Delta_i \supset \Delta_{ij} \supset \Delta_{ijk} \supset \dots$ and obtain a continuous mapping from the segment $[0, 1]$ onto the triangle.

Fig. 38

Fig. 39

Fig. 40

K. The Jordan Curve Theorem

The **Jordan curve theorem** states: A Jordan curve J in the plane \mathbf{R}^2 separates \mathbf{R}^2 into inner and outer †regions (C. Jordan, *Cours d'analyse*, 2nd ed., 1893). More precisely, $\mathbf{R}^2 - J$ is the disjoint union $G_1 \cup G_2$ of two regions G_1 and G_2 whose common †boundary is J . Let p be a point of J . Then there is a Jordan arc with p as an endpoint such that all points of the Jordan arc are contained in G_i ($i = 1$ or 2) except for p (A. Schönflies), that is, J is **accessible** from G_i . Conversely, let J be a compact subset of \mathbf{R}^2 such that $\mathbf{R}^2 - J = G_1 \cup G_2$ and $G_1 \cap G_2 = \emptyset$, where the G_i are regions such that J is accessible from both G_1 and G_2 . Then J is a Jordan curve (Schönflies, 1908). A homeomorphism between a Jordan curve J and the circle C extends to a homeomorphism (more precisely to a †conformal mapping) between a plane containing J and a plane containing the circle C (\rightarrow 65 Combinatorial Manifolds G; 77 Conformal Mappings).

94 (X.11) Curvilinear Integrals and Surface Integrals

A. General Remarks

The integral of a function (or more precisely, a †differential form) along a †curve (†surface) is called a **curvilinear integral (surface integral)**. Because a curvilinear integral is a special case of the Stieltjes integral, we shall first explain this notion, formulated by T. J. Stieltjes (1894) as a generalization of the †Riemann integral. The notion was introduced in connection with Stieltjes's study of †continued fractions, and led to the idea of integrals with respect to general measures.

B. The Riemann-Stieltjes Integral

Suppose that $f(x)$, $\alpha(x)$ are real-valued bounded functions defined on $[a, b]$. Take a partition of the interval $a = x_0 < x_1 < x_2 < \dots < x_{n-1} < x_n = b$ (\rightarrow 216 Integral Calculus) and consider the Riemann sum with respect to $\alpha(x)$:

$$\sum_{i=0}^{n-1} f(\xi_i)(\alpha(x_{i+1}) - \alpha(x_i)), \quad \xi_i \in [x_i, x_{i+1}].$$

Suppose that the Riemann sum tends to a fixed number as $\max(x_{i+1} - x_i)$ tends to zero. Then the limit is called the **Riemann-Stieltjes integral** (or simply **Stieltjes integral**) of $f(x)$ with respect to $\alpha(x)$ and is denoted by

$\int_a^b f(x) d\alpha(x)$. The Riemann integral of $f(x)$ is a special case, where $\alpha(x) = x$.

The Riemann-Stieltjes integral has the elementary properties, such as linearity, of the usual Riemann integral. We also have the following theorem: The integral $\int f(x) d\alpha(x)$ exists for every continuous function $f(x)$ if and only if $\alpha(x)$ is of \dagger bounded variation. Hence when we consider the Stieltjes integral of $f(x)$ with respect to $\alpha(x)$, we usually assume that $f(x)$ is continuous and $\alpha(x)$ is of bounded variation. However, the Stieltjes integral can be defined if $f(x)$ is of bounded variation (not necessarily continuous) and $\alpha(x)$ is continuous (not necessarily of bounded variation). If a sequence $f_n(x)$ ($n = 1, 2, \dots$) of uniformly bounded continuous functions defined on the interval $[a, b]$ converges to a continuous function $f(x)$ on the interval $[a, b]$, we have

$$\lim_{n \rightarrow \infty} \int_a^b f_n(x) d\alpha(x) = \int_a^b f(x) d\alpha(x),$$

where $\alpha(x)$ is a function of bounded variation. Furthermore, if $\alpha(x)$ and $\alpha_n(x)$ ($n = 1, 2, \dots$) are functions of bounded variation whose \dagger total variations are uniformly bounded and $\lim_{n \rightarrow \infty} \alpha_n(x) = \alpha(x)$ at every point of continuity of $\alpha(x)$, then we have

$$\lim_{n \rightarrow \infty} \int_a^b f(x) d\alpha_n(x) = \int_a^b f(x) d\alpha(x)$$

for every continuous function $f(x)$ on $[a, b]$ (**Helly's theorem**).

Let $\alpha(x)$ be a \dagger strictly monotone increasing continuous function, and let $\beta(y)$ be its inverse function. Then we have

$$\int_a^b f(x) d\alpha(x) = \int_{\alpha(a)}^{\alpha(b)} f(\beta(y)) dy, \quad (1)$$

where the right-hand side is the usual Riemann integral. A function $\alpha(x)$ of bounded variation is represented as the difference of two strictly monotone increasing functions $\alpha_1(x)$ and $\alpha_2(x)$. If we denote by $\beta_i(y)$ the inverse function of $\alpha_i(x)$ ($i = 1, 2$), we have

$$\begin{aligned} \int_a^b f(x) d\alpha(x) &= \int_{\alpha_1(a)}^{\alpha_1(b)} f(\beta_1(y)) dy \\ &\quad - \int_{\alpha_2(a)}^{\alpha_2(b)} f(\beta_2(y)) dy. \end{aligned} \quad (2)$$

If $\alpha'(x)$ exists and is continuous, we have

$$\int_a^b f(x) d\alpha(x) = \int_a^b f(x) \alpha'(x) dx. \quad (3)$$

C. The Lebesgue-Stieltjes Integral

Suppose that $\alpha(x)$ is a monotone increasing and right continuous function and $I = (x_1, x_2]$.

We define an \dagger interval function $U(I) = \alpha(x_2) - \alpha(x_1)$. It is nonnegative and countably additive. Hence by utilizing $U(I)$ we can construct the outer measure and also a completely additive measure (\rightarrow 270 Measure Theory; 380 Set Functions). The Lebesgue integral with respect to this measure is called the **Lebesgue-Stieltjes integral** (or **Lebesgue-Radon integral**) and is denoted by $\int_a^b f(x) d\alpha(x)$. If $\alpha(x)$ is a strictly monotone increasing continuous function and $\beta(y)$ its inverse function, then formula (1) is true if the left-hand side is a Lebesgue-Stieltjes integral and the right-hand side is a Lebesgue integral. If $\alpha(x)$ is a function of bounded variation, decomposing $\alpha(x)$ into the difference of two strictly monotone increasing functions, we also have formula (2). If $\alpha(x)$ is \dagger absolutely continuous, formula (3) is valid, where the right-hand side is a Lebesgue integral.

The Stieltjes integral has the following two properties.

Integration by parts: In the interval $[a, b]$, we have

$$\int_a^b U dV + \int_a^b V dU = U(b)V(b) - U(a)V(a)$$

if one of $U(x)$, $V(x)$ is continuous and the other is of bounded variation.

Second mean value theorem: If $U(x)$ is monotone increasing and $V(x)$ is continuous, then there exists a ξ in $[a, b]$ such that

$$\begin{aligned} \int_a^b U dV \\ = U(a)(V(\xi) - V(a)) + U(b)(V(b) - V(\xi)). \end{aligned}$$

D. The Curvilinear Integral

A continuous mapping from an interval $a \leq t \leq b$ in \mathbf{R}^1 into \mathbf{R}^n : $\varphi(t) = (\varphi_1(t), \dots, \varphi_n(t))$ is an oriented curve. Suppose that a function $f(x_1, \dots, x_n)$ is defined in a neighborhood U of the image C of the mapping $\varphi(t)$ or merely on C . The Stieltjes integral

$$\int_a^b f(\varphi_1(t), \dots, \varphi_n(t)) d\varphi_i(t), \quad i = 1, \dots, n, \quad (4)$$

is called the **curvilinear integral** of the function $f(x_1, \dots, x_n)$ along the curve C with respect to x_i and is denoted by $\int_C f dx_i$. The curve C is called the **contour** (or **path**) of the integration, $\varphi(a)$ is called the **initial point** (or **lower end**), and $\varphi(b)$ is called the **terminal point** (or **upper end**) of the integration. Let C be a rectifiable curve, and denote by $s(t)$ the arc length of C from the initial point to the point $\varphi(t)$. Then the Stieltjes integral

$$\int_a^b f(\varphi(t)) ds(t)$$

or simply $\int_C f ds$ is called the **curvilinear integral with respect to the line element**. Here, the line element, denoted by ds , means $\sqrt{(\varphi'_1(t))^2 + \dots + (\varphi'_n(t))^2} dt$ when $\varphi(t)$ is of class C^1 . If the integrand in (4) is of bounded variation as a function of t , the curvilinear integral is well defined. If C is a rectifiable curve, the curvilinear integral is defined for an arbitrary continuous function. In the usual case, we are concerned mainly with this sort of situation. For a differential form $\omega = f_1 dx_1 + \dots + f_n dx_n$ defined on U , the curvilinear integral $\int_C \omega$ is defined by $\sum_{i=1}^n \int_C f_i dx_i$.

The curvilinear integral is linear with respect to its integrand. If the terminal point of C_1 is the initial point of C_2 , we can construct the joint curve $C = C_1 + C_2$, and we have **additivity for the contours**

$$\int_C f dx_i = \int_{C_1} f dx_i + \int_{C_2} f dx_i$$

(a similar formula holds if we replace dx_i by ds). Monotonicity, which asserts that $\int_C f dx_i \leq \int_C g dx_i$ whenever $f \leq g$, holds if $\varphi_i(t)$ is monotone increasing, and monotonicity also holds for the curvilinear integral with respect to the line element.

If $n=2$, \mathbf{R}^2 can be identified with the complex plane $\mathbf{C} = \{z = x + iy\}$, and we define $\int_C f(z) dz$ by

$$\left\{ \int_C u(x) dx - \int_C v(z) dy \right\} + i \left\{ \int_C v(z) dx + \int_C u(z) dy \right\},$$

where $f(z) = u(z) + iv(z)$. The integral is then said to be an integral in the complex domain. (For the application of integrals in the complex domain to complex analysis → 198 Holomorphic Functions.)

E. The Surface Integral

By an m -dimensional smooth surface S we mean the image S of a regular mapping of class C^1 from a domain G in \mathbf{R}^m into \mathbf{R}^n ($m < n$), $\xi(u) = (\xi_1(u_1, \dots, u_m), \dots, \xi_n(u_1, \dots, u_m))$. Given a continuous function $f(x_1, \dots, x_n)$ defined in a neighborhood U of S in \mathbf{R}^n , the multiple integral

$$\int \dots \int_G f(\xi_1(u), \dots, \xi_n(u)) \times \frac{D(x_1, \dots, x_{i_m})}{D(u_1, \dots, u_m)} du_1 \dots du_m, \quad (5)$$

$\{i_1, \dots, i_m\} \subset \{1, \dots, n\}$,

is called the **surface integral** of f along S with respect to x_{i_1}, \dots, x_{i_m} and is denoted by

$\int_S f dx_{i_1} \dots dx_{i_m}$ or $\int \dots \int_S f dx_{i_1} \dots dx_{i_m}$. This definition depends on the choice of the parameters (u_1, \dots, u_m) in the following way. Let (u'_1, \dots, u'_m) be another parametrization of S . Since

$$\frac{D(x_{i_1}, \dots, x_{i_m})}{D(u_1, \dots, u_m)} = \frac{D(x_{i_1}, \dots, x_{i_m})}{D(u'_1, \dots, u'_m)} \frac{D(u'_1, \dots, u'_m)}{D(u_1, \dots, u_m)}$$

and

$$du'_1 \dots du'_m = \left| \frac{D(u'_1, \dots, u'_m)}{D(u_1, \dots, u_m)} \right| du_1 \dots du_m,$$

thus according as

$$\frac{D(u_1, \dots, u_m)}{D(u'_1, \dots, u'_m)} \geq 0,$$

the foregoing expression remains the same or changes its sign. Usually we assign to the parameters (u_1, \dots, u_m) positive or negative orientation, in which case S is called oriented. If we replace the Jacobian $D(x_{i_1}, \dots, x_{i_m})/D(u_1, \dots, u_m)$ in (5) by the quantity

$$\left(\sum_{i_1 < \dots < i_m} \left(\frac{D(x_{i_1}, \dots, x_{i_m})}{D(u_1, \dots, u_m)} \right)^2 \right)^{1/2},$$

which corresponds to the surface element of S , the integral is called a **surface integral with respect to the surface element** and is denoted by $\int_S f dS$ or $\int_S f d\sigma$. The surface integral of a differential form of degree m in \mathbf{R}^n is similarly defined. In the case $m=1$, the surface integral reduces to a curvilinear integral. Just as the Stieltjes integral is a generalization of the curvilinear integral, there are several ways to generalize the notion of surface integral without assuming that the mapping $\xi(u)$ is of class C^1 .

F. The Stokes Formula

Let S be an m -dimensional smooth surface in \mathbf{R}^n ($m \leq n$) and ∂S be the $(m-1)$ -dimensional surface corresponding to the boundary of S . Let ω be a differential form of class C^1 of degree $(m-1)$ and $d\omega$ be its exterior derivative. Then we have $\int_{\partial S} \omega = \int_S d\omega$, which is called the **Stokes formula** (or the **Green-Stokes formula**). (For the Stokes formula on a general differentiable manifold → 105 Differentiable Manifolds.) As special cases of the Stokes formula, we have the following three classical theorems:

(1) The case of a plane domain: Let D be a bounded domain on the xy -plane bounded by a finite number of smooth curves C with positive directions. If $\omega = P dx + Q dy$ is a differential form of class C^1 on \bar{D} , we have

$$\int_C P dx + Q dy = \iint_D \left(\frac{\partial Q}{\partial x} - \frac{\partial P}{\partial y} \right) dx dy, \quad (6)$$

Curvilinear Integrals and Surface Integrals

since $d\omega = (\partial Q/\partial x - \partial P/\partial y)dx \wedge dy$. This is called **Green's formula** (or **Green's formula on the plane**). Equality (6) is true if P, Q are totally differentiable and the integrand on the right-hand side is continuous (even if the functions $\partial Q/\partial x, \partial P/\partial y$ themselves are not continuous) (E. Goursat). This formula remains true under the following weaker assumptions: (i) C is rectifiable; (ii) P and Q are continuous in \bar{D} and $\partial P/\partial y$ and $\partial Q/\partial x$ are continuous and summable (in the sense of Lebesgue) in D .

(2) The case of a domain in a 3-dimensional space: Let D be a bounded domain in xyz -space surrounded by a finite number of smooth surfaces S . For a vector field $\mathbf{V} = \langle P, Q, R \rangle$ of class C^1 on \bar{D} , we put $\omega = P dy \wedge dz + Q dz \wedge dx + R dx \wedge dy$. Then since $d\omega = (\partial P/\partial x + \partial Q/\partial y + \partial R/\partial z)dx \wedge dy \wedge dz$, we have

$$\begin{aligned} & \iint_S P dy dz + Q dz dx + R dx dy \\ &= \iiint_D \operatorname{div} \mathbf{V} dx dy dz \\ &= \iiint_D \left(\frac{\partial P}{\partial x} + \frac{\partial Q}{\partial y} + \frac{\partial R}{\partial z} \right) dx dy dz. \end{aligned} \quad (7)$$

Equality (7) is called the **Gauss formula** (**Ostrogradskii's formula** or the **divergence theorem**). The left-hand side of (7) is equal to the surface integral $\iint_S (\mathbf{V}, \mathbf{n}) d\sigma$, which is the vector flux through S (where \mathbf{n} means the outer unit normal vector of the surface S). This formula remains true under the following weaker assumptions: (i) S is piecewise of class C^1 ; (ii) P, Q, R are continuous in \bar{D} and $\partial P/\partial x, \partial Q/\partial y$, and $\partial R/\partial z$ are continuous and summable in D .

(3) The case of a bordered surface in a 3-dimensional space: Let $\bar{S}: x = x(u, v), y = y(u, v), z = z(u, v)$ ($(u, v) \in \bar{G}$) be a smooth surface in xyz -space, and suppose that the boundary Γ of the domain of the parameters \bar{G} consists of a finite number of smooth curves with positive direction. The boundary C of the surface S is the image curve of Γ . Now let $\mathbf{V} = \langle P, Q, R \rangle$ be a vector field of class C^1 on S , \mathbf{n} be the unit normal vector of S (its direction being canonically assigned by the parameter (u, v)), and \mathbf{t} be the unit tangent vector, and set $\omega = P dx + Q dy + R dz$. Then since $d\omega = (\partial R/\partial y - \partial Q/\partial z)dy \wedge dz + (\partial P/\partial z - \partial R/\partial x)dz \wedge dx + (\partial Q/\partial x - \partial P/\partial y)dx \wedge dy$, we have

$$\begin{aligned} & \iint_S (\operatorname{rot} \mathbf{V}, \mathbf{n}) d\sigma = \iint_S \left(\left(\frac{\partial R}{\partial y} - \frac{\partial Q}{\partial z} \right) dy dz \right. \\ & \quad \left. + \left(\frac{\partial P}{\partial z} - \frac{\partial R}{\partial x} \right) dz dx + \left(\frac{\partial Q}{\partial x} - \frac{\partial P}{\partial y} \right) dx dy \right) \\ &= \int_C (P dx + Q dy + R dz) = \int_C (\mathbf{V}, \mathbf{t}) ds. \end{aligned} \quad (8)$$

Equation (8) is called the **Stokes formula** (—Appendix A, Table 3.III).

95 (XVI.4)
Cybernetics

The term **cybernetics** was invented in 1947 by Norbert Wiener [1] to denote a field of science that treats the system of control and communication in animals and machine. The term was derived from a Greek word κυβερνήτης, also the source of the word "governor." The stimulus for establishing such a new area of science came from studies of automatic computation, automatic control, and information processing. These fields had given rise to technological innovations such as the high-speed electronic computer and automatic control instruments. Such machines have had a profound influence on the information sciences, as well as on theoretical investigations in biology. However, even now, we can hardly say that cybernetics has been firmly established as a systematic branch of science or of applied mathematics. Nevertheless, it has had far-reaching influence on both biology and machine engineering as a methodology and as a philosophy. In the Soviet Union and in European countries, the word corresponding to cybernetics is still widely used for the "Grenzgebiete" between biology and machine engineering in the wider sense. Nonetheless, it is difficult to say that cybernetics as a whole has undergone systematic development. Systematic theories have

been established and developed for separate parts of the field, and these have become independent disciplines; they are, for example, *control theory, †information theory, the theory of artificial intelligence, the theory of †automata, mathematical biology, genetics, and ecology.

The contributions of Wiener to cybernetics include not only the invention of the concept itself, but also prediction theory or the theory of the Wiener filter [2]. The latter was subsequently formalized by R. E. Kalman from a different point of view as an estimation problem within a linear system, working from finite observation data, and including the non-stationary case (\rightarrow 405 Stochastic Control and Stochastic Filtering G). Another contribution by Wiener is the input-output identification of a nonlinear system using statistical time series analysis of the outputs when the inputs are white noises [4]. This is achieved by expansion of the output function in terms of the convolution of input functions, which corresponds to the expansion of functions in terms of †Hermite interpolation polynomials. The kernel of the expansion is called a **Wiener kernel**. Recently, this method has been applied to input-output identification for nervous systems; it also finds application in nonlinear system theory [5]. Wiener also studied brain waves [6, 9].

Cybernetics in the wider sense, although not necessarily called by this name, may include investigations of the following "Grenzgebiete": information processing of the nervous system [7]; self-organizing systems in the non-equilibrium thermodynamics of Prigogine and Haken; the self-reproducing machines of von Neumann; and the theory of pattern formation in biological or chemical systems [8].

D

96 (XVI.7) Data Processing

A. General Remarks

With the development of electronic computers, effective systems for data transmission and processing have been created on a large scale, and there is now a large literature concerning data-processing methods and techniques for such systems.

Research on data processing encompasses both specific techniques and entire systems of processing, for example, the system of programming techniques, as well as mathematical problems originating from them, such as the complexity of computations (\rightarrow 71 Complexity of Computations). As domains of application, we have, for example, information retrieval, stock management, program evaluation, and review techniques. We denote the set of data by D and assume that D is finite. Depending on the properties of D , we have various suitable representations and processing problems.

B. The Notion of Data

In recent applications of computers, the main task has been arranging and searching for items or attributes in storage, rather than numerical computation. Individual information is called a **record**. Records arranged and stored in the memories of computers are usually called **data**. A collection of such data is called a **file**. A complex, large-scale data collection is often called a **data base**.

In an abstract sense, the record consists of a string of letters, but it is usually convenient to view it as consisting of its identifying mark followed by a finite sequence of items. The contents can be classified according to their properties, such as topological relations, order relations, or items representing numerical values. For each case, there may be different suitable representations and operations.

We often store information after a suitable process of **information compression**. In some cases the operations are reversible, and complete recovery is possible. In other cases the operations are not completely reversible, and we must throw away part of the information in order to compress the rest. An example of recoverable information is the replacement of a run of 1's (or 0's) in a binary code by its length. An example of lost information often occurs in the graphical manipulation of numbers by means of **hashing**. In this process we

select a suitable function $s = f(a_1, \dots, a_n)$, where the vector (a_1, \dots, a_n) corresponds to the representation of the record in such a way that the value s can be monomorphic for the universe of the records as often as possible, and the data (a_1, \dots, a_n) is kept in the storage corresponding to the value s . Generally, the variable representing the location of data is called a **pointer**.

In the abstract sense, data bases are simply sets of items, but in most cases a base will also exhibit some mathematical structure, such as order relations. In order to handle a data base efficiently, we must take its particular structure into account, and suitably represent that structure. Such structures and their representations are called **data structures**.

C. Linear Structures

The component of a vector or the stations along a single railway line form linearly ordered sets. Their most essential feature is the notion of immediate predecessor or immediate successor. Such a data structure is called a **linear structure**, and the aligned sequence is called an **array**. Multidimensional arrays, such as the elements of a matrix, are stored in the form of 1-dimensional arrays in the memory of a computer.

When the set of data D is a linearly ordered set, it is usually represented as a suitable array. Here, the problems of **ordering** and **table look-up** are fundamental. Ordering in this sense means putting the given elements of D into the order defined for D . Since, historically, sorting machines were used to put punched cards in order, this process is also called **sorting**. The process of arranging several individually sorted data packs into one sorted pack is called **merging**.

A fundamental data-sorting operation is "comparison" with respect to the order for D . There have been many investigations of the estimation of the lower or upper bounds for the number of comparisons and of developing efficient algorithms. Asymptotically, $O(n \log n)$ is the theoretical lower bound for n elements, and some algorithms are known to achieve this bound (\rightarrow 71 Complexity of Computations).

If there is given a univalent correspondence $f: D \rightarrow D'$ and the correspondence table is stored in the memory in a suitable form, the problem of table look-up arises, which requires finding $f(d)$ for a given $d \in D$. In this process, a fundamental operation is a comparison of $d \in D$ with some $x \in D$ in the table. There have been many investigations of efficient arrange-

ments and of algorithms with minimal numbers of comparisons.

D. List Representation

If the given finite set D has an order satisfying the reflexive and transitive laws, addressing is often used as a medium for representing the order in the memory. Let d_1, \dots, d_n be all the immediate successors to an element $d \in D$. We can represent them by the following sequence of triplets:

If $n=0$, we take $(d, 0, 0)$;
 If $n=1$, we take $(d, d_1^*, 0)$;
 If $n=2$, we take (d, d_1^*, d_2^*) ;
 If $n=3$, we take $(d, d_1^*, e_1^*), (e_1, d_2^*, d_3^*)$;
 If $n \geq 4$, we take $(d, d_1^*, e_1^*), (e_1, d_2^*, e_2^*),$
 $(e_2, d_3^*, e_3^*), \dots, (e_{n-2}, d_{n-1}^*, d_n^*),$

where d_i^* means the pointer to d_i , e_i is an element introduced for convenience, and e_i^* is the pointer to e_i . This is called a **list representation**. If we denote by $d \rightarrow d_1$, the fact that d_1 is an immediate successor of d , then the total set can be regarded as a \dagger direct graph. Usually, this graph is a \dagger tree, and then the graph is called a **tree structure** and its representation a **tree representation**. The advantage of this representation is that addition or deletion is quite easy.

The set of logical formulas is partially ordered, with the order given by the rules of inference. The set consisting of a series of inferences forms an ordered subset. Thus, if a tree representation can be automatically treated, so can the process of inference.

In dealing with linguistic data (words or sentences, for example), it is often natural to consider a noncommutative \dagger free semigroup D generated by a finite number of generators (the alphabet or vocabulary). In this case, if there exists a natural order for the generators, it determines in D a lexicographic partial ordering. Then the tree representation can be used for representing a dictionary whose entires are elements of D . This method is not efficient with respect to speed of table look-up and economy of memory, but it sometimes has the advantage of simplifying the treatment of complicated data.

E. Memory Devices for Processing

In dealing with algebraic formulas or languages with parentheses, data maintenance methods such as tree representation or push-down storage are often convenient as auxiliary memory-controlling methods. The character-

istic of the **push-down storage** method is that it returns the data in reverse order with respect to the time of acceptance and remittance.

It is sometimes called a **stack** or a **first-in-last-out memory**. Contrary to a stack, there is a storage that returns the data in the same order as the acceptance. It is called a **queue** or a **first-in-first-out memory**.

F. Information Retrieval

A request to obtain all the records qualified by some property in a data base Ω is called a **query**. The part of the collection of records Ω qualified for a query, therefore, can be identified by its characteristic subset of the space of all possible records. A procedure that determines the subset Ω_q of Ω composed of all the records relevant to a query q is called the **information retrieval** of the query. A system which provides such a procedure for every query $q \in Q$ is called an **information retrieval system** organized for Ω with respect to Q .

It is essential to design the system in such a way that records can be retrieved quickly for queries in a certain class. Such a selected set of queries can be composed of all the first-order queries specifying an item and asking for all the records containing the attribute value or the key characterizing the item. It can, in some cases, include second- or higher-order queries specifying a number of items and asking for all the records in which attribute values or keys characterizing the item occur simultaneously.

In an information retrieval system, the master file of a data base Ω is usually organized by way of auxiliary memories on data structures such as sequential files, indexed sequential files, virtual storage files, or direct access files, using the magnitude of the accession number or primary key of each record. Various management systems, called SAM (Sequential Access Method), ISAM (Index Sequential Access Method), VSAM (Virtual Storage Access Method), or DAM (Direct Access Method), exist.

In addition to the organization of such a master file, various directory files or indexes are organized in order to retrieve each query $q \in Q$ quickly, because there are many relevant keys or combination of keys other than the primary key. An **inverted filing scheme** (IFS) is a typical scheme for organizing such indexes or directory files. A bucket B_i or an addressable set of secondary memories is provided for each canonical query $q_i \in Q$ in a one-to-one way. An index or a list of accession numbers of pertinent records is organized in each of the buckets contiguously so as to make it possible

to retrieve all accession numbers of relevant records quickly. The essentials of an IFS is to define a one-to-one QAT (Query to Address Transformation) from the inverted set of queries $Q = \{q_i\}$ to the set of buckets $B = \{B_i\}$.

An IFS has efficient retrieval performance with respect to the inverted canonical queries. The scheme, however, may in some cases require a large number of buckets. Moreover, the scheme requires quite redundant storage of accession numbers by a number of buckets because a record may be pertinent to a number of canonical queries simultaneously. Although higher retrieval performance can be expected by including higher-order queries in the inverted set, the space and machine time needed for such organization is prohibitive. This is one of the reasons why an IFS for first-order queries is preferable in almost all practical cases. Another reason is that if the first-order queries are inverted, every retrieval can logically be performed by certain Boolean operations executed among a certain number of retrieved sets of accession numbers. A trade-off of space and time needed for the organization of a scheme and its retrieval performance might be the determining factor for the selection of the set of canonical queries to be inverted.

An attempt to overcome the limitations inherent in the inverted scheme can be found in the work on the balanced file organization scheme due to Abraham et al. [7]. By extracting the essentials, Yamamoto et al. [9, 10] defined a BFS (Balanced File-organization Scheme) in a wider sense as follows:

- (i) Buckets are organized in such a manner that every bucket is associated with more than one query.
- (ii) Every canonical query is associated with a unique bucket.
- (iii) The accession number of a record with some additional information is stored in a bucket once if and only if it is pertinent to at least one of the associated queries.

The essentials of a BFS is to define a many-to-one transformation from the set of canonical queries Q to the set of bucket addresses B , or an MQAT (Multiple Queries to Address Transformation). An MQAT defines a partition of Q into mutually disjoint subsets. It is a generalization of a QAT which defines an IFS. If c is the number of queries to be associated simultaneously with a unique bucket in a BFS, then the number of buckets to be prepared is $1/c$, which is a drastic reduction from that for an IFS. This reduction makes it possible to extend the feasible range of canonical queries. Actually, in the system HUNDRED (Hiroshima University New Documents REtrieval and Dissemination), a

51-to-1 MQAT is used for the organization of indexes.

Although some space overload may occur by storing some additional information in order to tell which record is pertinent to which query in a bucket, reduction of redundancy can be expected, because a record may be pertinent to more than one query simultaneously. The reduction in the number of buckets and redundancy would contribute much in saving time and space needed for the organization of indexes.

Among those BFS's defined by MQAT's with a given data base Ω , Q , and the number c of queries associated with the same bucket, one BFS can be called the best if its redundancy is the least under some reasonable assumptions imposed on the distribution of keys. Several combinatorial problems have been raised and solved in this connection [10].

97 (I.10) Decision Problem

Suppose that we are given a set S and a proposition $P(x_1, x_2, \dots, x_n)$ for elements x_i of S . Then we have the **problem of universal validity of P** , which is the problem of finding a general **algorithm** (i.e., a finitary procedure) by which we can discern whether $P(x_1, \dots, x_n)$ is true for all n -tuples (x_1, \dots, x_n) . The problem of finding an algorithm by which we can discern the validity of $P(x_1, \dots, x_n)$ for some specifically chosen n -tuples (x_1, \dots, x_n) is called the **problem of satisfiability of P** . These two problems are customarily called **decision problems**. The problems are such that affirmative solution of one of them implies negative solution of the other.

To give a precise definition of decision problems, let us note that a \dagger free semigroup with countable generators can be identified with a subset of the set \mathbb{N} of natural numbers (by virtue of \dagger Gödel numbering; \rightarrow 185 Gödel numbers). On the other hand, if \mathfrak{S} is a given \dagger formal system with countably many symbols, the set of all \dagger formulas in \mathfrak{S} is a subset of the free semigroup generated by the symbols in \mathfrak{S} . Thus the set of all formulas in \mathfrak{S} is identified with a subset of \mathbb{N} . A subset M of \mathbb{N} (or $\mathbb{N} \times \mathbb{N} \times \dots \times \mathbb{N}$) is (**general**) **recursive** if its \dagger representing function is general recursive (\rightarrow 356 Recursive Functions). By using the concept of recursive function, a precise definition of the decision problem can be given as follows: **The decision problem of M is solved affirmatively** if and only if we can obtain effectively a procedure defining the representing function of M , and the function is general recursive. **The decision problem of M is solved negatively** if and only if we can obtain a proof that M is not recursive.

For a set A of formulas in \mathfrak{S} , we let $g(A)$ be the set of all Gödel numbers corresponding to the elements of A . Let A' be the set of formulas in A that are deducible in \mathfrak{S} , and let $\tau(A) = g(A')$. The decision problem of the set A of formulas is said to be solved affirmatively (negatively) if the decision problem of $\tau(A)$ is solved affirmatively (negatively). By refining this concept we arrive at the notion of the **degree of (recursive) unsolvability**. Let A and B be subsets of \mathbb{N} . The relation " A is recursive in B and B is recursive in A " (\rightarrow 356 Recursive Functions) is reflexive, symmetric, and transitive. Hence this relation decomposes the class of all subsets in \mathbb{N} into disjoint nonempty equivalence classes. A and B are defined to have the same degree of unsolvability if they belong to the same equivalence class. Thus the degrees of unsolvability can be identified with

the equivalence classes. The degree of recursive sets is 0 .

The relation $\mathbf{a} \leq \mathbf{b}$ is defined between the degrees \mathbf{a} of A and \mathbf{b} of B to mean " A is recursive in B ." Clearly, for any degree \mathbf{a} , we have $0 \leq \mathbf{a}$. The partially ordered system of degrees constitutes an \dagger upper semilattice.

Research on the decision problem has been done mostly in areas related to the \dagger first-order predicate calculus L^1 and the formal systems on it. We now list some important results.

(I) Results concerning L^1 . The decision problem has been solved negatively for the sets of formulas of the following forms. (Here it is assumed that no function symbols appear and that \mathfrak{A} represents a formula involving no occurrence of \forall , \exists , or free variables.)

(1) All formulas in L^1 (A. Church, A. M.

Turning),

(2) $\exists x_1 \exists x_2 \dots \exists x_m \forall y_1 \forall y_2 \dots \forall y_n \mathfrak{A}$ (T. Skolem),

(3) $\exists x_1 \exists x_2 \exists x_3 \forall y_1 \forall y_2 \dots \forall y_n \exists z \mathfrak{A}$ (K. Gödel),

(4) $\exists x_1 \exists x_2 \forall y_1 \forall y_2 \dots \forall y_n \exists z \mathfrak{A}$ (L. Kalmar),

(5) $\exists x_1 \exists x_2 \forall y \exists z_1 \exists z_2 \dots \exists z_n \mathfrak{A}$ (J. Pepis),

(6) $\forall x \exists y \forall z \exists u_1 \exists u_2 \dots \exists u_n \mathfrak{A}$ (W. Ackermann),

(7) $\exists x_1 \exists x_2 \exists x_3 \forall y \mathfrak{A}$ or

$\exists x_1 \exists x_2 \forall y \exists z \mathfrak{A}$ (J. Surányi),

(8) $\exists x \forall y_1 \forall y_2 \exists z_1 \exists z_2 \mathfrak{A}$ or

$\forall x \exists y \forall z \exists u_1 \exists u_2 \mathfrak{A}$ (Surányi).

The decision problem has been solved affirmatively for the sets of formulas of the following forms, where it is assumed again that no function symbols appear and that \mathfrak{A} is as above.

(1) All formulas involving variables only on predicates with one argument. (L. Löwenheim, Skolem, H. Behmann),

(2) $\forall x_1 \forall x_2 \dots \forall x_m \mathfrak{A}$ (P. Bernays, M. Schönfinkel, Ackermann),

(3) $\forall x_1 \forall x_2 \dots \forall x_m \exists y_1 \exists y_2 \dots \exists y_n \mathfrak{A}$ (Bernays, Schönfinkel, Ackermann),

(4) $\forall x_1 \forall x_2 \dots \forall x_m \exists y_1 \exists y_2 \forall z_1 \forall z_2 \dots \forall z_n \mathfrak{A}$ (Gödel, Kalmar, K. Schütte).

(II) Results concerning formal systems on L^1 . Throughout the rest of this article we assume that no \dagger function variables appear. Predicate constants, function constants, and object constants may appear. By the decision problem for a formal system \mathfrak{Q} we mean the decision problem for all \dagger closed formulas in \mathfrak{Q} . Most of the results obtained so far concerning the decision problem for formal systems have been negative. Such results include those for formal systems formalizing natural number theory, the theory of rational integers, the elementary theory of \dagger groups, \dagger rings, \dagger fields, \dagger lattices, and the like, and axiomatic set theory (A. Tarski et al.).

The word problem for groups was solved negatively by P. S. Novikov (\rightarrow 161 Free Groups B). In connection with this decision problem, there are some investigations

by W. W. Boone, G. Higman, and others [14–17].

The decision problem for a formal system formalizing the elementary theory of \dagger Abelian groups has been solved affirmatively (W. Szmielew). Little is known about the decision problem concerning partial systems of formulas of given formal systems except the following: (1) the decision problem for the set of formulas of the form $\forall x_1 \forall x_2 \dots \forall x_m \mathcal{A}$ in a formal system (\rightarrow 161 Free Groups); (2) the Hilbert-type problem, which is the decision problem for the set of formulas of the form $\exists x_1 \exists x_2 \dots \exists x_m (t=s)$ in a formal system. In particular, the Hilbert-type problem in a formal system formalizing natural number theory is called Hilbert's tenth problem (\rightarrow 196 Hilbert). The latter is the problem of finding an algorithm for deciding whether a \dagger Diophantine equation has an integral solution.

This decision problem was studied by M. Davis, H. Putnam, J. Robinson, and others, and finally Yu. V. Matiyasevich solved it negatively by showing that every recursively enumerable relation is Diophantine [9]. (A relation $R(m_1, \dots, m_j)$ is called **Diophantine** if there is a polynomial $P(x_1, \dots, x_j, y_1, \dots, y_k)$ with integer coefficients such that $R(m_1, \dots, m_j)$ holds if and only if $P(m_1, \dots, m_j, y_1, \dots, y_k)=0$ has a solution for y_1, \dots, y_k in natural numbers.) In addition, some investigations have been made about the \dagger second-order predicate calculus L^2 , \dagger intuitionistic logic, etc. [1, 2].

98 (XXI.18) Dedekind, Julius Wilhelm Richard

Julius Wilhelm Richard Dedekind (October 6, 1831–February 12, 1916) was born in the city of Braunschweig in central Germany and studied at the University of Göttingen under C. F. \dagger Gauss, who was then in his later years. He received his doctorate at Göttingen with a thesis on the \dagger Euler integral. He was professor of mathematics from 1858 to 1862 at Zürich and from 1863 to 1894 at the Technische Hochschule in Braunschweig. During his early twenties, he wrote papers concerning analysis and the theory of probability, but in 1857 he began publishing papers on the theory of numbers. He edited \dagger Dirichlet's lectures on number theory (*Vorlesungen über Zahlen-theorie*, first edition 1863, fourth edition 1899) and concentrated on research in arithmetic and algebra. The theory of \dagger ideals, which he founded, was originally set out in a supplement (1863) to Dirichlet's *Vorlesungen*.

Dedekind treated subjects ranging from the axiomatic foundations of the theory of ideals to \dagger lattices and \dagger groups as algebraic systems. He was a pioneer of the abstract algebra of the 20th century. Among his notable achievements are the \dagger Dedekind zeta functions of \dagger algebraic number fields, \dagger Dedekind cuts in the theory of real numbers, the algebraic theory of \dagger algebraic functions (of which he was a coauthor with H. Weber), and the theory of natural numbers. He was one of the first to support

†Cantor's set theory. His theory of natural numbers was founded on the concept of sets and included the idea of †recursive functions.

99 (IX.4) Degree of Mapping

A. Degree of Mapping

Let M^n and N^n be n -dimensional †closed †oriented † C^r manifolds (or †combinatorial manifolds). For example, $M^n = N^n = S^n$ (the † n -sphere). Their n th †homology groups with integral coefficients $H_n(M^n; \mathbf{Z})$ and $H_n(N^n; \mathbf{Z})$ are infinite cyclic groups generated by the fundamental homology classes $[M^n]$ and $[N^n]$, respectively (\rightarrow 201 Homology Theory). A continuous mapping $f: M^n \rightarrow N^n$ induces a homomorphism $f_*: H_n(M^n; \mathbf{Z}) \rightarrow H_n(N^n; \mathbf{Z})$, and there exists an integer d_f such that $f_*([M^n]) = d_f[N^n]$. This integer d_f is called the **degree of mapping** (or the **mapping degree**) of f . When $M^n = N^n$, d_f does not depend on the orientation of M^n .

If a continuous mapping $g: M^n \rightarrow N^n$ is †homotopic to f ($f \simeq g$), then we have $d_f = d_g$. If f is homotopic to a †constant mapping ($f \simeq 0$), then $d_f = 0$, while if f is a homeomorphism, then $d_f = \pm 1$. When $M^n = N^n$, a homeomorphism $f: M^n \rightarrow M^n$ is called an **orientation-preserving mapping** if $d_f = 1$ and an **orientation-reversing mapping** if $d_f = -1$.

Suppose that M^n and N^n are closed oriented n -dimensional combinatorial manifolds and that $f: M^n \rightarrow N^n$ is a †simplicial mapping. Let $\sum_i \sigma_i^n$ and $\sum_j s_j^n$ (σ_i^n, s_j^n are n -simplexes of M^n, N^n , respectively) represent $[M^n], [N^n]$, and let p_j (resp. q_j) be the number of n -simplexes σ_i^n such that $f(\sigma_i^n)$ is equal to s_j^n (resp. $-s_j^n$). Then $p_j - q_j$ is independent of the index j and equal to d_f .

Suppose that $f, g: S^n \rightarrow S^n$ are continuous mappings ($n \geq 1$). Then $f \simeq g$ if and only if $d_f = d_g$ (**Brouwer mapping theorem**). This implies that $\pi_n(S^n) \cong \mathbf{Z}$ (\rightarrow 202 Homotopy Theory).

B. Local Degree of Mapping

Suppose that M^n and N^n are n -dimensional oriented C^r (or combinatorial) manifolds and $f: M^n \rightarrow N^n$ is a continuous mapping. Suppose further that a point p of M^n has a neighborhood U such that $f(p) \neq f(q)$ for any point q contained in $U - \{p\}$. Then f induces a homomorphism $f_*: H_n(U, U - \{p\}) \rightarrow H_n(N, N - \{f(p)\})$ of n -dimensional †local homology groups with integral coefficients that are both isomorphic to \mathbf{Z} . If u and v are generators of the groups $H_n(U, U - \{p\})$ and $H_n(N, N - \{f(p)\})$ corresponding to orientations, respectively, then there exists an integer k such that $f_*(u) = kv$. We call this integer k the **local degree of mapping** f at p . If M^n and N^n are closed oriented C^r manifolds ($r \geq 1$) and $f: M^n \rightarrow N^n$ is a C^r mapping, then there exists a point r of N^n such that the set $f^{-1}(r)$ is a discrete subset $\{p_1, \dots, p_i\}$ of M^n , and each p_i has a neighborhood U_i satisfying the foregoing condition (†Sard's theorem). If k_i is the local degree of f at p_i , then $d_f = \sum k_i$.

C. Linking Numbers

Given two mutually disjoint smooth closed curves C_1 and C_2 in Euclidean 3-space, a quantity $\text{Lk}(C_1, C_2)$ indicating how closely they are interlinked with each other was given by Gauss as follows: Let C_i be expressed by the parameters $x_i = x_i(t_i)$ ($i = 1, 2$), where $x_i(t_i)$ are †continuously differentiable. Then the quantity

$$\text{Lk}(C_1, C_2) = -\frac{1}{4\pi} \int_{C_1} \int_{C_2} \frac{1}{|x_2 - x_1|^3} \times \det \begin{pmatrix} x_2 - x_1, \frac{dx_1}{dt_1}, \frac{dx_2}{dt_2} \end{pmatrix} dt_2 dt_1$$

is an integer called the **linking number** of C_1 and C_2 .

More generally, let M^n be an n -dimensional oriented †combinatorial manifold (or C^r manifold ($r \geq 1$)) and K and K^* its †cellular decompositions such that K^* is dual to K . Let z_1^r and z_2^s ($r + s = n - 1$) be †boundaries belonging to the complex K and K^* . Suppose that C^{r+1} is any †chain of K whose boundary is z_1^r . Then the †intersection number $[C^{r+1}] \cdot [z_2^s]$ does not depend on the choice of such a chain C^{r+1} . We set $\text{Lk}(z_1^r, z_2^s) = [C^{r+1}] \cdot [z_2^s]$ and call it the **linking number** of z_1^r and z_2^s . The **linking number** $\text{Lk}(\tilde{z}_1^r, \tilde{z}_2^s)$ of †singular boundaries $\tilde{z}_1^r, \tilde{z}_2^s$ ($r + s = n - 1$) of M^n is similarly defined by considering the approximations z_1^r, z_2^s of $\tilde{z}_1^r, \tilde{z}_2^s$ belonging to a suitable cellular decomposition K and its dual K^* . The number $\text{Lk}(\tilde{z}_1^r, \tilde{z}_2^s)$ is bilinear with respect to $\tilde{z}_1^r, \tilde{z}_2^s$, and we have $\text{Lk}(\tilde{z}_1^r, \tilde{z}_2^s) = (-1)^{r+s+1} \text{Lk}(\tilde{z}_2^s, \tilde{z}_1^r)$. In the example in 3-dimen-

sional Euclidean space \mathbf{R}^3 shown in the left half of Fig. 1, we have $\text{Lk}(\tilde{z}_1^1, \tilde{z}_2^2) = 1$, while $\text{Lk}(\tilde{z}_1^1, \tilde{z}_2^2) = 2$ for the example shown in the right half of the same figure. In particular, if \tilde{z}_1^1 is homologous to 0 in $M^n - |\tilde{z}_2^2|$, then we have $\text{Lk}(\tilde{z}_1^1, \tilde{z}_2^2) = 0$ (Fig. 2). Generally, if \tilde{z}_1^r and \tilde{z}_1^r are homologous in $M^n - |\tilde{z}_2^2|$, then $\text{Lk}(\tilde{z}_1^r, \tilde{z}_2^2) = \text{Lk}(\tilde{z}_1^r, \tilde{z}_2^2)$.

Fig. 1

D. Order of a Point with Respect to a Cycle

Let M^n be an n -dimensional oriented combinatorial manifold (or C^r manifold ($r \geq 1$)) with the n th Betti number $b_n = 0$, \tilde{z}^{n-1} an $(n-1)$ -dimensional singular boundary of M^n , and o a point of M^n that is not contained in $|\tilde{z}^{n-1}|$. We set $\text{ord}(\tilde{z}^{n-1}, o) = \text{Lk}(\tilde{z}^{n-1}, o)$ and call it the **order of the point** o with respect to \tilde{z}^{n-1} . For example, when $M^n = \mathbf{R}^2$ and $\tilde{z}^1 = \{f(t) | 0 \leq t \leq 1, f(0) = f(1)\}$, where f is a continuous function, the order $\text{ord}(\tilde{z}^1, o)$ is equal to the **rotation number** around o of a moving vector $\overrightarrow{of}(t)$ as t varies from 0 to 1. This $\text{ord}(\tilde{z}^1, o)$ stays invariant as the point o moves in a * connected component of the complement $\mathbf{R}^2 - |\tilde{z}^1|$ (Fig. 3). On the other hand, if $\tilde{z}_i^1 = \{f_i(t) | 0 \leq t \leq 1, f_i(0) = f_i(1)\}$ ($i = 0, 1$) are closed curves in \mathbf{R}^2 and the distance $\rho(f_0(t), f_1(t))$ is smaller than $\rho(f_0(t), o)$ for all t in the interval $[0, 1]$, then we have $\text{ord}(\tilde{z}_0^1, o) = \text{ord}(\tilde{z}_1^1, o)$ (**Rouché's theorem**).

100 (X.17) Denjoy Integrals

A. History

For a real-valued function $f(x)$ of a real variable to be * Lebesgue integrable, it is necessary and sufficient that there exist an * absolutely continuous function $F(x)$ such that $F'(x) = f(x)$ at * almost all points x (\rightarrow 221 Integration Theory D). In general, the derivative of a function is not necessarily Lebesgue integrable. A function $f(x)$ is Lebesgue integrable if and only if $|f(x)|$ is integrable. Hence a function which has an improper Riemann integral is not necessarily Lebesgue integrable (\rightarrow 221 Integration Theory A). For this reason, it is desirable to extend the concept of Lebesgue integrals. In 1912, A. Denjoy constructively defined a new concept of integrals (Denjoy integral in the restricted sense; \rightarrow Section D), which is an extension of both Lebesgue and Riemann integrals. Later, N. N. Luzin provided the descriptive theory of this integral. Independently, and nearly simultaneously, A. J. Khinchin and Denjoy defined a more general integration (Denjoy integral in the wide sense (1916); \rightarrow Section D).

In 1914, O. Perron, independently of Denjoy, defined a concept of integrals (Perron integrals) that is equivalent to that of Denjoy integrals in the restricted sense. To establish this concept, Perron considered the differential equation $y' = f(x)$ and utilized a method similar to the one used in the proof of the existence theorem for the solution of the differential equation $y' = f(x, y)$. However, the concept of Denjoy integrals is inadequate to treat unbounded functions. Thus to extend the concepts of Riemann and Lebesgue integrals, various ideas have been introduced; for example, Denjoy (1921), J. C. Burkill (1951), and R. D. James (1950) introduced new concepts as byproducts of investigations concerning the coefficients of trigonometric series [2, 3]. The A -integral concept devised by A. N. Kolmogorov was meant to deal with the problem of the conjugate function of Fourier series [4]. As a certain completion of the space of functionals of step functions, K. Kunugui defined the notion of E. R. integrals (1956), which coincides with that of A -integrals in a special case [5, 6].

What has been stated so far deals only with functions of a real variable. Concerning the extension of Denjoy integrals to the case of several variables, research has been done by M. Loomis, S. Kempisty, S. Nakanishi (née Enomoto), and others [7, 8].

B. Approximate Derivative

If we have $\lim_{h \rightarrow 0, k \rightarrow 0} m\{E \cap (\xi - h, \xi + k)\} / (h + k) = 1$ at a point ξ of a measurable subset E of the real line, where m is the 1-dimensional Lebesgue measure, the point ξ is called a **point of density** for E . Almost all the points of E are points of density for E (**Lebesgue's density theorem**). Let E be a measurable set having x_0 as a point of density, and let $F(x)$ be a measurable function on E . If there exists a number l such that for each $\varepsilon > 0$, x_0 is a point of density for the set $\{x | l - \varepsilon \leq (F(x) - F(x_0)) / (x - x_0) \leq l + \varepsilon, x \in E\}$, then l is called the **approximate derivative** of $F(x)$ at x_0 and is denoted by $ADF(x_0)$. If $ADF(x_0)$ exists, $F(x)$ is said to be **approximately derivable** at x_0 . If $F(x)$ is approximately derivable at each point of E , then $F(x)$ is said to be **approximately derivable in E** . If $F'(x)$ exists at a point x , then $ADF(x)$ exists at x , and we have $ADF(x) = F'(x)$. However, there exists a continuous function $F(x)$ that is approximately derivable at almost all points of an interval and yet not differentiable at any point of a set of positive measure.

C. Generalized Absolute Continuity

Let E be a set in \mathbf{R} , and let $F(x)$ be a real-valued function whose domain contains E . If for each $\varepsilon > 0$, there is a $\delta > 0$ such that for every sequence $\{[a_n, b_n]\}$ of nonoverlapping intervals whose endpoints belong to E the inequality $\sum(b_n - a_n) < \delta$ implies $\sum|F(b_n) - F(a_n)| < \varepsilon$, then the function $F(x)$ is said to be **absolutely continuous** on E . We denote by AC the set of all functions that are absolutely continuous on E . If $F(x)$ is continuous on E and E is the union of a countable sequence of sets E_n on each of which $F \in AC$, then $F(x)$ is called a **generalized absolutely continuous function**, and we write $F \in GAC$. If $F \in GAC$, $ADF(x)$ exists almost everywhere.

If, for each $\varepsilon > 0$, there is a $\delta > 0$ such that for every sequence $\{[a_n, b_n]\}$ of nonoverlapping intervals whose endpoints belong to E the inequality $\sum(b_n - a_n) < \varepsilon$ implies $\sum O\{F; [a_n, b_n]\} < \varepsilon$ ($O\{F; [a_n, b_n]\}$ denotes the oscillation of the function $F(x)$ in $[a_n, b_n]$, i.e., the difference between the least upper bound and the greatest lower bound of the values assumed by $F(x)$ on $[a_n, b_n]$), then $F(x)$ is said to be **absolutely continuous in the restricted sense** (or **absolutely continuous (*)**) on E ; and we write $F \in AC(*)$. Just as we defined the notions of generalized absolute continuity and absolute continuity, so we define the notions of **generalized absolute continuity in the restricted sense** and **generalized absolute continuity (*)**. Thus $F \in GAC(*)$ means that $F(x)$ is a generalized ab-

solute continuous (*) function on E . If $F \in GAC(*)$, then $F'(x)$ exists almost everywhere.

D. Definitions of Denjoy Integrals

Let $f(x)$ be a real-valued function defined on $I = [a, b]$. If for $f(x)$ there exists a function $F(x)$ that belongs to GAC on I and for which $ADF(x) = f(x)$ holds almost everywhere, then $f(x)$ is said to be **Denjoy integrable in the wide sense** (or **D-integrable**) on I . We call $F(b) - F(a)$ the **definite D-integral** of $f(x)$ over I , and denote the value by $(D) \int_a^b f(x) dx$. The function $F(x)$ is called an **indefinite D-integral** of $f(x)$ on I . Similarly, we obtain the definition of **Denjoy integral in the restricted sense** (or **D(*)-integral**) by replacing GAC by $GAC(*)$ and $ADF(x)$ by $F'(x)$ in the definition of the D-integral. If a continuous function $F(x)$ satisfies the equality $ADF(x) = f(x) \neq \pm \infty$ ($F'(x) = f(x) \neq \pm \infty$) for all except countably many points in I , then $F(x)$ is an **indefinite D-integral** (D(*)-integral) of $f(x)$. A Lebesgue-integrable function is D(*)-integrable, a D(*)-integrable function is D-integrable, and a D-integrable function that is almost everywhere nonnegative is Lebesgue integrable.

E. Constructive Definition of Integrals

Let S be a functional whose domain $\bigcup_I K(S; I)$ consists of the union of sets $K(S; I)$ of real-valued functions defined on closed intervals $I = [a, b]$. If f belongs to $K(S; I)$, we denote the value $S(f)$ by $S(f; I)$. Such a functional S is called an **integral operator** if the following three conditions are satisfied: (1) If $f \in K(S; I_0)$ and I is an arbitrary interval contained in I_0 , then the restriction f_I to I of f also belongs to $K(S; I)$. Also, $S(f; I)$ is a continuous additive function of the interval $I \subset I_0$. (2) Let $I_1 = [a, b]$, $I_2 = [b, c]$, and $I = [a, c]$ ($a < b < c$). If for a function f defined on I , $f_1 \in K(S; I_1)$ and $f_2 \in K(S; I_2)$, where $f_1 = f_{I_1}$ and $f_2 = f_{I_2}$, then $f \in K(S; I)$. (3) If f is identically 0 on I , then $f \in K(S; I)$ and $S(f; I) = 0$. For two integral operators S_1 and S_2 , we say that S_2 includes S_1 (or S_1 is weaker than S_2) if $K(S_1; I) \subset K(S_2; I)$ for every I and $S_1(f; I) = S_2(f; I)$ for every $f \in K(S_1; I)$. The D-integral (D(*)-integral) is the weakest integral operator containing the Lebesgue integral and satisfying the following two conditions, (C) and (H) (resp. H(*)): (C) **Cauchy's condition**. If, for every function f defined on I_0 , we have $f_I \in K(S; I)$ for any $I = [a + \delta, b - \varepsilon] \subset I_0 = [a, b]$, and also if the finite limit $\lim_{\delta \rightarrow 0, \varepsilon \rightarrow 0} S(f; I)$ exists, then $f \in K(S; I_0)$ and $S(f; I_0)$ coincides with the foregoing limit value. (H) **Harnack's condition**. Let E be a closed subset of I_0 , $\{I_k\}$ be a sequence of inter-

vals contiguous to the set consisting of the points of E and the endpoints of I_0 , and f be a function on I_0 satisfying the following three conditions: (i) $f_E \in K(S; I_0)$, where $f_E(x) = f(x)$ whenever $x \in E$ and $f_E = 0$ otherwise; (ii) $f_k = f_{I_k} \in K(S; I_k)$ for each k ; and (iii) $\sum_k |S(f_k; I_k)| < +\infty$ and $\lim_{k \rightarrow \infty} O(S; f_k; I_k) = 0$ when the sequence $\{I_k\}$ is infinite. Then it follows that $f \in K(S; I_0)$ and $S(f; I_0) = S(f_E; I_0) + \sum_k S(f_k; I_k)$. (Here $O(S; f_k; I_k)$ denotes the **variation** of $S(f_k)$ on I_k , that is, the least upper bound of the numbers $|S(f_j; J)|$, where J denotes any subinterval of I_k .) We obtain condition (H*) by replacing condition (iii) in (H) with a more restrictive condition: $\sum_k O(S; f_k; I_k) < +\infty$. The constructive definition of the Denjoy integral in the wide sense (the Denjoy integral in the restricted sense) is obtained by †transfinite induction starting with the Lebesgue integral and using two methods, (C) and (H) (resp. (H*)), of extensions.

F. Perron Integrals

Given a function $f(x)$ defined on an interval $[a, b]$, suppose that $F(x)$ is a function defined on the same interval such that (1) $F(x) \geq f(x)$; (2) $F(x) \neq -\infty$ (resp. (1') $\bar{F}(x) \leq f(x)$; (2') $\bar{F}(x) \neq +\infty$) at every point x , where $\underline{F}(x)$ (resp. $\bar{F}(x)$) denotes the †lower (upper) derivative of $F(x)$. In this case, $F(x)$ is called a **major (minor) function** of $f(x)$. If for any $\varepsilon > 0$ there is a major function $\psi(x)$ and a minor function $\varphi(x)$ of $f(x)$ such that $\psi(b) - \varphi(b) < \varepsilon$, then $f(x)$ is said to be **Perron integrable**. We denote by $(P) \int_a^b f(x) dx$ the value $\inf_{\psi} \{\psi(b) - \psi(a)\} = \sup_{\varphi} \{\varphi(b) - \varphi(a)\}$.

G. Properties of Integrals

If $\{f_n\}$ is a nondecreasing sequence of functions that are D-integrable on an interval $[a, b]$ and whose D-integrals over $[a, b]$ constitute a sequence bounded from above, then the function $f(x) = \lim_{n \rightarrow \infty} f_n(x)$ is D-integrable on $[a, b]$, and we have

$$(D) \int_a^b f(x) dx = \lim_{n \rightarrow \infty} (D) \int_a^b f_n(x) dx.$$

If $F(x)$ is a function of †bounded variation and $g(x)$ is a D-integrable function on an interval $[a, b]$, then $F(x)g(x)$ is D-integrable on $[a, b]$; moreover, denoting by $G(x)$ the indefinite D-integral of $g(x)$, the following formula is valid:

$$(D) \int_a^b F(x)g(x) dx = G(b)F(b) - G(a)F(a) - \int_a^b G(x)dF(x),$$

where the last term is the †Stieltjes integral (**integration by parts**).

If $F(x)$ is a nondecreasing function and $g(x)$ is D-integrable on $[a, b]$, there is a point ξ in $[a, b]$ for which the following formula is valid:

$$(D) \int_a^b g(x)F(x) dx = F(a) \cdot (D) \int_a^{\xi} g(x) dx + F(b) \cdot (D) \int_{\xi}^b g(x) dx$$

(the **second mean value theorem**).

The foregoing theorems remain valid if D is replaced by D^* in the hypotheses and conclusions.

101 (XXI.19) Descartes, René

René Descartes, (March 31, 1596–February 11, 1650), philosopher, mathematician, and natural scientist, was born in the province of Touraine in France. He became dissatisfied with his studies of scholastic philosophy in the Jesuit Academy in La Flèche, and later, in 1619, while stationed in Ulm during a tour of duty in the army, he underwent a philosophical conversion. He had an idea of methodologically unifying the various fields of interest to him using mathematics as a model. He returned to Paris in 1621, but moved to Holland in 1628 to concentrate on his work. Swe-

den's Queen Christina invited him in 1649 to that country, where he died the next year, evidently from a combination of cold and overwork.

Descartes, often considered the founder of modern philosophy, discarded early the traditional theological view of the world and stated that all knowledge should be recognized as logical only after it has been submitted to rational criticism. This ushered in the modern view of the world based on mathematics and physics. In 1637, he published *Géométrie* as an appendix to his *Discours de la méthode*, which also contained his works on optics and meteorology. In it, he promoted F. Viète's symbolic algebra, which he applied to geometric problems. His idea that algebra could be used as a general method for geometry established him as the founder of analytic geometry.

102 (XVIII.12) Design of Experiments

A. General Remarks

The **design of experiments** is a part of the **statistical planning** required to collect the data appropriate to the purpose of statistical inference (→ 401 Statistical Inference) in various fields of scientific research and application. The main purposes of the design of experiments are (1) to analyze a given statistical linear model (→ 403 Statistical Models) and (2) to devise a “good” statistical linear model. Sometimes this term also refers to a statistical method including the analysis of variances. Thus the purpose of designing an experiment is to provide the most efficient and economical methods of reaching valid and relevant conclusions from that experiment (→ 403 Statistical Models).

R. A. Fisher, whose contributions to statistical theory were remarkable and far-ranging, propounded three required principles to control the experimental field in order to guarantee the validity of statistical methods and to increase the sensitivity of experiments: (i) **replication**, or the repetition of the set of all the phenomena to be compared in the experiment, for the evaluation of experimental error variance; (ii) **randomization**, or the procedure

allotting various experimental treatments at random, in order to change systematic errors into random errors; and (iii) **local control**, or the procedure which makes the variation within each experimental block as small as possible, in order to minimize or remove systematic errors. These are called **Fisher's three principles**. A design satisfying principles (i) and (ii) is called a **completely randomized design**; it enables us to attach a probability statement to estimated treatment differences by obtaining valid estimate of experimental error variance.

Let an n -dimensional random variable $\mathbf{Y} = (Y_1, \dots, Y_n)'$ be represented by a linear model

$$\mathbf{Y} = \mathbf{X}\boldsymbol{\xi} + \mathbf{W}, \quad (1)$$

where \mathbf{X} is a given $n \times s$ real matrix, $\boldsymbol{\xi} = (\xi_1, \dots, \xi_s)'$ is an s -vector, and $\mathbf{W} = (W_1, \dots, W_n)'$ is a random vector with the expectation $E(\mathbf{W}) = \mathbf{0}$. Then \mathbf{Y} is called the **observation vector**, \mathbf{W} the **error vector**, $\boldsymbol{\xi}$ the **effect vector** of \mathbf{Y} , and \mathbf{X} the **design matrix**.

According to the properties of the effect vector $\boldsymbol{\xi}$, the linear model (1) is separated into three classes: (i) The class of **fixed-effects models** for which $\boldsymbol{\xi}$ is a fixed unknown parameter. In this case, the component ξ_i of $\boldsymbol{\xi}$ is called a **fixed effect**, and a linear function $\pi = \mathbf{F}'\boldsymbol{\xi}$ of $\boldsymbol{\xi}$, with a given coefficient vector \mathbf{F} is called a **linear parameter** or **parametric function**. (ii) The class of **random-effects models** for which the components ξ_i of $\boldsymbol{\xi}$ are random variables. In this case, each component ξ_i is called a **random effect**, and $\boldsymbol{\xi}$ is denoted by $\boldsymbol{\Xi}$. (iii) The class of **mixed models** for which there are both fixed effects ξ_i and random effects ξ_j in $\boldsymbol{\xi}$. In this case, the model (1) becomes

$$\mathbf{Y} = \mathbf{X}_1\boldsymbol{\xi}^1 + \mathbf{X}_2\boldsymbol{\Xi}^2 + \mathbf{W}, \quad (2)$$

where $\boldsymbol{\xi}^1 = (\xi_1, \dots, \xi_r)'$ is a fixed-effect vector and $\boldsymbol{\Xi}^2 = (\xi_{r+1}, \dots, \xi_s)'$ is a random-effect vector. The conditions frequently assumed for the distribution law of \mathbf{Y} are: (a) The errors W_i ($i = 1, \dots, n$) are uncorrelated and $E(W_i) = \dots = E(W_n) = 0$. (b) The errors W_i ($i = 1, \dots, n$) have a common unknown variance σ^2 . (c) The errors W_i ($i = 1, \dots, n$) have the normal distribution. (d) The random effects ξ_j are uncorrelated and independent of the error vector \mathbf{W} . (e) The random effects ξ_j have a common unknown variance σ_j^2 . (f) The random effects ξ_j have the normal distribution.

Let $L(\mathbf{X})$ be a linear subspace of \mathbf{R}^n spanned by the column vectors of \mathbf{X} . The linear model

$$\mathbf{Y} = \tilde{\mathbf{X}}\boldsymbol{\xi} + \mathbf{W} \quad (3)$$

is called a hypothesis on the linear model (1) if $L(\tilde{\mathbf{X}}) \subset L(\mathbf{X})$.

The main issues of the theory of design of experiments are concerned with (I) statis-

tical inferences, such as estimation or testing hypotheses, under models (1), (2), (3), (i), (ii), (iii); (II) determination of the design matrix X satisfying certain optimal conditions; (III) construction of a theoretical foundation that can explain the validity of the statistical treatment of the observed data by means of the above models.

B. Block Design

The design of experiments is described here in terms of the so-called **block design**. There are n experimental units $\alpha = 1, \dots, n$ called **plots**, and an observation Y_α is assigned to each plot α . A **block** is constructed with several plots under Fisher's principle (iii), and the number of plots in a block is called the **block size**, the j th one being denoted by k_j , $j = 1, \dots, b$, with $\sum_j k_j = n$. One of v operations, called **treatments or varieties**, is applied to each plot. It is assumed that the observation Y_α at the plot α in the j th block under the i th treatment has the structure

$$Y_\alpha = \xi_i + \eta_j + W_\alpha.$$

The ξ_i , $i = 1, \dots, v$, are called **treatment effects**, and the η_j , $j = 1, \dots, b$, **block effects**. It is also assumed that $\sum_i \xi_i = 0$. In this case, Y is represented in matrix notation as

$$Y = \Phi\xi + \Psi\eta + W, \quad (4)$$

where $\Phi = (\varphi_{\alpha i})$, $\alpha = 1, \dots, n$, $i = 1, \dots, v$, with

$$\varphi_{\alpha i} = \begin{cases} 1 & \text{when the } i\text{th treatment is applied} \\ & \text{to the plot } \alpha, \\ 0 & \text{otherwise,} \end{cases}$$

and $\Psi = (\psi_{\alpha j})$, $\alpha = 1, \dots, n$, $j = 1, \dots, b$, with

$$\psi_{\alpha j} = \begin{cases} 1 & \text{when the plot } \alpha \text{ belongs to} \\ & \text{the } j\text{th block,} \\ 0 & \text{otherwise.} \end{cases}$$

Here it is assumed that $\sum_i \varphi_{\alpha i} = 1$, $\sum_\alpha \varphi_{\alpha i} = r_i \geq 1$, $\sum_i r_i = n$, $\sum_j \psi_{\alpha j} = 1$, and $\sum_\alpha \psi_{\alpha j} = k_j \geq 1$. We call r_i the **number of replications** of the i th treatment. We set $N = (n_{ij}) = \Phi'\Psi$. Then n_{ij} is the number of observations in the j th block to which the i th treatment is applied. The matrix N is called the **incidence matrix** of the block design.

In any experiment, each plot has its own effect. The blocks are constructed so that this plot effect in each block becomes as homogeneous as possible, although it is impossible to eliminate the effect completely. For this purpose, randomization is adopted. Suppose that we are given k plots in a block and v treatments ($k \leq v$). Then randomization is

utilized to select a treatment out of v treatments to be allocated to each plot so that the selection is "at random." Then the plot effects are random, and the error term in model (4) can be considered to be the sum of a plot effect and an original error.

A block design satisfying Fisher's three principles is called a **randomized block design**. Blocks that can accommodate all the treatments to be studied are called **complete blocks**. Those that do not contain all the treatments are called **incomplete blocks**. Blocking can be considered to be an extension of pairing. In the terminology of block design, we can say that many experiments are block experiments, or even (tautologically, if we allow those with only one block) that all experiments are block experiments.

In a block design $N = (n_{ij})$, treatments i_0 and i_l are said to be **connected** if there exists a chain

$$i_0 j_1 i_1 j_2 \dots i_{l-1} j_l i_l$$

of integers such that $1 \leq i_p \leq v$ ($p = 0, 1, 2, \dots, l$), $1 \leq j_q \leq b$ ($q = 1, 2, \dots, l$), and $n_{i_0 j_1} > 0$, $n_{i_1 j_2} > 0, \dots, n_{i_{l-1} j_l} > 0$, $n_{i_l j_l} > 0$. If all pairs of treatments are mutually connected, then the design is said to be **connected**. In this case, the rank of the matrix C defined in Section C is $v - 1$. If the design is disconnected, then the incidence matrix N can be partitioned into two or more connected portions, e.g.,

$$N = \begin{pmatrix} N_1 & 0 \\ 0 & N_2 \end{pmatrix}.$$

Thus without loss of generality we can restrict ourselves to the connected case.

C. Estimation under the Fixed-Effects Model

Conditions (a) and (b) of Section A are assumed here. The normal equation which gives the least square estimates $\hat{\xi}$ and $\hat{\eta}$ of ξ and η , respectively, is

$$\begin{pmatrix} \Phi' \\ \Psi' \end{pmatrix} (\Phi, \Psi) \begin{pmatrix} \hat{\xi} \\ \hat{\eta} \end{pmatrix} = \begin{pmatrix} \Phi' \\ \Psi' \end{pmatrix} Y. \quad (5)$$

Set $\Phi'\Phi = \text{diag}(r_1, \dots, r_v) = D_r$, $\Psi'\Psi = \text{diag}(k_1, \dots, k_b) = D_k$, $C = D_r - N D_k^{-1} N'$, $Q = (\Phi' - N D_k^{-1} \Psi') Y$, where $\text{diag}(\dots)$ means a diagonal matrix with the diagonal elements \dots . Then (5) reduces to

$$C\hat{\xi} = Q, \quad \hat{\eta} = D_k^{-1} (\Psi' Y - N' \hat{\xi}). \quad (6)$$

Let L be an orthogonal matrix that transforms the matrix C to a diagonal form; that is, $L'CL = \text{diag}(\rho_1, \dots, \rho_{v-1}, 0) = \Lambda$, $\rho_i > 0$ for all i . Set $\Lambda^* = \text{diag}(\rho_1^{-1}, \dots, \rho_{v-1}^{-1}, 0)$, $C^* = L\Lambda^*L'$. Then $\hat{\xi}$

$= C^*Q$ is a particular solution of (6) and $\sum_i \hat{\xi}_i = 0$. A parametric function $\pi = F'\xi$ with coefficient vector $F = (F_1, F_2, \dots, F_v)'$ is called a **treatment contrast** if the sum $\sum_i F_i$ of coefficients vanishes. A treatment contrast $\pi = F'\xi$ is called a **normalized contrast** if $F'F = 1$. It is called the **elementary contrast** if F has only two nonzero elements 1 and -1 . Elementary contrasts of treatment effects show the comparison of treatments involved in them. When a design is connected, any contrast π is estimable, and the best linear unbiased estimate of π is $\hat{\pi} = F'\hat{\xi}$. Furthermore, if f_i is the eigenvector of the matrix C with unit length corresponding to an eigenvalue ρ_i and $F = \sum_i a_i f_i$, then the variance of the estimate $\hat{\pi}$ is given by $\sigma^2 \sum_i a_i^2 / \rho_i$. The following properties are equivalent: (i) A design is connected. (ii) Any treatment contrast is estimable. (iii) The rank of the matrix C is $v-1$. (iv) The minimum eigenvalue 0 of $D_r^{-1/2} C D_r^{-1/2}$ is simple and other eigenvalues θ_1 satisfy $0 < \theta_1 \leq 1$. (v) The maximum eigenvalue 1 of $D_r^{-1/2} N D_k^{-1} N' D_r^{-1/2}$ is simple and other eigenvalues θ_2 satisfy $0 \leq \theta_2 < 1$. (vi) There exists a positive integer p such that each element of $(D_r^{-1/2} N D_k^{-1} N' D_r^{-1/2})^p$ is positive. It holds that $\theta_2 = 1 - \theta_1$.

D. Test of a Hypothesis $H: \xi_1 = \dots = \xi_v$ in the Fixed-Effects Model

Conditions (a), (b), and (c) of Section A are assumed here. The hypothesis $H: \xi_1 = \dots = \xi_v$ is represented by

$$Y = \Psi\eta + W, \quad (7)$$

Consider a direct sum decomposition $R^n = L(\Gamma) + L_F^\perp(\Psi) + L_\Psi^\perp(\Phi, \Psi) + L_{\Phi, \Psi}^\perp$ of R^n , where $L_B^\perp(A)$ and L_B^\perp stand for the orthocomplements of $L(B)$ with respect to $L(A)$ and R^n , respectively, and $\Gamma = (1, 1, \dots, 1)' \in R^n$. The projection operator matrices for the decomposed subspaces $L(\Gamma)$, $L_F^\perp(\Psi)$, $L_\Psi^\perp(\Phi, \Psi)$, and $L_{\Phi, \Psi}^\perp$ are denoted by P_1 , P_2 , P_3 , and P_4 , respectively. Then we have

$$\begin{aligned} P_1 &= n^{-1} E_{nn}, & P_2 &= \Psi D_k^{-1} \Psi' - n^{-1} E_{nn}, \\ P_3 &= (I_n - \Psi D_k^{-1} \Psi') \Phi C^* \Phi' (I_n - \Psi D_k^{-1} \Psi'), \\ P_4 &= I_n - P_1 - P_2 - P_3, \end{aligned}$$

where E_{ab} is an $a \times b$ matrix whose entries are all unity and I_n is the $n \times n$ identity matrix.

The analysis of variance for the hypothesis (7) in model (4) is given by

$$Y'Y = Y'P_1 Y + Y'P_2 Y + Y'P_3 Y + Y'P_4 Y.$$

This is called an **intra-block analysis**. A usual test for the hypothesis H is given by a critical

region with

$$F = \frac{n-v-b+1}{v-1} \frac{Y'P_3 Y}{Y'P_4 Y} > \text{constant}$$

(\rightarrow 403 Statistical Models).

E. Optimal Block Design

A block design is said to be **optimal** when it minimizes the variance of the estimate $\hat{\pi}$ of a normalized contrast π . Suppose that the number v of treatments, the number b of blocks, and each block size k_j , $j = 1, \dots, b$, are given. Under each of the following criteria the corresponding block design is optimal in the sense indicated: For positive eigenvalues, $\rho_1, \rho_2, \dots, \rho_{v-1}$, of the matrix C in Section C, (I) $\prod_{i=1}^{v-1} \rho_i$ is maximal (**D-optimality**); (II) $\min \rho_i$ is maximal (**E-optimality**); (III) $\sum_{i=1}^{v-1} \rho_i^{-1}$ is minimal (or the average variance of the estimates of all normalized contrasts of the parameters ξ_i is minimal) (**A-optimality**).

If $\rho_1 = \dots = \rho_{v-1} = (n-b)/(v-1) (= \rho, \text{ say})$ and n_{ij} is either 1 or 0, then the design is optimal for each of the optimality criteria (I), (II), and (III). In this case, we have

$$C = \rho(I_v - v^{-1} E_{vv}).$$

Such a design is called a **variance-balanced block design** in which every normalized contrast is estimable with the same variance. If $D_r^{-1} N D_k^{-1} N' - n^{-1} E_{v1} r' = \mu(I_v - n^{-1} E_{v1} r')$ (or $C = (1 - \mu)(D_r - n^{-1} r r')$), every normalized contrast is estimable with the same efficiency $1 - \mu$, where $r = D_r E_{v1}$ and $0 < \mu < 1$. Such a design is called an **efficiency-balanced block design**. For a block design, any two of the following properties imply the third: (i) The design is variance-balanced; (ii) the design is efficiency-balanced; (iii) the design is equireplicated.

When all block sizes k_j equal some number k independent of j , all numbers r_i of replications equal some number r independent of i , and $\lambda_{ii'} = \sum_j n_{ij} n_{i'j}$ (number of times that both treatments i and i' are applied to the same block) equals some number λ independent of i and i' , then the design is combinatorially balanced. The design is usually called the **balanced incomplete block design (BIBD)** if these three conditions are fulfilled and $k < v$. A BIBD is both variance-balanced and efficiency-balanced. If all the treatments are replicated the same number of times and the blocks are of the same size in a block design, then the only variance-balanced design is a BIBD, provided such a design exists. A BIBD is often denoted by $\text{BIBD}(v, b, r, k, \lambda)$ and we have the relations $vr = bk$, $\lambda(v-1) = r(k-1)$ and $v \leq b$, among the parameters; the last

relation is called **Fisher's inequality**. The design is said to be **symmetric** when $v=b$. Furthermore, if $v=b$ is even, then $r-\lambda$ must be a perfect square. If $v=b$ is odd, then the equation $x^2=(r-\lambda)y^2+(-1)^{(v-1)/2}\lambda z^2$ must have a solution in integers x, y, z not all zero. This is called the **Bruck-Ryser-Chowla theorem**. Necessary conditions for the existence of a BIBD have been obtained. One of these conditions is stated in terms of the Hasse-Minkowski p -invariant $C_p(A)=(-1, -1)_p \prod_{i=1}^n (D_i, -D_{i-1})_p$, where $(m, m')_p$ is the \dagger Hilbert norm-residue symbol, $D_0=1$, and D_i is the principal minor of the $n \times n$ matrix A . Another is described in terms of the embedding of a quasiresidual design into the corresponding symmetric BIBD. No effective necessary and sufficient condition for the existence of a BIBD has been obtained. In general, it is conjectured that for a positive integer k , with finitely many exceptions, BIBD(v, b, r, k, λ)s exist for all pairs v, λ of positive integers satisfying $v > k$, $\lambda(v-1) \equiv 0 \pmod{k-1}$ and $\lambda v(v-1) \equiv 0 \pmod{k(k-1)}$.
